H.O. Pub. No. 9

AMERICAN PRACTICAL NAVIGATOR

AN EPITOME OF NAVIGATION

ORIGINALLY BY

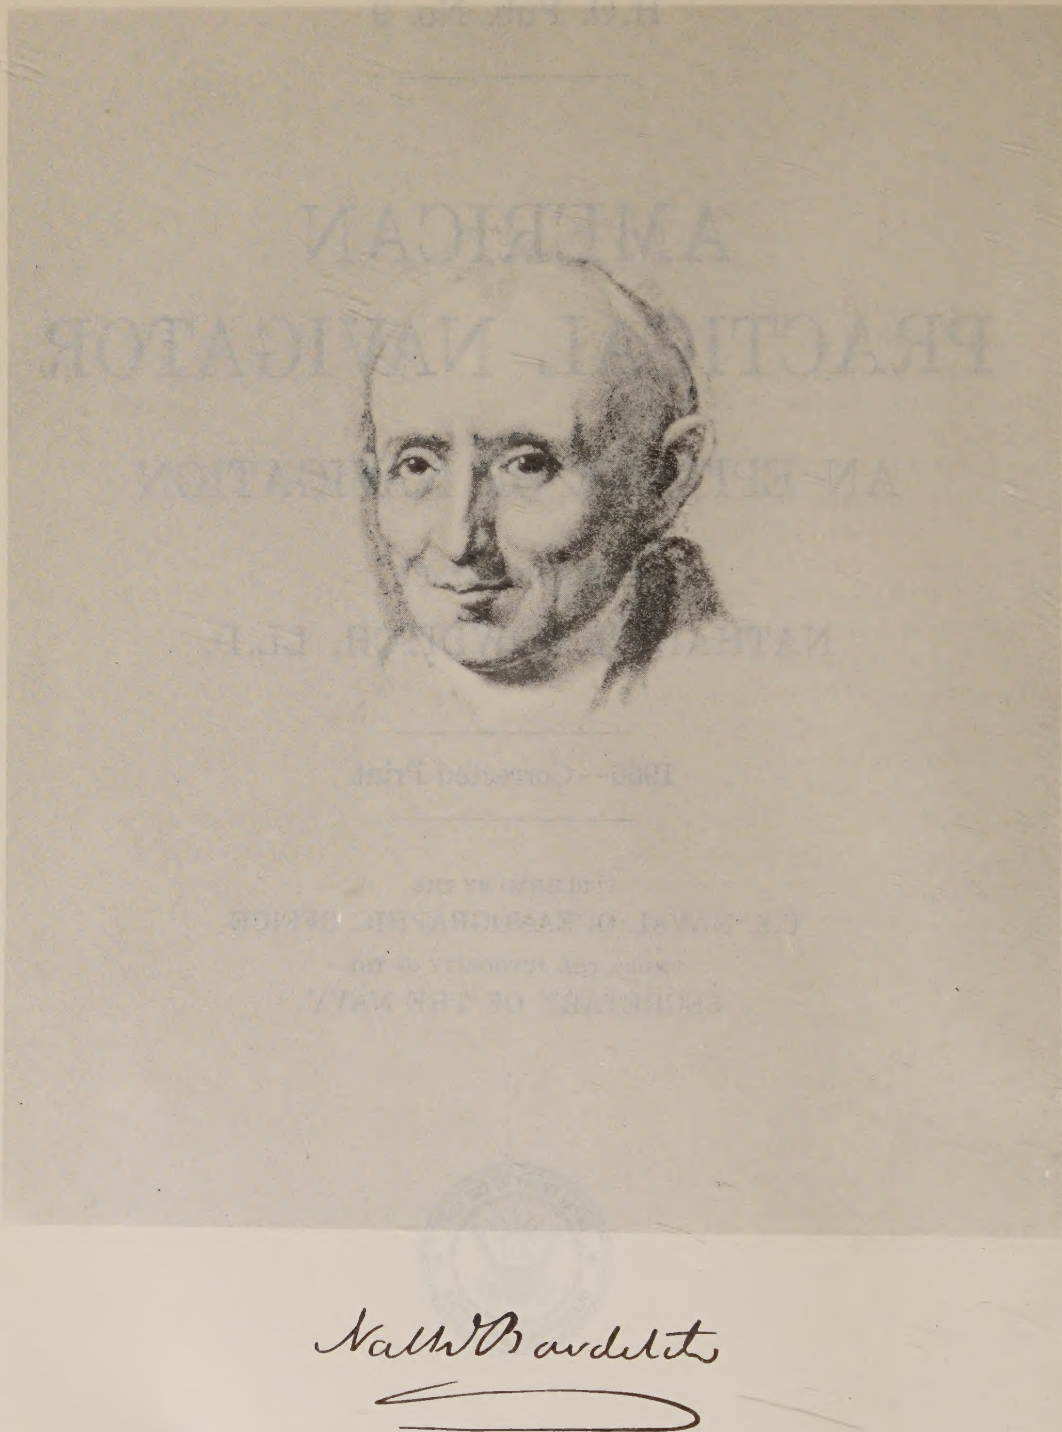
NATHANIEL BOWDITCH, LL.D.

1966—Corrected Print

PUBLISHED BY THE
U.S. NAVAL OCEANOGRAPHIC OFFICE
UNDER THE AUTHORITY OF THE
SECRETARY OF THE NAVY

U.S. GOVERNMENT PRINTING OFFICE
WASHINGTON : 1966

For sale by authorized Sales Agents of the U.S. Naval Oceanographic Office, also the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Price $7.



Last painting by Gilbert Stuart (1828). Considered by the family of Bowditch to be the best of various paintings made, although it was unfinished when the artist died.

NATHANIEL BOWDITCH

(1773–1838)

Nathaniel Bowditch was born on March 26, 1773, at Salem, Mass., fourth of the seven children of shipmaster Habakkuk Bowditch and his wife, Mary.

Since the migration of William Bowditch from England to the Colonies in the 17th century, the family had resided at Salem. Most of its sons, like those of other families in this New England seaport, had gone to sea, and many of them became shipmasters. Nathaniel Bowditch himself sailed as master on his last voyage, and two of his brothers met untimely deaths while pursuing careers at sea.

It is reported that Nathaniel Bowditch's father lost two ships at sea, and by late Revolutionary days he returned to the trade of cooper, which he had learned in his youth. This provided insufficient income to properly supply the needs of his growing family, and hunger and cold were often experienced. For many years the nearly destitute family received an annual grant of fifteen to twenty dollars from the Salem Marine Society. By the time Nathaniel had reached the age of ten, the family's poverty necessitated his leaving school and joining his father in the cooper's trade.

Nathaniel was unsuccessful as a cooper, and when he was about 12 years of age, he entered the first of two ship-chandlery firms by which he was employed. It was during the nearly ten years he was so employed that his great mind first attracted public attention. From the time he began school Bowditch had an all-consuming interest in learning, particularly mathematics. By his middle teens he was recognized in Salem as an authority on that subject. Salem being primarily a shipping town, most of the inhabitants sooner or later found their way to the ship chandler, and news of the brilliant young clerk spread until eventually it came to the attention of the learned men of his day. Impressed by his desire to educate himself, they supplied him with books that he might learn of the discoveries of other men. Since many of the best books were written by Europeans, Bowditch first taught himself their languages. French, Spanish, Latin, Greek, and German were among the two dozen or more languages and dialects he studied during his life. At the age of 16 he began the study of Newton's *Principia,* translating parts of it from the Latin. He even found an error in that classic, and though lacking the confidence to announce it at the time, he later published his findings and had them accepted.

During the Revolutionary War a privateer out of Beverly, a neighboring town to Salem, had taken as one of its prizes an English vessel which was carrying the philosophical library of a famed Irish scholar, Dr. Richard Kirwan. The books were brought to the Colonies and there bought by a group of educated Salem men who used them to found the Philosophical Library Company, reputed to have been the best library north of Philadelphia at the time. In 1791, when Bowditch was 18, two Harvard-educated ministers, Rev. John Prince and Rev. William Bentley, persuaded the Company to allow Bowditch the use of its library. Encouraged by these two men and a third—Nathan Read, an apothecary and also a Harvard man—Bowditch studied the works of the great men who had preceded him, especially the mathematicians and the astronomers. By the time he became of age, this knowledge, acquired before and after his long working hours and in his spare time, had made young Bowditch the outstanding mathematician in the Commonwealth, and perhaps in the country.

In the seafaring town of Salem, Bowditch was drawn to navigation early, learning the subject at the age of 13 from an old British sailor. A year later he began studying surveying, and in 1794 he assisted in a survey of the town. At 15 he devised an almanac reputed to have been of great accuracy. His other youthful accomplishments included the construction of a crude barometer and a sundial.

When Bowditch went to sea at the age of 21, it was as captain's writer and nominal second mate, the officer's berth being offered him because of his reputation as a scholar. Under Captain Henry Prince, the ship *Henry* sailed from Salem in the winter of 1795 on what was to be a year-long voyage to the Ile de Bourbon (now called Île de la Réunion) in the Indian Ocean.

Bowditch began his seagoing career when accurate time was not available to the average naval or merchant ship. A reliable marine chronometer had been invented some 60 years before, but the prohibitive cost, plus the long voyages without opportunity to check the error of the timepiece, made the large investment an impractical one. A system of determining longitude by "lunar distance," a method which did not require an accurate timepiece, was known, but this product of the minds of mathematicians and astronomers was so involved as to be beyond the capabilities of the uneducated seamen of that day. Consequently, ships navigated by a combination of dead reckoning and parallel sailing (a system of sailing north or south to the latitude of the destination and then east or west to the destination).

To Bowditch, the mathematical genius, computation of lunar distances was no mystery, of course, but he recognized the need for an easier method of working them in order to navigate ships more safely and efficiently. Through analysis and observation, he derived a new and simplified formula during his first trip, a formula which was to open the book of celestial navigation to all seamen.

John Hamilton Moore's *The Practical Navigator* was the leading navigational text when Bowditch first went to sea, and had been for many years. Early in his first voyage, however, the captain's writer-second mate began turning up errors in Moore's book, and before long he found it necessary to recompute some of the tables he most often used in working his sights. Bowditch recorded the errors he found, and by the end of his second voyage, made in the higher capacity of supercargo, the news of his findings in *The Practical Navigator* had reached Edmund Blunt, a publisher at Newburyport, Mass. At Blunt's request, Bowditch agreed to correct Moore's book. The first edition of *The New Practical Navigator* was published in 1799, with correction of the errors Bowditch had found to that time, and with some additional information. The following year a second edition was published with additional corrections. Bowditch eventually found more than 8,000 errors in the work, however, and it was finally decided to completely rewrite the book and to publish it under his own name. In 1802 the first edition of *The New American Practical Navigator* by Nathaniel Bowditch was published, and his vow to put nothing in the book he could not teach every member of his crew served to keep the work within the understanding of the average seaman. In addition to the improved method of determining longitude, Bowditch's book gave the ship's officer information on winds, currents, and tides; directions for surveying; statistics on marine insurance; a glossary of sea terms; instruction in mathematics; and numerous tables of navigational data. His simplified methods, easily grasped by the intelligent seaman willing to learn, paved the way for "Yankee" supremacy of the seas during the clipper ship era.

Two months before sailing for Cadiz on his third voyage, in 1798, Bowditch married Elizabeth Boardman, daughter of a shipmaster. While he was away, his wife died at

the age of 18. Two years later, on October 28, 1800, he married his cousin, Mary Ingersoll, she, too, the daughter of a shipmaster. They had eight children.

Bowditch made a total of five trips to sea, over a period of about nine years, his last as master and part owner of the three-masted *Putnam*. Homeward bound from a 13-month voyage to Sumatra and the Ile de France (now called Mauritius) the *Putnam* approached Salem harbor on December 25, 1803, during a thick fog without having had a celestial observation since noon on the 24th. Relying upon his dead reckoning, Bowditch conned his wooden-hulled ship to the entrance of the rocky harbor, where he had the good fortune to get a momentary glimpse of Eastern Point, Cape Ann, enough to confirm his position. The *Putnam* proceeded in, past such hazards as "Bowditch's Ledge" (named after a great-grandfather who had wrecked his ship on the rock more than a century before) and anchored safely at 1900 that evening. Word of the daring feat, performed when other masters were hove-to outside the harbor, spread along the coast and added greatly to Bowditch's reputation. He was, indeed, the "practical navigator."

His standing as a mathematician and successful shipmaster earned him a lucrative (for those times) position ashore within a matter of weeks after his last voyage. He was installed as president of a Salem fire and marine insurance company, at the age of 30, and during the 20 years he held that position the company prospered. In 1823 he left Salem to take a similar position with a Boston insurance firm, serving that company with equal success until his death.

From the time he finished the "*Navigator*" until 1814, Bowditch's mathematical and scientific pursuits consisted of studies and papers on the orbits of comets, applications of Napier's rules, magnetic variation, eclipses, calculations on tides, and the charting of Salem harbor. In that year, however, he turned to what he considered the greatest work of his life, the translation into English of *Mécanique Céleste*, by Pierre Laplace. *Mécanique Céleste* was a summary of all the then known facts about the workings of the heavens. Bowditch translated four of the five volumes before his death, and published them at his own expense. He gave many formula derivations which Laplace had not shown, and also included further discoveries following the time of publication. His work made this information available to American astronomers and enabled them to pursue their studies on the basis of that which was already known. Continuing his style of writing for the learner, Bowditch presented his English version of *Mécanique Céleste* in such a manner that the student of mathematics could easily trace the steps involved in reaching the most complicated conclusions.

Shortly after the publication of *The New American Practical Navigator*, Harvard College honored its author with the presentation of the honorary degree of Master of Arts, and in 1816 the college made him an honorary Doctor of Laws. From the time the Harvard graduates of Salem first assisted him in his studies, Bowditch had a great interest in that college, and in 1810 he was elected one of its Overseers, a position he held until 1826, when he was elected to the Corporation. During 1826–27 he was the leader of a small group of men who saved the school from financial disaster by forcing necessary economies on the college's reluctant president. At one time Bowditch was offered a Professorship in Mathematics at Harvard but this, as well as similar offers from West Point and the University of Virginia, he declined. In all his life he was never known to have made a public speech or to have addressed any large group of people.

Many other honors came to Bowditch in recognition of his astronomical, mathematical, and marine accomplishments. He became a member of the American

Academy of Arts and Sciences, the East India Marine Society, the Royal Academy of Edinburgh, the Royal Society of London, the Royal Irish Academy, the American Philosophical Society, the Connecticut Academy of Arts and Sciences, the Boston Marine Society, the Royal Astronomical Society, the Palermo Academy of Science, and the Royal Academy of Berlin.

Nathaniel Bowditch outlived all of his brothers and sisters by nearly 30 years. Death came to him on March 16, 1838, in his sixty-fifth year. The following eulogy by the Salem Marine Society indicates the regard in which this distinguished American was held by his contemporaries:

"In his death a public, a national, a human benefactor has departed. Not this community, nor our country only, but the whole world, has reason to do honor to his memory. When the voice of Eulogy shall be still, when the tear of Sorrow shall cease to flow, no monument will be needed to keep alive his memory among men; but as long as ships shall sail, the needle point to the north, and the stars go through their wonted courses in the heavens, the name of Dr. Bowditch will be revered as of one who helped his fellow-men in a time of need, who was and is a guide to them over the pathless ocean, and of one who forwarded the great interests of mankind."

The New American Practical Navigator was revised by Nathaniel Bowditch several times after 1802 for subsequent editions of the book. After his death, Jonathan Ingersoll Bowditch, a son who made several voyages, took up the work and his name appeared on the title page from the eleventh edition through the thirty-fifth, in 1867. In 1868 the newly organized U. S. Navy Hydrographic Office bought the copyright and has published the book since that time, revisions being made from time to time to keep the work in step with navigational improvements. The name has been altered to the *American Practical Navigator*, Hydrographic Office Publication No. 9, but the book is still commonly known as "Bowditch." A total of more than 700,000 copies has been printed in about 70 editions during the more than a century and a half since the book was first published in 1802. It has lived because it has combined the best thoughts of each generation of navigators, who have looked to it as their final authority.

PREFACE

This epitome of navigation has been maintained since its initial publication in 1802. The account of its origin, immediate success, and perpetuation appears so inseparable from the accomplishments of its original author, Nathaniel Bowditch, that it has been included in the life résumé of this illustrious navigator and author.

In this extensively revised edition, the U. S. Navy Hydrographic Office has included timely information consistent with modern practices and techniques. The text has been completely rewritten. Since a primary objective has been to provide a reference publication, some duplication exists, cross-referencing is extensive, and the index is detailed. All illustrations are new. Color has been added where it serves a useful purpose. Practice problems have been included with some chapters. Selected references have been given where complete coverage would be inappropriate.

The appendix has been enlarged, and the table arrangement improved. Certain tables of previous editions have been omitted, some of those retained have been altered, and new ones have been added.

The intent of the original author to provide a compendium of navigational material understandable to the mariner has been consistently followed. However, navigation is not presented as a mechanical process to be followed blindly. Rather, emphasis has been given to the fact that the aids provided by *science* can be used effectively to improve the *art* of navigation only if a well-informed person of mature judgment and experience is on hand to interpret information as it becomes available. Thus, the facts needed to perform the mechanics of navigation have been supplemented with additional material intended to help the navigator acquire perspective in meeting the various needs that arise.

Many institutions, organizations, groups, and individuals have assisted in the preparation of this publication, but all of the material has been edited by one individual to assure continuity and consistency. Particular acknowledgment is given the following: Mr. Charles L. Petze, Jr. for assistance in preparation of chapter I; the U. S. Navy Bureau of Ships for information relating to chapters VI and VII; the U. S. Naval Research Laboratory for review of part three; the U. S. Naval Observatory for information relating to chapter XIV and for suggestions relating to appendices F, H, I, and X; the Corps of Engineers of the U. S. Army for assistance in preparation of chapter XXVII; the U. S. Coast and Geodetic Survey of the Department of Commerce for preparation of chapter XXXI, and for providing information on geomagnetism and data for appendix M and most of table 5; the U. S. Weather Bureau for assistance in preparation of part seven and tables 16 and 17; the National Bureau of Standards of the Department of Commerce for assistance in preparation of appendix D; the U. S. Naval Institute for permission to use modified versions of work forms published in Dutton's *Navigation and Nautical Astronomy* (copyrighted 1943, 1948, 1951); the U. S. Power Squadrons for suggestions relating to the graph of article 924 for height of tide determination, navigation of small craft (art. 2310), and table 3; and many individuals, especially experienced practicing navigators, who have offered constructive suggestions or directed attention to errors in previous editions.

PREFACE TO THE 1962 REPRINT

This 1962 corrected reprint has presented the opportunity to incorporate new and timely information. Adoption by the United States of new equivalents for length and mass and of new values for absolute zero necessitated a major revision of Appendix D. Minor corrections to tables 6, 11, 17, 20, 21, and the text, resulting from these changes, have been made. Hydrographic Office publication numbers now conform to the numbering system in use since 1960. The sections relating to air navigation publications and space navigation have been rewritten. The revised Loran-A coverage diagram includes all rates operational in 1961. Appendix S, Maritime Positions, now includes revised material for Africa as well as several new ports.

In addition to the correction of errors published in errata sheets for the 1958 edition, other minor unpublished ones have been corrected. Editorial changes have provided clarification of certain parts of the text and some illustrations have been modified to present information more clearly. All appendices now carry their numerical or alphabetical designation at the top of each page. A list of contents now immediately precedes each part of the volume.

For practical navigation, the additions, corrections, and revisions incorporated in this reprint are not considered to be of sufficient scope and magnitude to necessitate replacement of the 1958 printing.

H.O. Pub. No. 9—Tables, including 1 through 34, is now available as a separate volume entitled "Tables from the American Practical Navigator—Bowditch."

PREFACE TO THE 1966 CORRECTED PRINT

This printing includes modifications and minor corrections to the previous 1962 printing. Appendix K has been revised so that it conforms to the nautical chart symbols listed in the September 1963 edition of Chart No. 1. The text, references, appendices, and index have been modified to reflect recent changes in United States Government publications.

The change in the name of the U.S. Navy Hydrographic Office to U.S. Naval Oceanographic Office has not been indicated in this print.

The modifications and corrections incorporated in this 1966 print are not considered sufficient to warrant replacement of either the 1958 edition or the 1962 corrected print for ordinary purposes of navigation.

CHAPTER I

HISTORY OF NAVIGATION

Introduction

101. Background.—Navigation began with the first man. One of his first conscious acts probably was to home on some object that caught his eye, and thus **land navigation** was undoubtedly the earliest form. His first venture upon the waters may have come shortly after he observed that some objects float, and through curiosity or an attempt at self-preservation he learned that a larger object, perhaps a log, would support him. **Marine navigation** was born when he attempted to guide his craft. **Air navigation** by men, of course, came much later.

The earliest marine navigation was a form of **piloting,** which came into being as man became familiar with landmarks and used them as guides. **Dead reckoning** probably came next as he sought to predict his future positions, or perhaps as he bravely ventured farther from landmarks. **Celestial navigation,** as it is known today, had to await acquisition of information regarding the motions of the heavenly bodies, although these bodies were used to steer by almost from the beginning. **Electronic navigation** is the modern application of a different form of energy to solve an old problem, its principal use being to extend the range of piloting.

102. From art to science.—Navigation is the process of directing the movements of a craft from one point to another. To do this safely is an *art*. In perhaps 6,000 years—some writers make it 8,000—man has transformed this art almost into a *science*, and navigation today is so nearly a science that the inclination is to forget that it was ever anything else. It is commonly thought that to navigate a ship one must have a chart to determine the course and distance, a compass to steer by, and a means of determining the positions of the ship during the passage. *Must* have? The word "must" betrays how dependent the modern navigator has become upon the tools now in his hands. Many of the great voyages of history—voyages that made known much of the world—were made without one or more of these "essentials."

103. Epic voyages.—History records a number of great voyages of varying navigational significance. Little or nothing is known of the navigational accomplishments of the ancient mariners, but the record of the knowledge and equipment used during later voyages serves to illustrate periodic developments in the field.

104. Pre-Christian navigation.—Down through the stream of time a number of voyages have occurred without navigational significance. Noah's experience in the ark is of little interest navigationally, except for his use of a dove to locate land. There is evidence to support the view that at least some American Indians reached these shores by sea, the earliest of several groups probably having come about 2200 BC, the approximate time that a general exodus seems to have occurred from a center in southwestern Asia. This is about the time the Tower of Babel is believed to have been built. It is noteworthy that almost every land reached by the great European explorers was already inhabited.

It is not difficult to understand how a people not accustomed to the sea might make a single great voyage without contributing anything of significance to the advancement of navigation. Not so clear, however, is the fact that the Norsemen and the Poly-

nesians, great seafaring people, left nothing more than conflicting traditions of their methods. The reputed length of the voyages made by these people suggests more advanced navigational methods than their records indicate, although the explanation may be that they left few written accounts of any kind. Or perhaps they developed their powers of perception to such an extent that navigation, to them, was a highly advanced art. In this respect their navigation may not have differed greatly from that of some birds, insects, fishes, and animals.

One of the earliest well-recorded voyages is known today through the book of observations written by Pytheas of Massalia, a Greek astronomer and navigator. Sometime between the years 350 BC and 300 BC he sailed from a Mediterranean port and followed an established trade route to England. From there he ventured north to Scotland and Thule, the legendary land of the midnight sun. He went on to explore Norwegian fiords, and rivers in northwest Germany. He may have made his way into the Baltic.

Pytheas' voyage, and others of his time, were significant in that they were the work of men who had no compasses, no sextants, no chronometers, no electronic devices such as are commonplace today. The explanation of how they did it is not what some historians have said, that before seafaring men had adequate equipment, the compass especially, they hugged the shore and sailed only by daylight in fair weather. Many undoubtedly did use this practice. But the more intrepid did not creep along the coast, venturing nothing more daring than sailing from headland to headland. They were often out of sight of land, and yet knew sufficiently well where they were and how to get home again. They were able to use the sun, the stars, and the winds without the aid of mechanical devices.

Pytheas had none of the equipment considered essential by the modern navigator—none, at least, as it is thought of today. It would be incorrect, however, to say that he had no navigational aids whatever. He was not the first to venture upon the sea, and even in his time man was the inheritor of his predecessors' knowledge.

He must have known what the mariners of his time, Phoenician and Greek, knew about navigation. There was a fair store of knowledge about the movements of the stars, for example, which all seafaring men shared. They had a practical grasp of some part of what is now called celestial navigation, for the moving celestial bodies were their compasses. Pytheas may not have been acquainted with the *Periplus* of Scylax, the earliest known sailing directions, but it is reasonable to suppose that he had similar information.

If there were sailing directions, there may well have been charts of a sort, even though no record of them exists.

Even if Pytheas and his contemporaries had sailing directions and charts, these must have been far from comprehensive, and they undoubtedly did not cover the areas north of Britain. But these early seamen knew direction by day or night if the sky was clear, and they could judge it reasonably well when the sky was overcast, using the wind and the sea. They knew the hot Libyan wind from the desert—today called the **sirocco**—and the northern wind, the **mistral.**

They could estimate distance. Their ships must have carried some means of measuring time—the sand glass was known to the ancients—and they could estimate speed by counting the strokes of the oars, a common practice from galley to modern college racing shell. Mariners who spent their lives traveling the Mediterranean knew what their ships could do, even if today it is not known what they meant by "a day's sail"—whether 35 miles, or 50, or 100.

105. Sixteenth century navigation.—Progress in the art of navigation came slowly during the early centuries of the Christian era, all but stopped during the Dark Ages,

and then spurted forward when Europe entered a golden age of discovery. The circumnavigation of the globe by the expedition organized by Ferdinand Magellan, a disgraced Portuguese nobleman who sailed under the flag of Spain, was a voyage which illustrates the advances made during the 1,800 years following Pytheas.

Magellan was able to find justification for his belief that a navigable pass to the Pacific Ocean existed in high southern latitudes, in Martin Behaim's globe or chart of the world, in the globe constructed by Johann Schoner of Nuremberg in 1515, and in Leonardo da Vinci's map of the world drawn in the same year. He obtained further information for his voyage from Ruy Faleiro, an astronomer and cartographer whose charts, sailing directions, nautical tables, and instructions for use of the astrolabe and cross-staff were considered to be among the best available. Faleiro was also an advocate of the fallacious methods of determining longitude by variation.

When Magellan sailed in 1519, his equipment included sea charts, parchment skins to be made into charts en route, a terrestrial globe, wooden and metal theodolites, wooden and wood-and-bronze quadrants, compasses, magnetic needles, hour glasses and "timepieces," and a log to be towed astern.

So the 16th century navigator had crude charts of the known world, a compass to steer by, instruments with which he could determine his latitude, a log to estimate speed, certain sailing directions, and solar and traverse tables. The huge obstacle yet to be overcome was an accurate method of determining longitude.

106. Eighteenth century navigation.—Little is known today of the "timepieces" carried by Magellan, but surely they were not used to determine longitude. Two hundred years later, however, the chronometer began to emerge. With it, the navigator, for the first time, was able to determine his longitude accurately and fix his position at sea.

The three voyages of discovery made by James Cook of the Royal Navy in the Pacific Ocean between 1768 and 1779 may be said to mark the dawn of modern navigation. Cook's expedition had the full backing of England's scientific organizations, and he was the first captain to undertake extended explorations at sea with navigational equipment, techniques, and knowledge that might be considered modern.

On his first voyage Cook was provided with an astronomical clock, a "journeyman" clock, and a watch lent by the Astronomer Royal. With these he could determine longitude, using the long and tedious lunar distance method. On his second voyage four chronometers were provided. These instruments, added to those already possessed by the mariner, enabled Cook to navigate his vessels with a precision undreamed of by Pytheas and Magellan.

By the time Cook began his explorations, astronomers had made great contributions to navigational advancement, and the acceptance of the heliocentric theory of the universe had led to the publication of the first official nautical almanac. Charts had progressed steadily, and adequate projections were available. With increased understanding of variation, the compass had become reliable. Good schools of navigation existed, and textbooks which reduced the mathematics of navigation to the essentials had been published. Speed through the water could be determined with reasonable accuracy by the logs then in use. Most important, the first chronometers were being produced.

107. Twentieth century navigation.—The maiden voyage of the SS *United States* in July 1952 served to illustrate the progress made in navigation during the 175 years since Cook's voyages. Outstanding because of its record trans-Atlantic passage, the vessel is of interest navigationally in that it carried the most modern equipment available and exemplified the fact that navigation had become nearly a science.

Each of the deck officers owned a sextant with which he could make observations more accurately than did Cook. Reliable chronometers, the product of hundreds of

years of experimental work, were available to determine the time of each observation. The gyro compass indicated true north regardless of variation and deviation.

Modern, convenient almanacs were used to obtain the coordinates of various celestial bodies, to an accuracy greater than needed. Easily used altitude and azimuth tables gave the navigator data for determining his Sumner (celestial) line of position by the method of Marcq St.-Hilaire. Accurate charts were available for the waters plied, sailing directions for coasts and ports visited, light lists giving the characteristics of the various aids to navigation along these coasts, and pilot charts and navigational texts for reference purposes.

Electronics served the navigator in a number of ways. Radio time signals and weather reports enabled him to check his chronometers and avoid foul weather. A radio direction finder was available to obtain bearings, and a radio telephone was used to communicate with persons on land and sea. The electrically operated echo sounder indicated the depth of water under the keel, radar the distances and bearings of objects within range, even in the densest fog. Using loran, the navigator could fix the position of his ship a thousand miles and more from transmitting stations.

Piloting and Dead Reckoning

108. Background.—The history of piloting and dead reckoning extends from man's earliest use of landmarks to the latest model of the gyro compass. In the thousands of years between, navigation by these methods has progressed from short passages along known coast lines to transoceanic voyages during which celestial observations cannot be, or are not, made.

109. Charts.—A form of sailing directions was written several hundred years before Christ. Although charts cannot be traced back that far, they may have existed during the same time. From earliest times men have undoubtedly known that it is more difficult to explain how to get to a place than it is to draw a diagram, and since the first charts known are comparatively accurate and cover large areas, it seems logical that earlier charts served as guides for the cartographers.

Undoubtedly, the first charts were not made on any "projection" (ch. III) but were simple diagrams which took no notice of the shape of the earth. In fact, these "plane" charts were used for many centuries after chart projections were available.

The **gnomonic projection** (art. 317) is believed to have been developed by Thales of Miletus (640–546 BC), who was chief of the Seven Wise Men of ancient Greece; founder of Greek geometry, astronomy, and philosophy; and a navigator and cartographer.

The size of the earth was measured at least as early as the third century BC, by Eratosthenes. He observed that at noon on the day of the summer solstice, a certain well at Syene (Assuan) on the tropic of Cancer was lighted throughout its depth by the light of the sun as it crossed the meridian; but that at Alexandria, about 500 miles to the north, shadows were cast by the sun at high noon. He reasoned that this was due to curvature of the earth, which must be spherical. By means of the shadow of an object of known height at Alexandria, Eratosthenes determined the zenith distance to be about 7°5, or $\frac{1}{48}$ of the earth's circumference. The earth must therefore be $48 \times 500 = 24{,}000$ (statute) miles. The correct value is about 24,900 statute miles.

Eratosthenes is believed to have been the first person to measure latitude, using the degree for this purpose. He constructed a 16-point wind rose, prepared a table of winds, and recognized local and prevailing winds. From his own discoveries and from information gleaned from the manuscripts of mariners, explorers, land travelers, historians, and philosophers, he wrote an outstanding description of the known world, which helped elevate geography to the status of a science.

Stereographic (art. 318) and **orthographic** (art. 319) **projections** were originated by Hipparchus in the second century BC.

Ptolemy's World Map. The Egyptian Claudius Ptolemy was a second century AD astronomer, writer, geographer, and mathematician who had no equal in astronomy until the arrival of Copernicus in the 16th century. An outstanding cartographer, for his time, Ptolemy constructed many charts and listed the latitudes and longitudes, as determined by celestial observations, of the places shown. As a geographer, however, he made his most serious mistake. Though Eratosthenes' calculations on the circumference of the earth were available to him, he took the estimate of the Stoic philosopher, Posidonius (circa 130–51 BC), who calculated the earth to be 18,000 miles in circumference. The result was that those who accepted his work—and for many hundreds of years few thought to question it—had to deal with a concept that was far too small. In 1409 the Greek original of Ptolemy's *Cosmographia*, a book in which he declared this doctrine, was discovered and translated into Latin. It served as the basis for future cartographic work, and so it was that Columbus died convinced that he had found a shorter route to the East Indies. Not until 1669, when Jean Picard computed the circumference of the earth to be 24,500 miles, was a more accurate figure generally used.

Ptolemy's map of the world (fig. 109a) was a great achievement, however. It was the original conic projection, and on it he located some 8,000 places by latitude and longitude. It was he who fixed the convention that the top of the map is north.

Asian Charts. Through the Dark Ages some progress was made. Moslem cartographers as well as astronomers took inspiration from Ptolemy. However, they knew that Ptolemy had overestimated the length of the Mediterranean by some 20°. Charts of the Indian Ocean, bearing horizontal lines indicating parallels of latitude,

and vertical lines dividing the seas according to the direction of the wind, were drawn by Persian and Arabian navigators. The prime meridian separated a windward from a leeward region and other meridians were drawn at intervals indicating "three hours sail." This information, though far from exact, was helpful to the sailing ship masters.

Portolan Charts. The mariners of Venezia (Venice), Livorno (Leghorn), and Genova (Genoa) must have had charts when they competed for Mediterranean trade before, during, and after the Crusades. Venice at one time had 300 ships, a navy of 45 galleys, and 11,000 men engaged in her maritime industry. But perhaps the rivalry was too keen for masters carelessly to leave charts lying about. At any rate, the earliest useful charts of the Middle Ages that are known today were drawn by seamen of Catalonia (now part of Spain).

The Portolan charts were constructed from the knowledge acquired by seamen during their voyages about the Mediterranean. The actual courses and dead reckoning distances between land points were used as a skeleton for the charts, and the coasts between were usually filled in from data obtained in land surveys. After the compass came into use, these charts became quite accurate. Some, for example, indicated the distance between Gibraltar and Bayrūt (Beirut) to be 3,000 Portolan miles, or 40°.5 of longitude. The actual difference of longitude is 40°.8.

These charts were distinguished by a group of long rhumb lines intersecting at a common point, surrounded by eight or 16 similar groups of shorter lines. Later *Portolanis* had a *rose dei venti* (rose of the winds), the forerunner of the compass rose, superimposed over the center (fig. 109b). They carried a scale of miles, located nearly all the known hazards to navigation, and had numerous notes of interest to the pilot. They were not marked with parallels of latitude or meridians of longitude, but present-day harbor and coastal charts trace their ancestry directly to them.

Padrón Real. The growing habit of assembling information for charts took concrete form in the *Padrón Real.* This was the pattern, or master, map kept after 1508 by the *Casa de Contratación* at Seville. It was intended to contain everything known about the world, and it was constructed from facts brought back by mariners from voyages to newly discovered lands. From it were drawn the charts upon which the explorers of the Age of Discovery most depended.

World maps of the Middle Ages. In 1515 Leonardo da Vinci drew his famous map of the world. On it, America is represented as extending more to the east and west

FIGURE 109c.—Ortelius' world map, from his atlas *Theatrum Orbis Terra*, published at Antwerp in 1570.

than to the north and south, with only a chain of islands, the largest named Florida, between it and South America. A wide stretch of ocean is shown between South America and *Terra Australis Nondum Cognita*, the mythical south-seas continent whose existence in the position shown was not disproved until 250 years later.

Ortelius' atlas *Theatrum Orbis Terra* was published at Antwerp in 1570. One of the most magnificent ever produced, it illustrates Europe, Africa, and Asia with comparative accuracy. North and South America are poorly depicted, but Magellan's Strait is shown. All land to the south of it, as well as Australia, is considered part of *Terra Australis Nondum Cognita* (fig. 109c).

The Mercator projection (art. 305). For hundreds, perhaps thousands, of years cartographers drew their charts as "plane" projections, making no use of the discoveries of Ptolemy and Hipparchus. As the area of the known world increased, however, the attempt to depict that larger area on the flat surface of the plane chart brought map makers to the realization that allowance would have to be made for the curvature of the earth.

Gerardus Mercator (Latinized form of Gerhard Kremer) was a brilliant Flemish geographer who recognized the need for a better method of chart projection. In 1569 he published a world chart which he had constructed on the principle since known by his name. The theory of his work was correct, but Mercator made errors in his computation, and because he never published a complete description of the mathematics involved, mariners were deprived of the full advantages of the projection for another 30 years.

Then Edward Wright published the results of his own independent study in the matter, explaining the Mercator projection fully and providing the table of meridional parts which enabled all cartographers to make use of the principle.

Wright was a mathematician at Caius College who developed the method and table and gave them to certain navigators for testing. After these proved their usefulness, Wright decided upon publication, and in 1599 *Certaine Errors in Navigation Detected and Corrected* was printed.

The Lambert projections. Johann Heinrich Lambert, 1728–1777, self-educated son of an Alsace tailor, designed a number of map projections. Some of these are still widely used, the most renowned being the **Lambert conformal** (art. 314).

110. Sailing directions.—From earliest times there has been a demand for knowledge of what lay ahead, and this gave rise to the early development of sailing directions (art. 420).

The *Periplus* of Scylax, written sometime between the sixth and fourth centuries BC, is the earliest known book of this type. Surprisingly similar to modern sailing directions, it provided the mariner with information on distances between ports, aids and dangers, port facilities, and other pertinent matters. The following excerpt is typical:

"Libya begins beyond the Canopic mouth of the Nile. . . . The first people in Libya are the Adrymachidae. From Thonis the voyage to Pharos, a desert island (good harbourage but no drinking water), is 150 stadia. In Pharos are many harbors. But ships water at the Marian Mere, for it is drinkable. . . . The mouth of the bay of Plinthine to Leuce Acte (the white beach) is a day and night's sail; but sailing round by the head of the bay of Plinthine is twice as long. . . ."

Parts Around the World, Pytheas' book of observations made during his epic voyage in the fourth century BC, was another early volume of sailing directions. His rough estimates of distances and descriptions of coast lines would be considered crude today, but they served as an invaluable aid to navigators who followed him into these otherwise unknown waters.

Sailing directions during the Renaissance. No particularly noteworthy improvements were made in sailing directions during the Middle Ages, but in 1490 the *Portolano Rizo* was published, the first of a series of improved design. Other early volumes of this kind appeared in France and were called "routiers"—the **rutters** of the English sailor. In 1557 the Italian pilot Battista Testa Rossa published *Brieve Compendio del Arte del Navigar*, which was designed to serve the mariner on soundings and off. It forecast the single, all-inclusive volume that was soon to come, the **Waggoner.**

About 1584 the Dutch pilot Lucas Jans Zoon Waghenaer published a volume of navigational principles, tables, charts, and sailing directions which served as a guide for such books for the next 200 years. In *Spieghel der Zeevaerdt* (The Mariner's Mirror), Waghenaer gave directions and charts for sailing the waters of the Low Countries and later a second volume was published covering waters of the North and Baltic seas.

These "Waggoners" met with great success and in 1588 an English translation of the original book was made by Anthony Ashley. During the next 30 years, 24 editions of the book were published in Dutch, German, Latin, and English. Other authors followed the profitable example set by Waghenaer, and American, British, and French navigators soon had "Waggoners" for most of the waters they sailed.

The success of these books and the resulting competition among authors were responsible for their eventual discontinuance. Each writer attempted to make his work more inclusive than any other (the 1780 *Atlantic Neptune* contained 257 charts of North America alone) and the result was a tremendous book difficult to handle. They were too bulky, the sailing directions were unnecessarily detailed, and the charts too large. In 1795 the British Hydrographic Department was established, and charts and sailing directions were issued separately. The latter, issued for specific waters, were returned to the form of the original *Periplus*.

Modern sailing directions. The publication of modern sailing directions by the U. S. Navy Hydrographic Office is one of the achievements properly attributed to Matthew Fontaine Maury. During the two decades he headed the institution, Maury gathered data that led directly to the publication of eight volumes of sailing directions. Today there are more than 65 volumes providing the mariner with detailed information on almost all foreign coasts, in addition to eight volumes of **coast pilots** of the United States and its possessions, published by the U. S. Coast and Geodetic Survey.

111. The compass.—Early in the history of navigation man noted that the pole star (it may have been α *Draconis* then) remained close to one point in the northern sky. This served as his compass. When it was not visible, he used other stars, the sun and moon, winds, clouds, and waves. The development of the magnetic compass, perhaps a thousand years ago, and the 20th century development of the gyro compass, offer today's navigator a method of steering his course with an accuracy as great as he is capable of using.

The **magnetic compass** (art. 623) is one of the oldest of the navigator's instruments. Its origin is not known. In 203 BC, when Hannibal set sail from Italy, his pilot was said to be one *Pelorus*. Perhaps the compass was in use then; no one can say for certain that it was not. There is little to substantiate the story that the Chinese invented it, and the legend that Marco Polo introduced it into Italy in the 13th century is almost certainly false. It is sometimes stated that the Arabs brought it to Europe, but this, too, is unlikely. Probably it was known first in the west. The Norsemen of the 11th century were familiar with it, and about 1200 a compass used by mariners when the pole star was hidden was described by a French poet, Guyot de Provins.

A needle thrust through a straw and floated in water in a container comprised the earliest compass known. A 1248 writer, Hugo de Bercy, spoke of a new compass construction, the needle "now" being supported on two floats. Petrus Peregrinus de Maricourt, in his *Epistola de Magnete* of 1269, wrote of a pivoted floating compass with a lubber's line, and said that it was equipped with sights for taking bearings.

The reliability of the magnetic compass of today is a comparatively recent achievement. As late as 1820 Peter Barlow reported to the British Admiralty "half of the compasses in the Royal Navy were mere lumber, and ought to be destroyed." Some 75 years ago, Lord Kelvin developed the Admiralty type compass used today.

The **compass card,** according to tradition, originated about the beginning of the 14th century, when Flavio Gioja of Amalfi attached a sliver of lodestone or a magnetized needle to a card. But the rose on the compass card is probably older than the needle. It is the wind rose of the ancients. Primitive man naturally named directions by the winds. The prophet Jeremiah speaks of the winds from the four quarters of heaven (Jer. 49:36) and Homer named four winds—Boreas, Eurus, Notus, and Lephyrus. Aristotle is said to have suggested a circle of 12 winds, and Eratosthenes, who measured the world correctly, reduced the number to eight about 200 BC. The "Tower of Winds" at Athens, built about 100 BC, had eight sides. The Latin rose of 12 points was common on most compasses used in the Middle Ages.

Variation (art. 709) was well understood 200 years ago, and navigators made allowance for it, but earliest recognition of its existence is not known. Columbus and even the 11th century Chinese have been given credit for its discovery, but little proof can be offered for either claim.

The secular change in variation was determined by a series of magnetic observations made at Limehouse, England. In 1580 William Borough fixed the variation in that area at approximately 11°25′ east. Thirty-two years later Edmund Gunter, professor of astronomy at Gresham College, determined it to be 6°13′ east. At first

it was believed that Borough had made an error in his work, but in 1633 a further decrease was found, and the earth's changing magnetic field was established.

A South Atlantic expedition was led by Edmond Halley at the close of the 17th century to gather data and to map, for the first time, lines of variation. In 1724 George Graham published his observations in proof of the diurnal change in variation. Canton determined that the change was considerably less in winter than in summer, and about 1785 the strength of the magnetic force was shown by Paul de Lamanon to vary in different places.

The existence of **deviation** (art. 709) was known to John Smith in 1627 when he wrote of the "bittacle" as being a "square box nailed together with wooden pinnes, because iron nails would attract the Compasse." But no one knew how to correct a compass for deviation until Captain Matthew Flinders, while on a voyage to Australia in HMS *Investigator* in 1801–02, discovered a method of doing so. Flinders did not understand deviation completely, but the vertical bar he erected to correct for it was part of the solution, and the **Flinders bar** (art. 720) used today is a memorial to its discoverer. Between 1839 and 1855 Sir George Airy, then Astronomer Royal, studied the matter further and developed combinations of permanent magnets and soft iron masses for adjusting the compass. The introduction, by Lord Kelvin, of short needles as compass magnets made adjustment more precise.

The gyro compass (art. 631). The age of iron ships demanded a compass which could be relied upon to indicate true north at all times, free from disturbing forces of variation and deviation.

In 1851, at the Pantheon in Paris, Leon Foucault performed his famous pendulum experiment to demonstrate the rotation of the earth. Foucault's realization that the swinging pendulum would maintain the plane of its motion led him, the following year, to develop and name the first gyroscope, using the principle of a common toy called a "rotascope." Handicapped by the lack of a source of power to maintain the spin of his gyroscope, Foucault used a microscope to observe the indication of the earth's rotation during the short period in which his manually operated gyroscope remained in rotation. A gyro compass was not practical until electric power became available, more than 50 years later, to maintain the spin of the gyroscope.

Elmer A. Sperry, an American, and Anschutz-Kampfe, a German, independently invented gyro compasses during the first decade of the 20th century. Tested first in 1911 on a freighter operating off the East Coast of the United States and then on American warships, Sperry's compass was found adequate, and in the years following World War I gyro compasses became standard equipment on all large naval and merchant ships.

Gyro compass auxiliaries commonly used today were added later. These include gyro repeaters, to indicate the vessel's heading at various locations; gyro pilots, to steer vessels automatically; course recorders, to provide a graphic record of courses steered; gyro-magnetic compasses, to repeat headings of magnetic compasses so located as to be least affected by deviation; and others in the fields of fire control, aviation, and guided missiles.

112. The log.—Since virtually the beginning of navigation, the mariner has attempted to determine his speed in traveling from one point to another. The earliest method was probably by estimate.

The oldest speed measuring device known is the **Dutchman's log.** Originally, any object which would float was thrown overboard on the lee side, from a point well forward, and the time required for it to pass between two points on the deck was noted. The time, as determined by sand glass, was compared with the known distance along the deck between the two points to determine the speed.

Near the end of the 16th century a line was attached to the log, and as the line was paid out a sailor recited certain sentences. The length of line which was paid out during the recitation was used to determine the speed. There is record of this method having been used as recently as the early 17th century. In its final form this **chip log, ship log,** or **common log** consisted of the *log chip* (or *log ship*), *log line*, *log reel*, and *log glass*. The chip was a quadrant-shaped piece of wood weighted along its circumference to keep it upright in the water (fig. 112). The log line was made fast to the log chip by means of a bridle, in such manner that a sharp pull on the log line dislodged a wooden peg and permitted the log chip to be towed horizontally through the water, and hauled aboard. Sometimes a *stray line* was attached to the log to veer it clear of the ship's wake. In determining speed, the observer counted the knots in the log line which was paid out during a certain time. The length of line between knots and the number of seconds required for the sand to run out were changed from time to time as the accepted length of the mile was altered.

The chip log has been superseded by patent logs that register on dials. However, the common log has left its mark on modern navigation, as the use of the term **knot** to indicate a speed of one nautical mile per hour dates from this device. There is evidence to support the opinion that the expression "dead reckoning" had its origin in this same device, or perhaps in the earlier Dutchman's log. There is logic in attributing "dead" reckoning to a reckoning relative to an object "dead" in the water.

FIGURE 112.—The common or chip log, showing the log reel, the log line, the log chip, and the log glass.

Mechanical logs first appeared about the middle of the 17th century. By the beginning of the 19th century, the forerunners of modern mechanical logs were used by some navigators, although many years were to pass before they became generally accepted.

In 1773 logs on which the distance run was recorded on dials secured to the taffrail were tested on board a British warship and found reasonably adequate, although the comparative delicateness of the mechanism led to speculation about their long-term worth. Another type in existence at the time consisted of a wheel arrangement made fast on the underside of the keel, which transmitted readings to a dial inside the vessel as the wheel rotated.

An improved log was introduced by Edward Massey in 1802. This log gave considerably greater accuracy by means of a more sensitive rotator attached by a short length of line to a geared recording instrument. The difficulty with this log was that it had to be hauled aboard to take each reading. Various improvements were made, notably by Alexander Bain in 1846 and Thomas Walker in 1861, but it was not until 1878 that a log was developed in which the rotator could be used in conjunction with a dial secured to the after rail of the ship, and although refinements and improvements have been made, the patent log used today is essentially the same as that developed in 1878.

Engine revolution counters (art. 615) had their origin with the observations of the captains of the first paddle steamers, who discovered that by counting the paddle revolutions, they could, with practice, estimate their runs in thick weather as accurately as they could by streaming the log. Later developments led to the modern revolution

counter on screw-type vessels, which can be used with reasonable accuracy if the propeller is submerged and an accurate estimate of slip is made.

Pitot-static and impeller-type logs (arts. 613, 614) are recent mechanical developments in the field of speed measurement. Each utilizes a retractable "rodmeter" which projects through the hull of the ship into the water. In the Pitot-static log, static and dynamic pressures on the rodmeter transmit readings to the master speed indicator. In the impeller-type log an electrical means of transmitting speed indications is used.

113. Units of distance and depth.—The modern navigator is concerned principally with three units of linear measure: the **nautical mile,** the **fathom,** and the **foot** (sometimes also the **meter**). Primitive man, however, used such natural units as the width of a finger, the **span** of his hand, the length of his **foot,** the distance from elbow to the tip of the middle finger (the **cubit** of biblical renown), or the **pace** (sometimes one but usually a double step) to measure short distances.

These ancient measurements varied from place to place, and from person to person. One of the first recorded attempts to establish a tangible standard length was made by the Greeks, who used the length of the Olympic stadium as a unit called a **stadium.** This was set at 600 Greek feet (607.9 modern U. S. feet), or almost exactly one-tenth of a modern nautical mile. The Romans adopted this unit and extended its use to nautical and even astronomical measurements. The Roman stadium was 625 Roman feet, or 606.3 U.S. feet, in length. This approximates the modern British Navy **cable** of 608 feet. The U.S. Navy cable is 720 feet.

The origin of the **Mediterranean mile** of 4,035.43 U.S. feet is attributed to the Greeks. The **Roman mile** of 4,858.60 U.S. feet gradually replaced the shorter Greek unit, and was probably the value in use in Palestine when Christ in his Sermon on the Mount spoke of the "second mile" (Matt. 5:41). It is probable that the **mile** was given its name by the Romans, since the word is derived from the Latin **mille** (thousand). This unit was defined as a thousand paces. However, the Greek unit was similarly defined, as was the Arabian **mille** or **mil** of 6,000 Arabian feet, equal to 1.03 nautical miles.

The **nautical mile** bears little relation to these land measures, which were not associated with the size of the earth. With the emergence of the nautical chart, it became customary to show a scale of miles on the chart, and the accepted value of this unit varied over the centuries with the changing estimates of the size of the earth. These estimates varied widely, ranging from about 44.5 to 87.5 modern nautical miles per degree of latitude, although generally they were too small. Columbus and Magellan used the value 45.3. Actually, the earth is about 32 percent larger. The *Almagest* of Ptolemy considered 62 Roman miles equivalent to one degree, but a 1466 edition of this book contained a chart of southern Asia drawn by Nicolaus Germanus on which 60 miles were shown to a degree. Whether the change was considered a correction or an adaptation to provide a more convenient relationship between the mile and the degree is not clear, but this is the earliest known use of this ratio.

Later, when the size of the earth was determined by measurement, the relationship of 60 Roman miles of 4,858.60 U.S. feet to a degree of latitude was seen to be in error. Both possible solutions to the problem—changing the ratio of miles to a degree, or changing the length of the mile—had their supporters, and neither group was able to convince the other. As a result, the shorter mile remained as the **land** or **statute mile** (now established as 5,280 feet in the United States), and the longer **nautical mile** gradually became established at sea. The earliest known reference to it by this name occurred in 1730.

Finer instruments and new methods make increasingly more accurate determinations of the size of the earth an ever-present possibility. Hence, a unit of length

defined in terms of the size of the earth is undesirable. Recognition of this led, in 1875, to a change in the definition of the **meter** from one ten-millionth of the distance from the pole to the equator of the earth to the distance between two marks (approximately 39.37 U. S. inches) on a standard platinum-iridium bar kept at the Pavillon de Breteuill at Sevres, near Paris, France, by the International Commission of Weights and Measures. In further recognition of this principle, the International Hydrographic Bureau in 1929 recommended adoption of a standard value for the nautical mile, and proposed 1852 international meters. The length of 1852 meters has not changed, but in 1959, U. S. measurements were redefined; the length of one nautical mile was established at 6,076.11549 U. S. feet (approximately). Most major maritime nations now use the international value.

The **fathom** as a unit of length or depth is of obscure origin, but primitive man considered it a measure of the outstretched arms, and the modern seaman still estimates the length of a line in this manner. That the unit was used in early times is indicated by reference to it in the detailed account given of the Apostle Paul's voyage to Rome, as recorded in the 27th chapter of the *Acts of the Apostles*. Posidonius reported a sounding of more than 1,000 fathoms in the second century BC. How old the unit was at that time is unknown.

114. Soundings.—Probably the most dangerous phase of navigation occurs when the vessel is "on soundings." Since man first began navigating the waters, the possibility of grounding his vessel has been a major concern, and frequent soundings have been the most highly valued safeguard against that experience. Undoubtedly used long before the Christian era, the lead line is perhaps the oldest instrument of navigation.

The lead line. The **hand lead** (art. 617), consisting of a lead weight attached to a line usually marked in fathoms, has been known since antiquity and, with the exception of the markings, is probably the same today as it was 2,000 or more years ago. The **deep sea lead,** a heavier weight with a longer line, was a natural outrowgth of the hand lead. A 1585 navigator speaks of soundings of 330 fathoms, and in 1773, in the Norwegian Sea, Captain Phipps had all the sounding lines on board spliced together to obtain a sounding of 683 fathoms. Matthew Fontaine Maury made his deep sea soundings by securing a cannon shot to a ball of strong twine. The heavy weight caused the twine to run out rapidly, and when bottom was reached, the twine was cut and the depth deduced from the amount remaining on the ball.

The sounding machine. The biggest disadvantage of the deep sea lead is that the vessel must be stopped if depths are to be measured accurately. This led to the development of the sounding machine (art. 618).

Early in the 19th century a sounding machine similar to one of the earlier patent logs was invented. A wheel was secured just above the lead and the cast made in such a way that all the line required ran out freely and the lead sank directly to the bottom. The motion through the water during the descent set the wheel revolving, and this in turn caused the depth to be indicated on a dial. Ships sailing at perhaps 12 knots required 20 or 30 men to heave aboard the heavy line with its weight of 50 or more pounds after each cast. A somewhat similar device was the **buoy sounder.** The lead was passed through a buoy in which a spring catch was fitted and both were cast over the side. The lead ran freely until bottom was reached, when the catch locked, preventing further running out of the line. The whole assembly was then brought on board, the depth from the buoy to the lead being read.

The first use of the pressure principle to determine the depth of water occurred early in the 19th century when the "Self-acting Sounder" was introduced. A hollow glass tube open at its lower end contained an index which moved up in the tube as greater water pressure compressed the air inside. The index retained its highest

position when hauled aboard the vessel, and its height was proportional to the depth of the water.

The British scientist, William Thomson (Lord Kelvin) in 1878 perfected the sounding machine after repeated tests at sea. Prior to his invention, fibre line was used exclusively in soundings. His introduction of piano wire solved the problem of rapid descent of the lead and also that of hauling it back aboard quickly. The chemically coated glass tube which he used to determine depth was an improvement of earlier methods, and the worth of the entire machine is evidenced by the fact that it is still used in essentially the same form.

Echo sounding. Based upon the principle that sound travels through sea water at a nearly uniform rate, automatic depth-registering devices (art. 619) have been invented to indicate the depth of water under a vessel, regardless of its speed. In 1911 an account was published of an experiment performed by Alexander Behm of Kiel, who timed the echo of an underwater explosion, testing this theory. High frequency sounds in water were produced by Pierre Langevin, and in 1918 he used the principle for echo depth finding. The first practical echo sounder was developed by the United States Navy in 1922.

The actual time between emission of a sonic or ultrasonic signal and return of its echo from the bottom, the angle at which the signal is beamed downward in order that its echo will be received at another part of the vessel, and the phase difference between signal and echo have all been used in the development of the modern echo sounder.

115. Aids to navigation.—The Cushites and Libyans constructed towers along the Mediterranean coast of Egypt, and priests maintained beacon fires in them. These were the earliest known lighthouses. At Sigeum in the Troad (part of Troy) a lighthouse was built before 660 BC. One of the seven wonders of the ancient world was the lighthouse called the Pharos of Alexandria, which may have been more than 200 feet tall. It was built by Sostratus of Cnidus (Asia Minor) in the third century BC, during the reign of Ptolemy Philadelphus. The word "pharos" has since been a general term for lighthouses. Some time between 1584 and 1611 the light of Cordouan, the earliest wave-swept lighthouse, was erected at the entrance to the Gironde river in western France. An oak log fire illuminated this structure until the 18th century.

Wood or coal fires were used in the many lighthouses built along the European and British coasts in the 17th and 18th centuries. One of these, the oak pile structure erected by Henry Whiteside in 1776 to warn shipmasters of Small's Rocks, subsequently played a major role in navigational history, as it was this light which figured in the discovery of the celestial line of position by Captain Thomas Sumner some 60 years later (art. 131).

In England such structures were privately maintained by interested organizations. One of the most famous of these groups, popularly known as "Trinity House," was organized in the 16th century, perhaps earlier, when a "beaconage and buoyage" fee was levied on English vessels. This prompted the establishment of Trinity House "to make, erect, and set up beacons, marks, and signs for the sea" and to provide vessels with pilots. The organization is now in its fifth century of operation, and its chief duties are to serve as a general lighthouse and pilotage authority, and to supply pilots.

The first lightship was a small vessel with lanterns hung from its yardarms. It was stationed at the Nore, an estuary in the Thames River, England, in 1732.

The pilot's profession is not much younger than that of the mariner. The Bible relates (1 Kings 9:27) that Hiram of Tyre provided pilots for King Solomon. The duties of these pilots are not specified. In the first century AD, fishermen of the

Gulf of Cambay, India, met seagoing vessels and guided them into port. It is probable that pilots were established in Delaware Bay earlier than 1756.

Seafaring people of the United States had erected lighthouses and buoys before the Revolutionary War, and in 1789 Congress passed legislation providing for federal expansion of the work. About 1767 the first buoys were placed in the Delaware River. These were logs or barrels, but about 1820 they were replaced with spar buoys. In that same year, the first lightship was established in Chesapeake Bay.

As the maritime interests of various countries grew, more and better aids to navigation were made available. In 1850 Congress prescribed the present system of coloring and numbering United States buoys (app. J). Conformity as to shape resulted from the recommendations of the International Marine Conference of 1889. The second half of the 19th century saw the development of bell, whistle, and lighted buoys, and in 1910 the first lighted buoy in the United States utilizing high pressure acetylene apparatus was placed in service. Stationed at the entrance to Ambrose Channel in New York, it provided the basis for the high degree of perfection which has been achieved in the lighted buoy since that time. The complete buoyage system maintained by the U. S. Coast Guard today is chiefly a product of the 20th century. In 1900 there were approximately 5,000 buoys of all types in use in the United States, while today there are more than 20,000.

116. The sailings.—The various methods of mathematically determining course, distance, and position arrived at have a history almost as old as mathematics itself. Thales, Hipparchus, Napier, Wright, and others contributed the formulas that led to the tables permitting computation of course and distance by plane, traverse, parallel, middle-latitude, Mercator, and great-circle sailings.

Plane sailing (art. 813). Based upon the assumption that the surface of the earth is plane, or flat; this method was used by navigators for many centuries. The navigator solved problems by laying down his course relative to his meridian, and stepping off the distance run to the new position. This system is used with accuracy today in measuring short runs on a Mercator chart, which compensates for the convergence of the meridians, but on the plane chart, serious errors resulted. Early navigators might have obtained mathematical solutions to this problem, with no greater accuracy, but the graphical method was commonly used.

Traverse sailing (art. 814). Because sailing vessels were subject to the winds, navigators of old were seldom able to sail one course for great distances, and consequently a series of small triangles had to be solved. Equipment was designed to help seamen in maintaining their dead reckoning positions. The modern **rough log** evolved from the *log board*, hinged wooden boards that folded like a book and on which courses and distances were marked in chalk. Each day the position was determined from this data and entered in the ship's journal, today's **smooth log.**

The log board was succeeded by the **travas,** a board with lines radiating from the center in 32 compass directions. Regularly spaced along the lines were small holes into which pegs were fitted to indicate time run on the particular course. In 1627 John Smith described the travas as a "little round board full of holes upon lines like the compasse, upon which by the removing of a little sticke they (seamen) keepe an account, how many glasses (which are but halfe houres) they steare upon every point of the compasse."

These devices were of great value to the navigator in keeping a record of the courses and distances sailed, but still left him the long mathematical solutions necessary to determine the new position. In 1436 what appears to have been the first **traverse table** was prepared by Andrea Biancho. Using this table of solutions of right-angled

plane triangles, the navigator was able to determine his course and distance made good after sailing a number of distances in different directions.

Parallel sailing (art. 815) was an outgrowth of the navigator's inability to determine his longitude. Not a mathematical solution in the sense that the other sailings are, it involved converting the distance sailed along a parallel (departure), as determined by dead reckoning, into longitude.

Middle-latitude sailing (art. 816). The inaccuracies involved in plane sailing led to the improved method of middle-latitude sailing early in the 17th century. A mathematician named Ralph Handsen is believed to have been its inventor.

Middle-latitude sailing is based upon the assumption that the use of a parallel midway between those of departure and arrival will eliminate the errors inherent in plane sailing due to the convergence of the meridians. The assumption is reasonably accurate and although the use of Mercator sailing usually results in greater accuracy, middle-latitude sailing still serves a useful purpose.

Mercator sailing (art. 817). Included in Edward Wright's *Certaine Errors in Navigation Detected and Corrected*, of 1599, was the first published table of meridional parts, which provided the basis for the most accurate of rhumb line sailings—Mercator sailing.

Great-circle sailing (art. 819). For many hundreds of years mathematicians have known that a great circle is the shortest distance between two points on the surface of a sphere, but it was not until the 19th century that navigators began to regularly make use of this information.

The first printed description of great-circle sailing appeared in Pedro Nunes' 1537 *Tratado da Sphera*. The method had previously been proposed by Sebastian Cabot in 1498, and in 1524 Verrazano sailed a great-circle course to America. But the sailing ships could not regularly expect the steady winds necessary to sail such a course, and their lack of knowledge concerning longitude, plus the necessity of stopping at islands along their routes to take supplies, made it impractical for most voyages at that time.

The gradual accumulation of knowledge concerning seasonal and prevailing winds, weather conditions, and ocean currents eventually made it possible for the navigator to plan his voyage with more assurance. Nineteenth century writers of navigational texts recommended the use of great-circle sailing, and toward the close of that century such sailing became increasingly popular, particularly in the Pacific.

The mathematics involved in great-circle sailing may be tedious, but the use of the gnomonic projection in locating points along the great-circle track has simplified the method.

117. Hydrographic offices.—The practice of recording hydrographic data was centuries old before the establishment of the first official hydrographic office, in 1720. In that year the **Depot des Cartes, Plans, Journaux et Memoirs Relatifs a la Navigation** was formed in France with the Chevalier de Luynes in charge. The Hydrographic Department of the British Admiralty, though not established until 1795, has played a major part in European hydrographic work.

The **U. S. Coast and Geodetic Survey** was originally founded when Congress, in 1807, passed a resolution authorizing a survey of the coast, harbors, outlying islands, and fishing banks of the United States. On the recommendation of the American Philosophical Society, President Jefferson appointed Ferdinand Hassler, a Swiss immigrant who had founded the Geodetic Survey of his native land, the first Director of the "Coast Survey."

The approaches to New York were the first sections of the coast charted, and from there the work spread northward and southward along the eastern seaboard. In 1844

the work was expanded and arrangements made to chart simultaneously the Gulf and East Coasts. Investigation of tidal conditions began, and in 1855 the first tables of tide predictions were published. The California gold rush gave impetus to the survey of the West Coast, which began in 1850, the year California became a State. The survey ship *Washington* undertook investigations of the Gulf Stream. Coast pilots, or sailing directions, for the Atlantic coast of the United States were privately published in the first half of the 19th century, but about 1850 the Survey began accumulating data that led to federally produced coast pilots. The 1889 *Pacific Coast Pilot* was an outstanding contribution to the safety of West Coast shipping.

Today the U. S. Coast and Geodetic Survey, as it has been called since 1878, provides the mariner with the charts and coast pilots of all waters of the United States and its possessions, and tide and tidal current tables for much of the world.

U. S. Navy Hydrographic Office. In 1830 the U. S. Navy established a "Depot of Charts and Instruments" in Washington, D. C. Primarily, it was to serve as a storehouse where such charts and sailing directions as were available, together with navigational instruments, could be assembled for issue to Navy ships which required them. Lieutenant L. M. Goldsborough and one assistant, Passed Midshipman R. B. Hitchcock, constituted the entire staff.

The first chart published by the Depot was produced from data obtained in a survey made by Lieutenant Charles Wilkes, who had succeeded Goldsborough in 1834, and who later earned fame as the leader of a United States exploring expedition to Antarctica.

From 1842 until 1861 Lieutenant Matthew Fontaine Maury served as Officer-in-Charge. Under his command the office rose to international prominence. Maury decided upon an ambitious plan to increase the mariner's knowledge of existing winds, weather, and currents. He began by making a detailed record of pertinent matter included in old log books stored at the Depot. He then inaugurated a hydrographic reporting program among shipmasters, and the thousands of answers received, along with the log book data, were first utilized to publish the *Wind and Current Chart of the North Atlantic* of 1847. The United States instigated an international conference in 1853 to interest other nations in a system of exchanging nautical information. The plan, which was Maury's, was enthusiastically adopted by other maritime nations, and is the basis upon which hydrographic offices operate today.

In 1854 the Depot was redesignated the "U. S. Naval Observatory and Hydrographical Office," and in 1866 Congress separated the two, broadly increasing the functions of the latter. The Office was authorized to carry out surveys, collect information, and print every kind of nautical chart and publication, all "for the benefit and use of navigators generally."

One of the first acts of the new Office was to purchase the copyright of *The New American Practical Navigator*. Several volumes of sailing directions had already been published. The first *Notice to Mariners* appeared in 1869. Daily broadcast of navigational warnings was inaugurated in 1907, and in 1912, following the sinking of the SS *Titanic*, Hydrographic Office action led to the establishment of the International Ice Patrol.

The development by the U. S. Navy of an improved depth finder in 1922 made possible the acquisition of additional information concerning bottom topography. During the same year aerial photography was first employed as an aid in chart making. The Hydrographic Office published the first chart for lighter-than-air craft in 1923. Aerial geomagnetic surveys were instituted in 1953 to provide magnetic information for ocean areas. Since World War II various electronic means have been employed to improve and extend surveys.

Meanwhile, numerous books have been published to assist the mariner and aviator in the solution of celestial observations. The initials "H.O." preceding a publication number are familiar to most navigators.

The **International Hydrographic Bureau** is an organization whose purpose is to encourage world-wide uniformity in hydrographic procedures. From the time of the International Marine Conference, held at Washington, D. C. in 1889, a need for such an organization was felt, and in 1919, at the Conference held in London, a French proposal for the establishment of such a body was adopted by delegates from the 24 nations represented. The International Hydrographic Bureau, located at Monaco, has since served as a coordinating agency for hydrographic work throughout the world.

118. Navigation manuals.—Although navigation is as old as man himself, navigation textbooks, as they are thought of today, are a product of the last several centuries. Until the end of the Dark Ages such books, or manuscripts, as were available were written by astronomers for other astronomers. The navigator was forced to make use of these, gleaning what little was directly applicable to his profession. After 1500, however, the need for books on navigation resulted in the publication of a series of manuals of increasing value to the mariner.

Sixteenth century manuals. Frequently a command of Latin was required to study navigation during the 16th century. *Regimento do estrolabio e do quadrante* (fig. 130a), which was published at Lisbon in 1509, or earlier, explained the method of finding latitude by meridian observations of the sun and the pole star, contained a traverse table for finding the longitude by dead reckoning, and listed the longitudes of a number of places. Unfortunately, the author made several errors in transcribing the declination tables published by Abraham Zacuto in 1474, and this resulted in errors being made for many years in determining latitude. Nevertheless, the nameless writer of the *Regimento* performed a great service for all mariners. His "Handbook for the Astrolabe and Quadrant"—to translate the title—had many editions and many emulators.

In 1519 Fernandez de Encisco published his *Suma de Geographia*, the first Spanish manual. The book was largely a translation of the *Regimento*, but new information was included, and revisions were printed in 1530 and 1546.

The Flemish mathematician and astronomer R. Gemma Frisius published a book on navigation in 1530. This manual, entitled *De Principiis Astronomiae*, gave an excellent description of the sphere, although the astronomy was that of Ptolemy, and discussed at length the use of the globe in navigation. Gemma gave courses in terms of the principal winds, proposed that longitude be reckoned from the Fortunate Islands (Canary Islands), and gave rules for finding the dead reckoning position by courses and distances sailed.

Tratado da Sphera, Pedro Nunes' great work, appeared in 1537. In addition to the first printed description of great-circle sailing, Nunes' book included a section on determining the latitude by two altitudes of the sun (taken when the azimuths differed by not less than 40°) and solving the problem on a globe. The method was first proposed by Gemma. *Tratado da Sphera* contained the conclusion of a study of the "plane chart" which Nunes had made. He exposed its errors, but was unable to develop a satisfactory substitute.

During the years that followed, an extensive navigational literature became available. The Spaniards Pedro de Medina and Martin Cortes published successful manuals in 1545 and 1551, respectively. Medina's *Arte de Navegar* passed through 13 editions in several languages and *Breve de la Spera y de la Arte de Navegar*, Cortes' book, was eventually translated into English and became the favorite of the British navigator. Cortes discussed the principle which Mercator used 18 years later in constructing his

famous chart, and he also listed accurately the distance between meridians at all latitudes.

The first western hemisphere navigation manual was published by Diego Garcia de Palacio at Mexico City in 1587. His *Instrucion Nauthica* included a partial glossary of nautical terms and certain data on ship construction.

John Davis' *The Seaman's Secrets* of 1594 was the first of the "practical" books. Davis was a celebrated navigator who asserted that it was the purpose of his book to give "all that is necessary for sailors, not for scholars on shore." Davis' book discussed at length the navigator's instruments, and went into detail on the "sailings." He explained the method of dividing a great circle into a number of rhumb lines, and the work he had done with Edward Wright qualified him to report on the method and advantages of Mercator sailing. He endorsed the system of determining latitude by two observations of the sun and the intermediate bearing.

Although best known for the presentation of the theory of Mercator sailing, Edward Wright's *Certaine Errors in Navigation Detected and Corrected* (1599) was a sound navigation manual in its own right. Particularly, he advocated correcting sights for dip, refraction, and parallax (ch. XVI).

Later manuals. The next 200 years saw a succession of navigation manuals made available to the navigator; so many that only a few can be mentioned. Among those which enjoyed the greatest success were Blundeville's *Exercises*, John Napier's *Mirifici Logarithmorum Canonis Constructio* (which introduced the use of logarithms at sea), the tables and rules of Edmund Gunter, *Arithmetical Navigation* by Thomas Addison, and Richard Norwood's *The Sea-mans Practice* (which gave the length of the nautical mile as 6,120 feet). Robert Dudley filled four volumes in writing the *Arcano del Mare* (1646–47) as did John Robertson with *Elements of Navigation*. Jonas and John Moore, William Jones, and several Samuel Dunns were others who contributed navigation books before Nathaniel Bowditch in America and J. W. Norie in England wrote the manuals which navigators found best suited to their needs.

Bowditch's *The New American Practical Navigator* was first published in 1802 (fig. 118), and Norie's *Epitome of Navigation* appeared the following year. Both were outstanding books which enabled the mariner of little formal education to grasp the essentials of his profession. The Englishman's book passed through 22 editions in that country before losing its popularity to Captain Lecky's famous *"Wrinkles" in Practical Navigation* of 1881. The *American Practical Navigator* is still read widely, more than a century-and-a-half after its original printing.

A number of worthy navigation manuals have appeared in recent years.

Celestial Navigation

119. Astronomy is sometimes called the oldest of sciences. The movements of the sun, moon, stars, and planets were used by the earliest men as guides in hunting, fishing, and farming. The first maps were probably of the heavens.

Babylonian priests studied celestial mechanics at a very early date, possibly as early as 3800 BC, more probably about 1500 years later. These ancient astronomers predicted lunar and solar eclipses, constructed tables of the moon's hour angle, and are believed to have invented the zodiac. The week and month as known today originated with their calendar. They grouped the stars by constellations. It is probable that they were arranged in essentially their present order as early as 2000 BC. The five planets easily identified by the unaided eye were known to the Babylonians, who were apparently the first to divide the sun's apparent motion about the earth into 24 equal parts. They published this and other astronomical data in ephemerides. There is evidence that the prophet Abraham had an excellent knowledge of astronomy.

The Chinese, too, made outstanding contributions to the science of the heavens. They may have fixed the solstices and equinoxes before 2000 BC. They had quadrants and armillary spheres, used water clocks, and observed meridian transits. These ancient Chinese determined that the sun made its annual apparent revolution about the earth in 365¼ days, and divided circles into that many parts, rather than 360. About 1100 BC the astronomer Chou Kung determined the sun's maximum declination within about 15′.

Astronomy was used by the Egyptians in fixing the dates of their religious festivals almost as early as the Babylonian studies. By 2000 BC or earlier the new year began with the heliacal rising of Sirius; that is, the first reappearance of this star in the eastern sky during morning twilight after having last been seen just after sunset in the western sky. The heliacal rising of Sirius coincided approximately with the annual Nile flood. The famous Pyramid of Cheops, which was probably built in the 17th century BC, was so constructed that the light of Sirius shone down a southerly shaft when at upper transit, and the light of the pole star shone down a northerly shaft at lower transit, the axes of the two shafts intersecting in the royal burial chamber. When the pyramid was constructed, α *Draconis*, not Polaris, was the pole star.

The Greeks learned of navigational astronomy from the Phoenicians. The earliest Greek astronomer, Thales, was of Phoenician ancestry. He is given credit for dividing the year of the western world into 365 days, and he discovered that the sun does not move uniformly between solstices. Thales is most popularly known, however, for predicting the solar eclipse of 585 BC, which ended a battle between the Medes and the Lydians. He was the first of the great men whose work during the next 700 years was the controlling force in navigation, astronomy, and cartography until the Renaissance.

120. Shape of the earth.—Advanced as the Babylonians were, they apparently considered the earth to be flat. Land surveys of about 2300 BC show a "salt water river" encircling the country (fig. 120).

But seafarers knew that the last to be seen of a ship as it disappeared over the horizon was the masthead. They recognized the longer summer days in England when they sailed to the tin mines of Cornwall, as early as 900 BC. In that "north-

FIGURE 120.—The original and reconstruction of a Babylonian map of about 500 BC. The Babylonians believed the earth to be a flat disk encircled by a salt water river.

land" the Mediterranean sailors noticed that the pole star was higher in the sky and the lower southern constellations were no longer visible. When Thales invented the gnomonic projection, about 600 BC, he must have believed the earth to be a sphere. Two centuries later Aristotle wrote that the earth's shadow on the moon during an eclipse was always circular. Archimedes (287–212 BC) used a glass celestial globe with a smaller terrestrial globe inside it. Although the average man has understood the spherical nature of the earth for only a comparatively short period, learned astronomers have accepted the fact for more than 25 centuries.

121. Celestial mechanics.—Among astronomers the principal question for 2,000 years was not the shape of the earth, but whether it or the sun was the center of the universe. A stationary earth seemed logical to the early Greeks, who calculated that daily rotation would produce a wind of several hundred miles per hour at the equator. Failing to realize that the earth's atmosphere turns with it, they considered the absence of such a wind proof that the earth was stationary.

The belief among the ancients was that all celestial bodies moved in circles about the earth. However, the planets—the "wanderers," as they were called—contradicted this theory by their irregular motion. In the fourth century BC Eudoxus of Cnidus attempted to account for this by suggesting that planets were attached to concentric spheres which rotated about the earth at varying speeds. The plan of **epicycles,** the theory of the universe which was commonly accepted for 2,000 years, was first proposed by Apollonius of Perga in the third century BC. Ptolemy accepted and amplified the plan, explaining it in his famous books, the *Almagest* and *Cosmographia*. According to Ptolemy, the planets moved at uniform speeds in small circles, the centers of which moved at uniform speeds in circles about the earth (fig. 121).

At first the Ptolemaic theory was accepted without question, but as the years passed, forecasts based upon it proved to be inaccurate. By the time the *Alfonsine Tables* were published in the 13th century AD, a growing number of astronomers considered the Ptolemaic doctrine unacceptable. However, Purbach, Regiomontanus, Bernhard Walther of Nuremberg, and even Tycho Brahe in the latter part of the 16th century, were among those who tried to reconcile the earth-centered epicyclic plan to the observed phenomena of the heavens.

As early as the sixth century BC, a brotherhood founded by Pythagoras, a Greek philosopher, proposed that the earth was round and self-supported in space, and that it, the other planets, the sun, and the moon revolved about a central fire which they called *Hestia*, the hearth of the universe. The sun and the moon, they said, shone by reflected light from Hestia.

The central fire was never located, however, and a few hundred years later Aristarchus of Samos advanced a genuine heliocentric theory. He denied the existence of Hestia and placed the sun at the center of the universe, correctly considering it to be a star which shone by itself. The Hebrews apparently understood the correct relationship at least as early as Abraham (about 2000 BC), and the early inhabitants of the Western Hemisphere probably knew of it before the Europeans did.

The Ptolemaic theory was generally accepted until its inability to predict future positions of the planets could no longer be reconciled. Its replacement by the heliocentric theory is credited principally to Nicolaus Copernicus (or Koppernigk). After studying mathematics at the University of Cracow, Copernicus went to Bologna, where he attended the astronomical lectures of Domenicao Maria Novara, an advocate of the Pythagorean theory. Further study in Martianus Copella's *Satyricon*, which includes a discussion of the heliocentric doctrine, convinced him that the sun was truly the center of the universe.

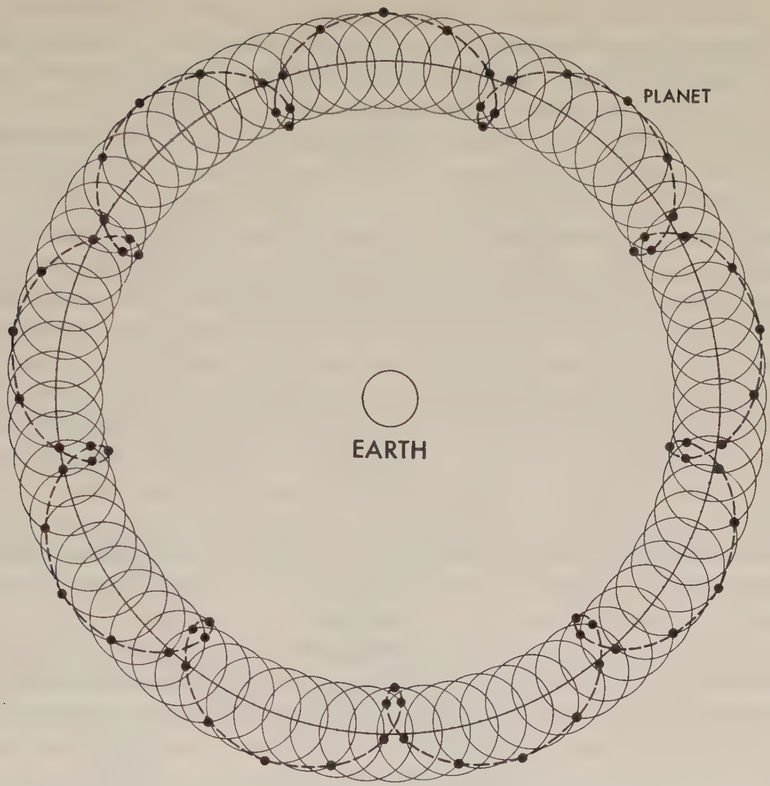

FIGURE 121.—The plan of epicycles, by which the ancients explained the retrograde motion of the planets. The planets were believed to rotate in small circles whose centers moved about the earth in a large circle.

Until the year of his death Copernicus tested his belief by continual observations, and in that year, 1543, he published *De Revolutionibus Orbium Coelestium.* In it he said that the earth rotated on its axis daily and revolved in a circle about the sun once each year. He placed the other planets in circular orbits about the sun also, recognizing that Mercury and Venus were closer than the earth, and the others farther out. He concluded that the stars were motionless in space and that the moon moved circularly about the earth. His conclusions did not become widely known until nearly a century later, when Galileo publicized them. Today, "heliocentric" and "Copernican" are synonymous terms used in describing the character of the solar system.

122. Other early discoveries.—A knowledge of the principal motions of the planets permitted reasonably accurate predictions of future positions. Other, less spectacular data, however, were being established to help round out the knowledge astronomers needed before they could produce the highly accurate almanacs known today.

More than a century before the birth of Christ, Hipparchus discovered the **precession of the equinoxes** (art. 1419) by comparing his own observations of the stars with those recorded by Timocharis and Aristyllus about 300 BC. Hipparchus cataloged more than a thousand stars, and compiled an additional list of time-keeping stars which differed in sidereal hour angle by 15° (one hour), accurate to 15′. A spherical star map, or planisphere, and a celestial globe were among the equipment he designed. However, his instruments did not permit measurements of such precision that stellar parallax could be detected, and, consequently, he advocated the geocentric theory of the universe.

Three centuries later Ptolemy examined and confirmed Hipparchus' discovery of precession. He published a catalog in which he arranged the stars by constellations and gave the magnitude, declination, and right ascension (art. 1426) of each. Following Hipparchus, Ptolemy determined longitudes by eclipses. In the *Almagest* he included the plane and spherical trigonometry tables which Hipparchus had developed, mathematical tables, and an explanation of the circumstances upon which the equation of time (art. 1912) depends.

The next thousand years saw little progress in the science of astronomy. Alexandria continued as a center of learning for several hundred years after Ptolemy, but succeeding astronomers at the observatory confined their work to comments on his great books. The long twilight of the Dark Ages had begun.

Alexandria was captured and destroyed by the Arabs in AD 640, and for the next 500 years Moslems exerted the primary influence in astronomy. Observatories were erected at Baghdād and Damascus during the ninth century. Ibn Yunis' observatory near Cairo gathered the data for the Hakimite tables in the 11th century. Earlier, the Spanish, under Moorish tutelage, set up schools of astronomy at Cordova and Toledo.

123. Modern astronomy may be said to date from Copernicus, although it was not until the invention of the telescope, about 1608, that precise measurement of the positions and motions of celestial bodies was possible.

Galileo Galilei, an Italian, made outstanding contributions to the cause of astronomy, and these served as a basis for the work of later men, particularly Isaac Newton. He discovered Jupiter's satellites, providing additional opportunities for determining longitude on land. He maintained that it is natural for motion to be uniform and in a straight line and that a force is required only when direction or speed is changing. Galileo's support of the heliocentric theory, his use and improvement of the telescope, and particularly the clarity and completeness of his records provided firm footing for succeeding astronomers.

Early in the 17th century, before the invention of the telescope, Tycho Brahe found the planet Mars to be in a position differing by as much as 8′ from that required by the geocentric theory. When the telescope became available, astronomers learned that the apparent diameter of the sun varied during the year, indicating that the earth's distance from the sun varies, and that its orbit is not circular.

Johannes Kepler, a German who had succeeded Brahe and who was attempting to account for his 8′ discrepancy, published in 1609 two of astronomy's most important doctrines, the **law of equal areas,** and the **law of elliptical orbits.** Nine years later he announced his third law, relating the periods of revolution of any two planets to their respective distances from the sun (art. 1407).

Kepler's discoveries provided a mathematical basis by which more accurate tables of astronomical data were computed for the maritime explorers of the age. His realization that the sun is the controlling power of the system and that the orbital planes of the planets pass through its center almost led him to the discovery of the law of gravitation.

Sir Isaac Newton reduced Kepler's conclusions to the **universal law of gravitation** (art. 1407) when he published his three laws of motions in 1687. Because the planets exert forces one upon the other, their orbits do not agree exactly with Kepler's laws. Newton's work compensated for this and, as a result, the astronomer was able to forecast with greater accuracy the positions of the celestial bodies. The navigator benefited through more exact tables of astronomical data.

Between the years 1764 and 1784, the Frenchmen Lagrange and Laplace conclusively proved the solar system's mechanical stability. Early in the 19th century,

Nathaniel Bowditch translated and commented upon Laplace's *Mécanique Céleste*, bringing it up-to-date. Prior to their work this stability had been questioned due to apparent inconsistencies in the motions of some of the planets. After their demonstrations, men were convinced and could turn to other important work necessary to refine and improve the navigator's almanac.

But there were real, as well as apparent, irregularities of motion which could not be explained by the law of gravitation alone. By this law the planets describe ellipses about the sun, and these orbits are repeated indefinitely, except as the other planets influence the orbits of each by their own gravitational pull. Urbain Leverrier, one-time Director of the Paris Observatory, found that the line of apsides of Mercury was advancing 43″ per century faster than it should, according to the law of gravitation and the positions of other known planets. In an attempt to compensate for the resulting errors in the predicted positions of the planet, he suggested that there must be a mass of circulating matter between the sun and Mercury. No such circulating matter has been found, however, and Leverrier's discovery is attributed to a shortcoming of Newton's law, as explained by Albert Einstein.

In Einstein's hands, Leverrier's 43″ became a fact as powerful as Brahe's 8′ had been in the hands of Kepler. Early in the 20th century, Einstein announced the theory of relativity (art. 1407). He stated that for the planets to revolve about the sun is natural, and gravitational force is unnecessary for this, and he asserted that there need be no circulating matter to account for the motion of the perihelion of Mercury as this, too, is in the natural order of things. Calculated from his theory, the correction to the previously computed motion of the perihelion in 100 years is 42″9.

Prior to Einstein's work, other discoveries had helped round out man's knowledge of the universe.

Aberration (art. 1417), discovered by James Bradley about 1726, accounted for the apparent shifting of the stars throughout the year, due to the combined orbital speed of the earth and the speed of light. Twenty years later Bradley described the periodic wobbling of the earth's axis, called **nutation** (art. 1417), and its effect upon precession of the equinoxes.

Meanwhile, in 1718 Edmond Halley, England's second Astronomer Royal, detected a motion of the stars, other than that caused by precession, that led him to conclude that they, too, were moving. By studying the works of the Alexandrian astronomers, he found that some of the most prominent stars had changed their positions by as much as 32′. Jacques Cassini gave Halley's discovery further support when he found, a few years later, that the declination of Arcturus had changed 5′ in the 100 years since Brahe made his observations. This **proper motion** (art. 1414) is motion in addition to that caused by precession, nutation, and aberration.

Sir William Herschel, the great astronomer who discovered the planet Uranus in 1781, proved that the solar system is moving toward the constellation *Hercules*. As early as 1828 Herschel advocated the establishment of a standard time system. Neptune was discovered in 1846 after its position had been predicted by the Frenchman Urbain Leverrier. Based upon the work of Percival Lowell, an American, Pluto was identified in 1930. Uranus, Neptune, and Pluto are of little concern to the navigator.

A more recent discovery may well have greater navigational significance. This is the existence of sources of electromagnetic energy in the sky in the form of **radio stars** (art. 1414). The sun has been found to transmit energy of radio frequency, and instruments have been built which are capable of tracking it across the sky regardless of weather conditions.

124. Sextant.—Prior to the development of the magnetic compass, the navigator used the heavenly bodies chiefly as guides by which to steer. The compass, however,

FIGURE 124a.—An ancient astrolabe, one of the earliest kinds of altitude-measuring instruments.

led to more frequent long voyages on the open sea, and the need for a vertical-angle measuring device which could be used for determining altitude, so that latitude could be found.

Probably the first such device used at sea was the **common quadrant,** the simplest form of all such instruments. Made of wood, it was a fourth part of a circle, held vertical by means of a plumb bob. An observation made with this instrument at sea was a two- or three-man job. This device was probably used ashore for centuries before it went to sea, although its earliest use by the mariner is unknown.

Invented perhaps by Apollonius of Perga in the third century BC, the **astrolabe** (fig. 124a)—from the Greek for *star* and *to take*—had been made portable by the Arabs possibly as early as AD 700. It was in the hands of Christian pilots by the end of the 13th century, often as an elaborate and beautiful creation wrought of precious metals. Some astrolabes could be used as **star finders** (art. 2210) by fitting an engraved plate to one side Large astrolabes were among the chief instruments of 15th and 16th century observatories, but the value of this instrument at sea was limited.

The principle of the astrolabe was similar to that of the common quadrant, but the astrolabe consisted of a metal disk, graduated in degrees, to which a movable sight

FIGURE 124b.—The cross-staff, the first instrument to utilize the visible horizon in making celestial observations.

vane was attached. In using the astrolabe, which may be likened to a pelorus held on its side, the navigator adjusted the sight vane until it was in line with the star, and then read the zenith distance from the scale. As with the common quadrant, the vertical was established by plumb bob.

Three men were needed to make an observation with the astrolabe (one held the instrument by a ring at its top, another aligned the sight vane with the body, a third made the reading) and even then the least rolling or pitching of a vessel caused large acceleration errors in observations. Therefore, navigators were forced to abandon the plumb bob and make the horizon their reference.

FIGURE 124c.—The backstaff, or sea quadrant, a favorite instrument of American colonial navigators.

The **cross-staff** (fig. 124b) was the first instrument which utilized the visible horizon in making celestial observations. The instrument consisted of a long, wooden shaft upon which one of several cross-pieces was mounted perpendicularly. The cross-pieces were of various lengths, the one being used depending upon the angle to be measured. The navigator fitted the appropriate cross-piece on the shaft and, holding one end of the shaft beside his eye, adjusted the cross until its lower end was in line with the horizon and its upper end with the body. The shaft was calibrated to indicate the altitude of the body observed.

In using the cross-staff, the navigator was forced to look at the horizon and the celestial body at the same time. In 1590 John Davis, author of *The Seaman's Secrets*, invented the **backstaff** (fig. 124c) or **sea quadrant.** He was one of the few practical

seamen (Davis Strait is named for him, in honor of his attempt to find the Northwest Passage) to invent a navigational device. The backstaff marked a long advance and was particularly popular among American colonial navigators.

In using this instrument, the navigator turned his back to the sun and aligned its shadow with the horizon. The backstaff had two arcs, and the sum of the values shown on each was the zenith distance of the sun. Later, this instrument was fitted with a mirror to permit observations of bodies other than the sun.

Another instrument developed about the same time was the **nocturnal** (fig. 124d). Its purpose was to provide the mariner with the appropriate correction to be made to the altitude of Polaris to determine latitude. By sighting on Polaris through the hole in the center of the instrument and adjusting the movable arm so that it pointed at Kochab, the navigator could read the correction from the instrument. Most nocturnals had an additional outer disk graduated for the months and days of the year and by adjusting this the navigator could also determine solar time.

FIGURE 124d.—The nocturnal, an instrument used to determine latitude by an observation of Polaris.

Tycho Brahe designed several instruments with arcs of 60°, having one fixed sight and another movable one. He called the instruments **sextants** and the name is now commonly applied to all altitude-measuring devices used by the navigator (ch. XV). In 1700 Sir Isaac Newton sent to Edmond Halley, the Astronomer Royal, a description of a device having double-reflecting mirrors, the principle of the modern marine sextant. However, this was not made public until after somewhat similar instruments had been made in 1730 by the Englishman John Hadley, and the American Thomas Godfrey.

The original instrument constructed by Hadley was, in fact, an *octant*, but due to the double-reflection principle it measured angles up to one-fourth of a circle, or 90°. Godfrey's instrument is reported to have been a *quadrant*, and so could measure angles through 180°. The two men received equal awards from England's Royal Society, as their work was considered to be a case of simultaneous independent invention, although Hadley probably preceded Godfrey by a few months in the actual construction of his sextant.

In the next few years both instruments were successfully tested at sea, but 20 years or more passed before the navigator gave up his backstaff or sea quadrant for the new device. In 1733 Hadley attached a spirit level to a quadrant, and with it was able to measure altitudes without reference to the horizon. Some years later the first bubble sextant (art. 1513) was developed.

Pierre Vernier, in 1631, had attached to the limb of a quadrant a second, smaller graduated arc, thereby permitting angles to be measured more accurately, and this device was incorporated in all later angle-measuring instruments.

The sextant has remained practically unchanged since its invention more than two centuries ago. The only notable improvements have been the addition of an endless tangent screw and a micrometer drum, both having been added during the 20th century.

125. Determining latitude.—The ability to determine longitude at sea is comparatively modern, but latitude has been available for thousands of years.

Meridian transit of the sun. Long before the Christian era, astronomers had determined the sun's declination for each day of the year, and prepared tables listing the data. This was a comparatively simple matter, for the zenith distance obtained by use of a shadow cast by the sun on the day of the winter solstice could be subtracted from that obtained on the day of the summer solstice to determine the range of the sun's declination, about 47°. Half of this is the sun's maximum declination, which could then be applied to the zenith distance recorded on either day to determine the latitude of the place. Daily observations thereafter enabled the ancient astronomers to construct reasonably accurate declination tables.

Such tables were available long before the average navigator was ready to use them, but certainly by the 15th century experienced seamen were determining their latitude at sea to within one or two degrees. In his 1594 *The Seaman's Secrets*, Davis made use of his experience in high latitudes to explain the method of determining latitude by lower transit observations of the sun.

Ex-meridian observation of the sun. The possibility of overcast skies at the one time each day when the navigator could get a reliable observation for latitude led to the development of the "ex-meridian" sight. Another method, involving two sights taken with a considerable time interval between, had previously been known, but the mathematics were so involved that it is doubtful that many seamen made use of it.

There are two methods by which ex-meridian observations can be solved. The direct process was the more accurate, although it required a trigonometrical solution. By the latter part of the 19th century, tables were introduced which made the method of reduction to the meridian more practical and, when occasion demands such an observation, this is the method generally used today. However, with the development of line of position methods and the modern inspection table, ex-meridian observations have lost much of their popularity.

Latitude by Polaris. First use of the pole star to determine latitude is not known, but many centuries ago seamen who used it as a guide by which to steer were known to comment upon its change of altitude as they sailed north or south.

By Columbus' time some navigators were using Polaris to determine latitude, and with the invention of the nocturnal late in the 16th century, providing corrections to the observed altitude, the method came into more general use. The development of the chronometer in the 18th century permitted exact corrections, and this made determination of latitude by Polaris a common practice. Even today, more than a century after discovery of the celestial line of position, the method is still in use. The modern inspection table has eliminated the need for meridian observations as a special method for determining latitude. Perhaps when the almanacs and sight reduction tables make the same provision for solution of Polaris sights as they do for any other navigational star, this last of the special methods will cease to be used for general navigation. But customs die slowly, and one as well established as that of position finding in terms of separate latitude and longitude observations—instead of lines of position—is not likely to disappear completely for many years to come.

126. The search for a method of "discovering" longitude at sea.—A statement once quite common was, "The navigator always knows his latitude." A more accurate statement would have been, "The navigator never knows his longitude." In 1594 Davis wrote: "Now there be some that are very inquisitive to have a way to get the longitude, but that is too tedious for seamen, since it requireth the deep knowledge of astronomy, wherefore I would not have any man think that the longitude is to be found at sea by any instrument, so let no seamen trouble themselves with any such rule, but let them keep a perfect account and reckoning of the way of their ship." In speaking of conditions of his day, he was correct, for it was not until the 19th century that the average navigator was able to determine his longitude with accuracy.

Parallel sailing. Without knowledge of his longitude, the navigator of old found it necessary on an ocean crossing to sail northward or southward to the latitude of his destination, and then to follow that parallel of latitude until the destination was reached, even though this might take him far out of his way. Because of this practice, parallel sailing was an important part of the navigator's store of knowledge. The method was a crude one, however, and the time of landfall was often in error by a matter of days, and, in extreme cases, even weeks.

Eclipses. Almost as early as the rotation of the earth was established, astronomers recognized that longitude could be determined by comparing local time with that at the reference meridian. The problem was the determination of time at the reference meridian.

One of the first methods proposed was that of observing the disappearance of Jupiter's satellites as they were eclipsed by their planet. This method, originally proposed by Galileo for use on land, required the ability to observe and identify the satellites by using a powerful telescope, knowledge of the times at which the eclipses would take place, and the skill to keep the instrument directed at the bodies while aboard a small vessel on the high seas. Although used in isolated cases for many years, the method was not satisfactory at sea, due largely to the difficulty of observation (some authorities recommended use of a telescope as long as 18 or 19 feet) and the lack of sufficiently accurate predictions.

Variation of the compass was seriously considered as a method of determining longitude for 200 years or more. Faleiro, Magellan's advisor, believed it could be so utilized, and, until the development of the chronometer, work was carried on to perfect the theory. Although there is no simple relationship between variation and longitude, those who advocated the method felt certain that research and investigation would eventually provide the answer. Many others were convinced that such a solution did not exist. In 1676, Henry Bond published *The Longitude Found*, in which he stated that the latitude of a place and its variation could be referred to the prime meridian to determine longitude. Two years later Peter Blackborrow rebutted with *The Longitude Not Found*.

Variation was put to good use in determining the nearness to land by shipmasters familiar with the waters they plied, but as the solution to the longitude problem it was a failure, and with the improvement of lunar distance methods and the invention of the chronometer, interest in the method waned. If it had been possible to provide the mariner with an accurate chart of variation, and to keep it up-to-date, a means of establishing an approximate line of position in areas where the gradient is large would have resulted; in many cases this would have established longitude if latitude were known.

Lunar distances. The first method widely used at sea to determine longitude with some accuracy was that of lunar distances (art. 131), by which the navigator

determined GMT by noting the position of the relatively fast-moving moon among the stars. Both Regiomontanus, in 1472, and John Werner, in 1514, have been credited with being the first to propose the use of the lunar distance method. At least one source states that Amerigo Vespucci, in 1497, determined longitude using the moon's position relative to that of another body. One of the principal reasons for establishing the Royal Observatory at Greenwich was to conduct the observations necessary to provide more accurate predictions of the future positions of the moon. Astronomers, including the Astronomers Royal, favored this method, and half a century after the invention of the chronometer it was still being perfected. In 1802 Nathaniel Bowditch simplified the method and its explanation, thus eliminating much of the mystery surrounding it and making it understandable to the average mariner. By using Bowditch's method, the navigator was able to head more or less directly toward his destination, rather than travel the many additional miles often required in "running down the latitude" and then using parallel sailing. An explanation of the lunar distance method, and tables for its use, were carried in the *American Practical Navigator* until 1914.

The Board of Longitude. The lunar distance method, using the data and equipment available early in the 18th century, was far from satisfactory. Ships, cargoes, and lives were lost because of inaccurately-determined longitudes. During the Age of Discovery, Spain and Holland posted rewards for solution to the problem, but in vain. When 2,000 men were lost as a squadron of British men-of-war ran aground on a foggy night in 1707, officers of the Royal Navy and Merchant Navy petitioned Parliament for action. As a result, the Board of Longitude was established in 1714, empowered to reward the person who could solve the problem of "discovering" longitude at sea. A voyage to the West Indies and back was to be the test of proposed methods which were deemed worthy. The discoverer of a system which could determine the longitude within 1° by the end of the voyage was to receive £10,000; within 40′, £15,000; and within 30′, £20,000. These would be handsome sums today. In the 18th century they were fortunes.

127. Evolution of the chronometer.—Many and varied were the solutions proposed for finding longitude, and as the different methods were found unsatisfactory, it became increasingly apparent that the problem was one of keeping the time of the prime meridian. But the development of a device that would keep accurate time during a long voyage seemed to most men to be beyond the realm of possibility. Astronomers were flatly opposed to the idea and felt that the problem was properly theirs. There is even some evidence to indicate that the astronomers of the Board of Longitude made unfair tests of chronometers submitted to them.

Christian Huygens (1629–95), a Dutch scientist and mathematician, made a number of contributions of great value in the field of astronomy, but his most memorable work, to the navigator, was his attempt at constructing a perfect timepiece. It was probably Galileo who first suggested using a pendulum in keeping time. Huygens realized that an error would result from the use of a simple pendulum, however, and he devised one in which the bob hung from a double cord that passed between two plates in such a way that it traced a cycloidal path.

In 1660 Huygens built his first chronometer. The instrument utilized his cycloidal pendulum, actuated by a spring. To compensate for rolling and pitching, Huygens mounted the clock in gimbals. Two years later the instrument was tested at sea, with promising results. The loss of tension in the spring as it ran down was the major weakness in this clock. Huygens compensated for this by attaching oppositely tapered cones and a chain to the spring. A 1665 sea test of the new timepiece showed greater accuracy, but still not enough for determination of longitude. In 1674 he constructed

a chronometer with a special balance and long balance-spring. Although it was the best marine timepiece then known, Huygens' last clock was also unsuited for use at sea due to the error caused by temperature changes.

John Harrison was a carpenter's son, born in Yorkshire in 1693. He followed his father's trade during his youth, but soon became interested in the repair and construction of clocks. At the age of 20 he completed his first timekeeper, a pendulum-type clock with wooden wheels and pinions. Harrison's gridiron pendulum, one which maintained its length despite temperature changes, was designed about 1720, and contained alternate iron and brass rods to eliminate distortion. Until the time that metal

FIGURE 127.—Harrison's No. 1 chronometer. The first of four timekeepers constructed by Harrison, this clock weighs 65 pounds.

alloys having small coefficients of temperature expansion were developed, Harrison's invention was the type pendulum used by almost all clockmakers.

By 1728 Harrison felt ready to take his pendulum, an escapement he had invented, and plans for his own marine timepiece before the Board of Longitude. In London, however, George Graham, a famous clockmaker, advised him to first construct the timekeeper. Harrison did, and in 1735 he submitted his No. 1 chronometer (fig. 127). The Board authorized a sea trial aboard HMS *Centurion*. The following year, that vessel sailed for Lisbon with Harrison's clock on board, and upon her return, the error was found to be three minutes of longitude, a performance which astounded members of the Board. But the chronometer was awkward and heavy, being enclosed in glass

and weighing some 65 pounds, and the Board voted to give Harrison only £500, to be used in producing a more practical timepiece.

During the next few years he constructed two other chronometers, which were stronger and less complicated, although there is no record of their being tested by the Board of Longitude. Harrison continued to devote his life to the construction of an accurate clock to be used in determining longitude, and finally, as he approached old age, he developed his No. 4. Again he went before the Board, and again a test was arranged. In November of 1761, HMS *Deptford* sailed for Jamaica with No. 4 aboard, in the custody of Harrison's son, William. On arrival, after a passage lasting two months, the watch was only nine seconds slow (2¼ minutes of longitude). In January of 1762 it was placed aboard HMS *Merlin* for the return voyage to England. When the *Merlin* anchored in English waters in April of that year, the total error shown by the chronometer was 1 minute, 54.5 seconds. This is equal to less than a half degree of longitude, or less than the minimum error prescribed by the Board for the largest prize. Harrison applied for the full £20,000, but the Board, led by the Astronomer Royal, allowed him only a fourth of that, and insisted on another test.

William Harrison sailed again with No. 4 for Barbados in March of 1764, and throughout the almost four-months-long voyage the chronometer showed an error of only 54 seconds, or 13.5 minutes of longitude. The astronomers of the Board reluctantly joined in a unanimous declaration that Harrison's timepiece had exceeded all expectations, but they still would not pay him the full reward. An additional £5,000 were paid on the condition that plans be submitted for the construction of similar chronometers. Even when this was done, the Board delayed payment further by having one of its members construct a timepiece from the plans. Not until 1773, Harrison's 80th year, was the rest of the reward paid, and only then because of intervention by the king himself.

Pierre LeRoy, a great French clockmaker, constructed a chronometer in 1766 which has since been the basis for all such instruments. LeRoy's several inventions made his chronometer a timepiece which has been described as a "masterpiece of simplicity, combined with efficiency." Others to contribute to the art of watchmaking included Ferdinand Berthoud of France and Thomas Mudge of England, each of whom developed new escapements. The balance wheel was improved by John Arnold, who invented the escapement acting in one direction only, substantially that used today. Acting independently, Thomas Earnshaw invented a similar escapement. He built the first reliable chronometer at a relatively low price. The chronometer the Board of Longitude had made from Harrison's plans cost £450; Earnshaw's cost £45.

Timepieces designed to provide the navigator with information other than time were popular a century or more ago. One showed the times of high and low water, the state of the tide at any time, and the phases of the moon; another gave the equation of time and the apparent motions of the stars and planets; a third offered the position of the sun and both mean and sidereal times. But the chronometers produced by LeRoy and Earnshaw were the ones of greatest value to the navigator; they gave him a simple and reliable method of determining his longitude.

Time signals, which permit the mariner at sea to check the error in his chronometer, are essentially a 20th century development. Telegraphic time signals were inaugurated in the United States at the end of the Civil War, and enabled ships to check their chronometers in port by **time ball** signals. Previously, the Navy's "standard" chronometer had been carried from port to port to allow such comparison. In their most advanced form, time balls were dropped by telegraphic action. In 1904 the first official "wireless" transmission of time signals began from a naval station at Navesink,

N. J. These were low-power signals which could be heard for a distance of about 50 miles. Five years later the range had been doubled, and, as other nations began sending time signals, the navigator was soon able to check his chronometer around the world.

The search for longitude was ended.

128. Establishment of the prime meridian.—Until the beginning of the 19th century, there was little uniformity among cartographers as to the meridian from which longitude was measured. The navigator was not particularly concerned, as he could not determine his longitude, anyway.

Ptolemy, in the second century AD, had measured longitude eastward from a reference meridian two degrees west of the Canary Islands. In 1493 Pope Alexander VI drew a line in the Atlantic west of the Azores to divide the territories of Spain and Portugal, and for many years this meridian was used by chart makers of the two countries. In 1570 the Dutch cartographer Ortelius used the easternmost of the Cape Verde Islands. John Davis, in his 1594 *The Seaman's Secrets*, said the Isle of Fez in the Canaries was used because there the variation was zero. Mariners paid little attention, however, and often reckoned their longitude from several different capes and ports during a voyage, depending upon their last reliable fix.

The meridian of London was used as early as 1676, and over the years its popularity grew as England's maritime interests increased. The system of measuring longitude both east and west through 180° may have first appeared in the middle of the 18th century. Toward the end of that century, as the Greenwich Observatory increased in prominence, English map makers began using the meridian of that observatory as a reference. The publication by the Observatory of the first British *Nautical Almanac* in 1767 further entrenched Greenwich as the prime meridian. A later and unsuccessful attempt was made in 1810 to establish Washington as the prime meridian for American navigators and cartographers. At an international conference held in Washington in 1884 the meridian of Greenwich was officially established, by the 25 nations in attendance, as the prime meridian. Today all maritime nations have designated the Greenwich meridian the prime meridian, except in a few cases where local references are used for certain harbor charts.

129. Astronomical observatories.—Thousands of years before the birth of Christ, crude observatories existed, and astronomers constructed primitive tables which were the forerunners of modern almanacs. The famous observatory at Alexandria, the first "true" observatory, was constructed in the third century BC, but the Egyptians, as well as the Babylonians and Chinese, had already studied the heavens for many centuries. The **armillary sphere** (fig. 129a) was the principal instrument used by the early astronomers. It consisted of a skeleton sphere with several movable rings which could be adjusted to indicate the orbits of the various celestial bodies. One source attributes the invention of the armillary sphere to Eratosthenes in the third century BC; another says the Chinese knew it 2,000 years earlier, as well as the water clock and a form of astrolabe. The Alexandrian observatory was the seat of astronomical learning in the western world for several centuries, and there Hipparchus discovered the precession of the equinoxes, and Ptolemy did the work which led to his *Almagest*.

Astronomical study did not cease entirely during the Dark Ages. The Arabians erected observatories at Baghdād and Damascus in the ninth century AD, and observatories in Cairo and northwestern Persia followed. The Moors brought the astronomical knowledge of the Arabs into Spain, and the *Toledan Tables* of 1080 resulted from an awakening of scientific interest that brought about the establishment of schools of astronomy at Cordova and Toledo in the tenth century.

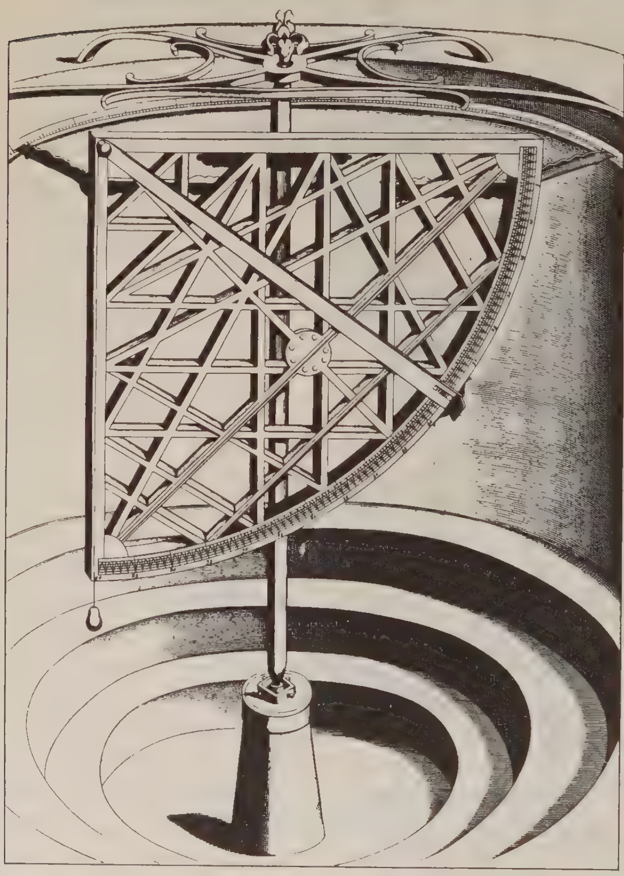
FIGURE 129a.—An armillary sphere, one of the most important instruments of the ancient astronomers.

The great voyages of western discovery began early in the 15th century, and chief among those who recognized the need for greater precision in navigation was Prince Henry "The Navigator" of Portugal. About 1420 he had an observatory constructed at Sagres, on the southern tip of Portugal, so that more accurate information might be available to his captains. Henry's hydrographic expeditions added to the geographical knowledge of the mariner, and he was responsible for the simplification of many navigational instruments.

The Sagres observatory was rudimentary, however, and not until 1472 was the first complete observatory built in Europe. In that year Bernard Walther, a wealthy astronomer, constructed the Nuremberg Observatory, and placed Regiomontanus in charge. Regiomontanus, born Johann Müller, contributed a wealth of astronomical data of the greatest importance to the navigator.

The observatory at Cassel, built in 1561, had a revolving dome and an instrument capable of measuring altitude and azimuth at the same time. Tycho Brahe's Uraniburgum Observatory, located on the Danish island Hveen, was opened in 1576, and the results of his observations contributed greatly to the navigator's knowledge. Prior to the discovery of the telescope, the astronomer could increase the accuracy of his observations only by using larger instruments. Brahe used a quadrant with a radius of 19 feet, with which he could measure altitudes to 0′.6, an unprecedented degree of precision at that time. He also had an instrument with which he could determine altitude and azimuth simultaneously (fig. 129b). After Brahe, Kepler made use of the observatory and his predecessor's records in determining the laws which bear his name.



Courtesy of the Map Division of the Library of Congress.

FIGURE 129b.—A reproduction of Brahe's pelorus. This instrument was used to determine altitude and azimuth simultaneously.

The **telescope,** the modern astronomer's most important tool, was invented by Hans Lippershey about 1608. Galileo heard of Lippershey's invention, and soon improved upon it. In 1610 he discovered the four great moons of Jupiter, which led to the "longitude by eclipse" method successfully used ashore for many years and experimented with at sea. With the 32-power telescope he eventually built, Galileo was able to observe clearly the motions of sun spots, by which he proved that the sun rotates on its axis. In Paris, in 1671, the French National Observatory was established.

Greenwich Royal Observatory. England had no early privately supported observatories such as those on the continent. The need for navigational advancement was ignored by Henry VIII and Elizabeth I, but in 1675 Charles II, at the urging of John Flamsteed, Jonas Moore, Le Sieur de Saint-Pierre, and Christopher Wren, established the Greenwich Royal Observatory. Charles limited construction costs to £500, and appointed Flamsteed the first Astronomer Royal, at an annual salary of £100. The equipment available in the early years of the observatory consisted of two clocks, a "sextant" of seven-foot radius, a quadrant of three-foot radius, two telescopes, and the star catalog published almost a century before by Tycho Brahe. Thirteen years passed before Flamsteed had an instrument with which he could determine his latitude accurately. In 1690 a transit instrument equipped with a telescope and vernier was invented by Romer, and he later added a vertical circle to the device. This enabled the astronomer to determine declination and right ascension at the same

time. One of these instruments was added to the equipment at Greenwich in 1721, replacing the huge quadrant previously used. The development and perfection of the chronometer in the next hundred years added further to the accuracy of observations.

Other national observatories were constructed in the years that followed; at Berlin in 1705, St. Petersburg in 1725, Palermo in 1790, Cape of Good Hope in 1820, Parramatta in New South Wales in 1822, and Sydney in 1855.

U. S. Naval Observatory.—The first observatory in the United States is said to have been built in 1831–1832 at Chapel Hill, N. C. The Depot of Charts and Instruments, established in 1830, was the agency from which the U. S. Navy Hydrographic Office and the Naval Observatory evolved 36 years later. Under Lieutenant Charles Wilkes, the second Officer-in-Charge, the Depot about 1835 installed a small transit instrument for rating chronometers. The Mallory Act of 1842 provided for the establishment of a permanent observatory, and the director was authorized to purchase all such supplies as were necessary to continue astronomical study. The observatory was completed in 1844 and the results of its first observations were published two years later. Congress established the Naval Observatory as a separate agency in 1866. In 1872 a refracting telescope with a 26-inch aperture, then the world's largest, was installed. The observatory, located at Washington, D. C., has occupied its present site since 1893.

The **Mount Wilson Observatory** of the Carnegie Institution of Washington was built in 1904–05. The observatory's 100-inch reflector telescope opened wider the view of the heavens, and enabled astronomers to study the movements of celestial bodies with greater accuracy than ever before. But a still finer tool was needed, and in 1934 the 200-inch reflector for the **Palomar Mountain Observatory** was cast. The six-million-dollar observatory was built by the Rockefeller General Education Board for the California Institute of Technology, which also operates the Mount Wilson Observatory. The 200-inch telescope makes it possible to see individual stars 20,000,000 light-years away and galaxies at least 1,600,000,000 light-years away.

As with earlier instruments, the telescope has about reached the limit of practical size. Present efforts are being directed toward application of the electron microscope to the telescope, to increase the range of present instruments.

130. Almanacs.—From the beginning, astronomers have undoubtedly recorded the results of their observations. Tables computed from such results have been known for centuries. The work of Hipparchus, in the second century BC, and Ptolemy, in his famous *Almagest,* are examples. Then the *Toledan Tables* appeared in AD 1080, and the *Alfonsine Tables* in 1252. Even with these later tables, however, few copies were made, for printing had not yet been invented, and those that were available were kept in the hands of astronomers. Not until the 15th century were the first almanacs printed and made available to the navigator. In Vienna, in 1457, George Purbach issued the first almanac. Fifteen years later the Nuremberg Observatory, under Regiomontanus, issued the first of the ephemerides it published until 1506. These tables gave the great maritime explorers of the age the most accurate information available. In 1474 Abraham Zacuto introduced his *Almanach Perpetuum* (fig. 130a) which contained tables of the sun's declination in the most useful form yet available to the mariner. *Tabulae Prutenicae,* the first tables to be calculated on Copernican principles, were published by Erasmus Reinhold in 1551 and gave the mariner a clearer picture of celestial movements than anything previously available. The work of Brahe and Kepler at the Uraniburgum Observatory provided the basis for the publication of the *Rudolphine Tables* in 1627.

Still, the information contained in these books was intended primarily for the use of the astronomer, and the navigator carried the various tables only that he might

make use of the portions applicable to his work. The first official almanac, *Connaissance des Temps,* was issued by the French National Observatory in 1696. The French Observatory rose to its greatest prominence during the 20 years that Urbain Leverrier held the position of director.

In 1767 the British *Nautical Almanac* was first published. Nevil Maskelyne was then Astronomer Royal, and he provided the navigator with the best information available. The book contained tables of the sun's declination, and corrections to the observed altitude of Polaris. The moon's position relative to other celestial bodies was included at 12-hour intervals, and lunar distance tables gave the angular distance between the moon and certain other bodies at three-hour intervals.

For almost a hundred years the British *Nautical Almanac* was the one used by American navigators, but in 1852 the Depot of Charts and Instruments published the first *American Ephemeris and Nautical Almanac,* for the year 1855.

Early American almanacs were distinguished by their excessive detail in some cases and shortage of data of importance to the navigator in others. Declination was given to the nearest 0".1 and the equation of time to the nearest 0^s.01. Most figures were given only for noon at Greenwich, and a tedious interpolation was involved in converting the information to that at a given time at the longitude of the observer. Lunar distances were given at three-hour intervals. Few star data were listed (fig. 130b).

FIGURE 130a.—An excerpt from the Portuguese *Regimento do estrolabio e do quadrante* of about 1509, giving the sun's declination and other data based upon Zacuto's calculations for the month of March. The first day of spring, the 11th by the Julian calendar then in use, is marked by the symbol of Aries, the ram (♈).

Since 1858 the *American Nautical Almanac* has been printed without the ephemeris section, that part of value chiefly to astronomers. Until 1908 the positions of the brighter stars were given only for January 1st, and in relation to the meridian of Washington. Beginning in that year, the apparent places of 55 major stars were given for the first of each month. In 1913, the tables of lunar distances were omitted. In 1919, sunrise and sunset tables were added.

One of the greatest inconveniences involved in using the old almanacs was the astronomical day, which began at noon of the civil day of the same date. This system was abolished in 1925, and the United States adopted the expression "civil time" to designate time by the new system. Greenwich hour angle was first published for the moon in the *Lunar Ephemeris for Aviators* for the last four months of 1929. This publication became a supplement to the *Nautical Almanac* in 1931, and for 1932 the two were merged.

The *Air Almanac,* designed by Lieutenant Commander P. V. H. Weems, was published for 1933, giving Greenwich hour angle for all bodies included. For 1934

this information was given in the *Nautical Almanac*, and the *Air Almanac* was discontinued. The first British air almanac was published for the last quarter of 1937, and modified for 1939 with features followed closely in the first *American Air Almanac*, for 1941. In 1950 a revised *Nautical Almanac* appeared, patterned after the popular *American Air Almanac*. Starting with the 1953 edition, the British and American air almanacs were combined in a single publication. In that year the United States reverted to the expression "mean time" in place of "civil time." In 1958, the British and American nautical almanacs were combined, and in 1960, the name was standardized.

FIGURE 130b.—Star data from the 1855 *Nautical Almanac*. The annual corrections in declination and right ascension can be used to obtain reasonably correct values today.

131. The navigational triangle.—It is customary for modern navigators to reduce their celestial observations by solving the triangle whose points are the elevated pole, the celestial body, and the zenith of the observer. The sides of this triangle are the polar distance of the body (codeclination), its zenith distance (coaltitude), and the polar distance of the zenith (colatitude of the observer).

Lunar distances. A spherical triangle was first used at sea in solving lunar distance problems. Simultaneous or nearly simultaneous observations were made of the altitudes of the moon and the sun or a star near the ecliptic, and the angular distance between the moon and the other body. The zenith of the observer and the two celestial bodies formed the vertices of the triangle, whose sides were the two coaltitudes and the angular distance between the bodies. By means of a mathematical calculation the navigator "cleared" this distance of the effects of refraction and parallax applicable to each altitude, and other errors. The corrected value was then used as an argument for entering the almanac, which gave the true lunar distance from the sun and several stars at three-hour intervals.

Previously, the navigator had set his watch or checked its error and rate, which could be relied upon for short periods, with the local mean time determined by celestial observations. The local mean time of the watch, properly corrected, applied to the Greenwich mean time obtained from the lunar distance observation, gave the longitude.

The mathematics involved was tedious, and few mariners were capable of solving the triangle until Nathaniel Bowditch published his simplified method in 1802 in *The New American Practical Navigator*. Chronometers were reliable by that time, but their high cost prevented their general use aboard the majority of naval and merchant ships. Using Bowditch's method, however, most navigators, for the first time, could determine their longitude, and so eliminate the need for parallel sailing and the lost time associated with it. The popularity of the lunar distance method is indicated by the fact that tables for its solution were carried in the *American Nautical Almanac* until the second decade of the 20th century.

The determination of latitude was considered a separate problem, usually solved by means of a meridian altitude or an observation of Polaris.

The time sight. The theory of the time sight (art. 2106) had been known to mathematicians since the dawn of spherical trigonometry, but not until the chronometer was developed could it be used by mariners.

The time sight made use of the modern navigational triangle. The codeclination, or polar distance, of the body could be determined from the almanac. The zenith distance (coaltitude) was determined by observation. If the colatitude were known, three sides of the triangle were available. From these the meridian angle was computed. The comparison of this with the Greenwich hour angle from the almanac yielded the longitude.

The time sight was mathematically sound, but the navigator was not always aware that the longitude determined was only as accurate as the latitude, and together they merely formed a point on what is known today as a line of position. If the observed body was on the prime vertical, the line of position ran north and south and a small error in latitude generally had little effect on the longitude. But when the body was close to the meridian, a small error in latitude produced a large error in longitude.

The line of position by celestial observation (art. 1703) was unknown until discovered in 1837 by 30-year-old Captain Thomas H. Sumner, a Harvard graduate and son of a United States Congressman from Massachusetts. The discovery of the "Sumner line," as it is sometimes called, was considered by Maury "the commencement of a new era in practical navigation." In Sumner's own words, the discovery took place in this manner:

"Having sailed from Charleston, S. C., 25th November, 1837, bound to Greenock, a series of heavy gales from the Westward promised a quick passage; after passing the Azores, the wind prevailed from the Southward, with thick weather; after passing Longitude 21° W., no observation was had until near the land; but soundings were had not far, as was supposed, from the edge of the Bank. The weather was now more boisterous, and very thick; and the wind still Southerly; arriving about midnight, 17th December, within 40 miles, by dead reckoning, of Tusker light; the wind hauled S. E., true, making the Irish coast a lee shore; the ship was then kept close to the wind, and several tacks made to preserve her position as nearly as possible until daylight; when nothing being in sight, she was kept on E. N. E. under short sail, with heavy gales; at about 10 A. M. an altitude of the sun was observed, and the Chronometer time noted; but, having run so far without any observation, it was plain the Latitude by dead reckoning was liable to error, and could not be entirely relied on.

"Using, however, this Latitude, in finding the Longitude by Chronometer, it was found to put the ship 15′ of Longitude, E. from her position by dead reckoning; which in Latitude 52° N. is 9 nautical miles; this seemed to agree tolerably well with the dead reckoning; but feeling doubtful of the Latitude, the observation was tried with a Latitude 10′ further N., finding this placed the ship E. N. E. 27 *nautical* miles, of the former position, it was tried again with a Latitude 20′ N. of the dead reckoning; this

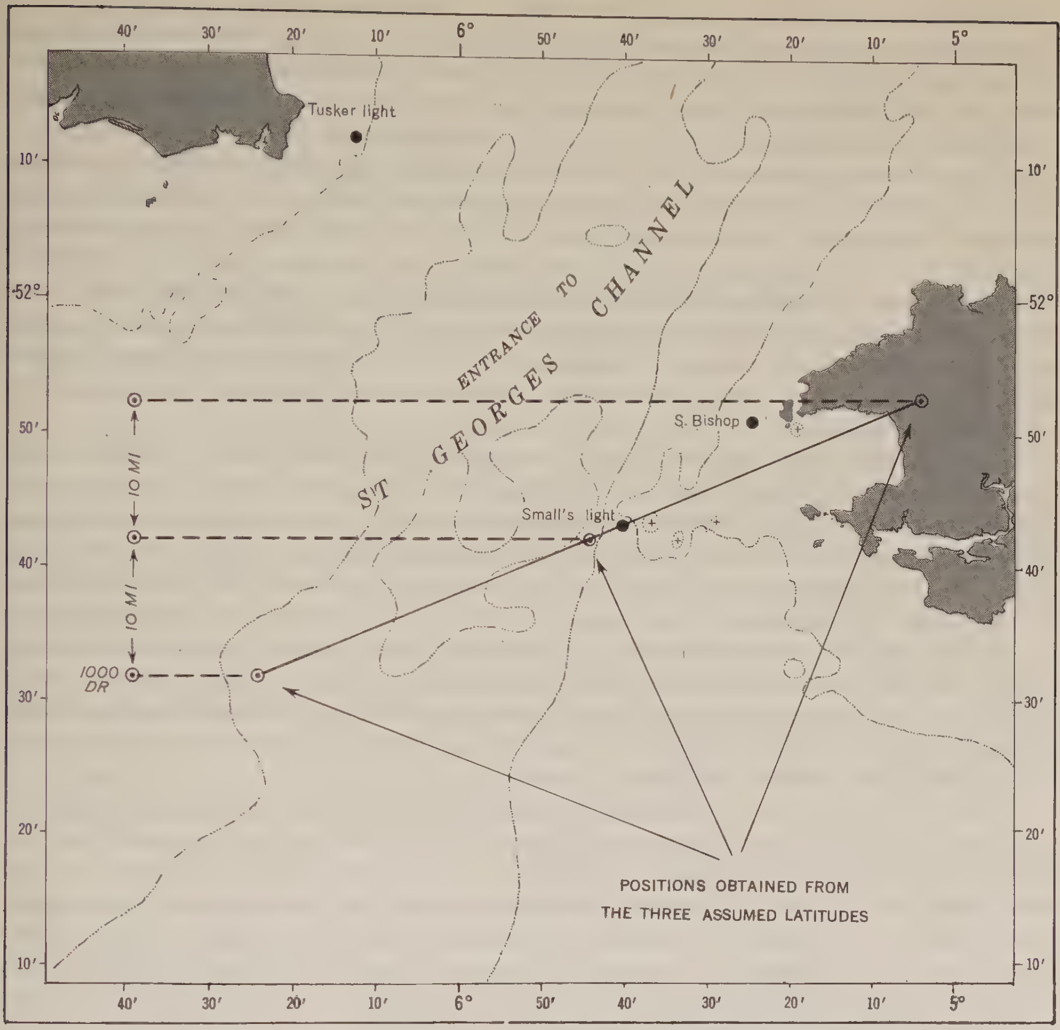

FIGURE 131.—The first celestial line of position, obtained by Captain Thomas Sumner in 1837.

also placed the ship still further E. N. E., and still 27 *nautical miles* further; these three positions were then seen to lie in the direction of *Small's light.* It then at once appeared, that the observed altitude must have happened at *all the three* points, and at *Small's light,* and at the ship, at the *same instant of time*; and it followed, that Small's light must bear E. N. E., if the Chronometer was right. Having been convinced of this truth, the ship was kept on her course, E. N. E., the wind being still S. E., and in less than an hour, Small's light was made bearing E. N. E. ½ E., and close aboard."

In 1843 Sumner published his book, *A New and Accurate Method of Finding a Ship's Position at Sea by Projection on Mercator's Chart,* which met with great acclaim. In it he proposed that a single time sight be solved twice, as he had done (fig. 131), using latitudes somewhat greater and somewhat less than that arrived at by dead reckoning, and joining the two positions obtained to form the line of position. It is significant that Sumner was able to introduce this revolutionary principle without seriously upsetting the method by which mariners had been navigating for years. Perhaps he realized that a better method could be derived, but almost certainly navigators would not have accepted the line of position so readily had he recommended that they abandon altogether the familiar time sight.

The Sumner method required the solution of two time sights to obtain each line of position. Many older navigators preferred not to draw the lines on their charts, but to fix their position mathematically by a method which Sumner had also devised and included in his book. This was a tedious procedure, but a popular one. Lecky recommended the method, and it was still in use early in the 20th century.

The alternative to working two time sights in the Sumner method was to determine the azimuth of the body and to draw a line perpendicular to it through the point obtained by working a single time sight. Several decades after the appearance of Sumner's book, this method was made available to navigators through the publication of accurate azimuth tables, and the system was widely used until comparatively recent times. The 1943 edition of the *American Practical Navigator* included examples of its use. The two-minute azimuth tables still found on many ships were designed principally for this purpose. The mathematical solution for azimuth was not at first a part of the time sight.

132. Modern methods of celestial navigation.—Sumner gave the mariner the line of position; St.-Hilaire the altitude difference or intercept method. Others who followed these men applied their principles to provide the navigator with rapid means for determining his position. The new navigational methods developed by these men, although based upon work done earlier, are largely a product of the 20th century.

Four hundred years ago Pedro Nunes used a globe to obtain a fix by two altitudes of the sun, and the azimuth angles. Fifty years later Robert Hues determined his latitude on a globe by using two observations and the time interval between them. G. W. Littlehales, of the U. S. Navy Hydrographic Office, advocated using a stereographic projection to obtain computed altitude and azimuth in his *Altitude, Azimuth, and Geographical Position*, published in 1906.

Various graphic and mechanical methods have also been proposed. Of these, only one, the *Star Altitude Curves* of Captain P. V. H. Weems, USN (Ret.), has had wide usage, almost entirely among aviators. During World War II, some aircraft were fitted with a device called an "astrograph," which projected star altitude curves from film upon a special plotting sheet. The curves could be moved to allow for the earth's rotation. When they were properly oriented, part of the line of position could be traced on the plotting sheet. More generally, however, the navigational triangle has been solved mathematically or by the use of tables.

Spherical trigonometry is the basis for solving every navigational triangle, and until about 80 years ago the navigator had no choice but to completely solve each triangle himself. The cosine formula is a fundamental spherical trigonometry formula by which the navigational triangle can be conveniently solved. This formula was commonly used in lunar distance solutions when they were first introduced, but, because ambiguous results are obtained when the azimuth is close to 90° or 270°, mathematicians turned to the haversine, which has the advantage of increasing numerically from 0° to 180°. The **cosine-haversine formula** (art. 2109) was used by navigators until recent years.

Toward the end of the 19th century the "short" methods began to appear. About 1875, A. C. Johnson of the British Royal Navy published his book *On Finding the Latitude and Longitude in Cloudy Weather*. No plotting was involved in Johnson's method, but he made use of the principle that a single time sight be worked, rather

than the two that Sumner proposed, and the line of position drawn through the point thus determined.

In 1879 Percy L. H. Davis, of the British Nautical Almanac Office, and Captain J. E. Davis collaborated on a *Sun's True Bearing or Azimuth Table*, which enabled the navigator to lay down a line of position using a computed azimuth. *Chronometer Tables*, published by Percy Davis 20 years later, covered latitudes up to 50° and gave local hour angle values for selected altitudes to one minute of arc. In 1905 his *Requisite Tables* were issued, enabling the mariner to "solve spherical triangles with three variable errors."

These were the first of a large number of "short" solutions which followed the work of Marcq St.-Hilaire. Generally, they consist of adaptations of the formulas of spherical trigonometry, and tables of logarithms in a convenient arrangement. It is customary for such methods to divide the navigational triangle into two right spherical triangles by dropping a perpendicular from one vertex to the side opposite. In some methods, partial solutions are made and the results tabulated. Aquino and Braga of Brazil; Ball, Comrie, Davis, and Smart of England; Bertin, Hugon, and Souillagouet of France; Fuss of Germany; Ogura and Yonemura of Japan; Blackburne of New Zealand; Pinto of Portugal; Garcia of Spain; and Ageton, Driesonstok, Gingrich, Rust, and Weems of the United States are but a few of those providing such solutions. Although "inspection tables" have largely superseded them, many of these "short" methods are still in use, kept alive largely by the compactness of their tables and the universality of their application. They are an intermediate step between the tedious earlier solutions and the fast tabulated ones, and they encouraged the navigator to work to a practical precision. The earlier custom of working to a precision not justified by the accuracy of the information used created a false sense of security in the mind of some navigators, especially those of little experience.

A book of tabulated solutions, from which an answer can be extracted by inspection, is not a new idea. Lord Kelvin, generally considered the father of modern navigational methods, expressed interest in such a method. However, solution of the many thousands of triangles involved would have made the project too costly if done by hand. Electronic computers have provided a practical means of preparing tables. In 1936 the first published volume of H.O. Pub. No. 214 was made available, and later H.O. Pub. No. 249 was provided for air navigators. British Admiralty editions of both these sets of tables have been published. Editions of H.O. Pub. No. 214 have also been published by the Instituto Hidrographico de la Marina, Cadiz, Spain, and by the Istituto Idrografico della Marina, Genova, Italy.

Electronic Navigation

133. Electricity.—Twenty-five hundred years ago Thales of Miletus commented on basic electrical phenomena, but more than two millenniums passed before men first approached an understanding of electricity and the uses to which it could be put.

Until about 1682 the only known method of creating electricity was by rubbing glass with silk or amber with wool. Then Otto von Guericke of Magdeburg invented an "electric machine" and made possible the creation of electricity for experimental work. The Leyden jar, the electrical condenser (or machine) commonly used today, had its origin in 1745 when its principle was accidentally discovered independently by P. van Musschenbroek, of the University of Leyden, and von Kleist.

Stephen Gray, about 1729, demonstrated the difference between conductors and non-conductors, or insulators, and ten years later Hawkesbee and DuFay, working independently, each discovered the positive and negative qualities of electricity.

In the middle of the 18th century Sir William Watson of England, developer of the Leyden jar in essentially its present form, sent electricity more than two miles by wire. Whether Watson was aware of the tremendous possibilities his experiment demonstrated is not known. Twenty-five years later, about 1774, Lesage devised what is believed to have been the first method of electrical communication. He had a separate wire for each letter of the alphabet and momentarily charged the appropriate wire to send each letter.

A German scholar, Francis Aepinus (1728–1802), was the first to recognize the reciprocal relationship of electricity and magnetism. In 1837 Karl Gauss and Wilhelm Weber collaborated in inventing a reflecting galvanometer for use in telegraphic work, which was the forerunner of the galvanometer at one time employed in submarine signaling. Michael Faraday (1791–1867), in a lifetime of experimental work, contributed most of what is known today in the field of electromagnetic induction. In 1864 James Clerk Maxwell of Edinburgh made public his electromagnetic theory of light. Many consider it the greatest single advancement in man's knowledge of electricity.

134. Electronics.—In 1887 Heinrich Hertz provided the proof of Maxwell's theory by producing electromagnetic waves and showing that they could be reflected. A decade later Joseph J. Thomson discovered the electron and so provided the basis for the development of the vacuum tube by Fleming and DeForest. In 1899 R. A. Fessenden pointed out that directional reception of radio signals was possible if a single coil or frame aerial was used as the receiving antenna. In 1895 Guglielmo Marconi transmitted a "wireless" message a distance of about one mile. By 1901 he was able to communicate between stations more than 2,000 miles apart. The following year Arthur Edwin Kennelly and Oliver Heaviside introduced the theory of an ionized layer in the atmosphere and its ability to reflect radio waves. Pulse ranging had its origin in 1925 when Gregory Breit and Merle A. Tuve used this principle to measure the height of the ionosphere.

135. Application of electronics to navigation.—Perhaps the first application of electronics to navigation was the transmission of radio **time signals** (art. 1909) in 1904, thus permitting the mariner to check his chronometer at sea. Telegraphic time signals had been sent since 1865, providing a means of checking the chronometer in various ports.

Next, radio broadcasts providing navigational warnings, begun in 1907 by the U. S. Navy Hydrographic Office, helped increase the safety of navigation at sea.

By the latter part of World War I the directional properties of a loop antenna were successfully utilized in the **radio direction finder** (art. 1202). The first radiobeacon was installed in 1921.

Early 20th century experiments by Behm and Langevin led to the development, by the U. S. Navy, of the first practical **echo sounder** (art. 619) in 1922.

As early as 1904, Christian Hulsmeyer, a German engineer, obtained patents in several countries on a proposed method of utilizing the reflection of radio waves as an obstacle detector and a navigational aid to ships. Apparently, the device was never constructed. In 1922 Marconi said, "It seems to me that it should be possible to design apparatus by means of which a ship could radiate or project a divergent beam of these rays (electromagnetic waves) in any desired direction, which rays if coming across a metallic object, such as another ship, would be reflected back to a receiver screened from the local transmitter on the sending ship, and thereby immediately reveal the presence and bearing of the other ship in fog or thick weather."

In that same year of 1922 two scientists, Dr. A. Hoyt Taylor and Leo C. Young, testing a communication system at the Naval Aircraft Radio Laboratory at

Anacostia, D. C., noted fluctuations in the signals when ships passed between stations on opposite sides of the Potomac River. Although the potential value of the discovery was recognized, work on its exploitation did not begin until March 1934, when Young suggested to Dr. Robert M. Page, an assistant, that this might bear further investigation. By December, Page had constructed a pulse-signal device that determined the positions of aircraft. This was the first **radar** (art. 1208). In the spring of 1935 the British, unaware of American efforts, began work in this field, and developed radar independently. In 1937 the USS *Leary* tested the first seagoing radar. In 1940 United States and British scientists combined their efforts, resulting in more rapid progress. Probably no scientific or industrial development in history expanded so rapidly in all phases—research, development, design, production, trials, and training—and on such a scale. In 1945, at the close of hostilities of World War II, radar was made available for commercial use.

Meanwhile, the pulse technique upon which radar is based was utilized for other navigational aids. Work on **loran** (art. 1302) began at the Radiation Laboratory at the Massachusetts Institute of Technology in 1941. By the end of 1942 the first stations had been established, in the North Atlantic. Installations in the Aleutians and the South Pacific soon followed. With the termination of hostilities, loran, like radar, was made available for public use. A somewhat similar system, **gee** (art. 1308), was developed simultaneously in Great Britain. Another pulse system, **shoran** (art. 1213), was developed by the United States for bombing through undercast. Following World War II this aid was further perfected and used for measurement of distances in surveying. A lower frequency, longer range system called **electronic position indicator** (**EPI**) (art. 1213) was developed by the U. S. Coast and Geodetic Survey for use in locating survey ships a considerable distance offshore. Another American development, **Raydist** (arts. 1214, 1311), is used in accurate measurement of distance for surveying and for ship speed trials. Raydist; **Decca** (art. 1309), a British hyperbolic system of high accuracy used for navigation and surveying; and **lorac** (art. 1310), a somewhat similar American system, use continuous waves, rather than pulses. Not only are such devices improving the accuracy of charted features, but they may well apply directly to geodesy, permitting a more accurate determination of the size and shape of the earth, for they make possible measurement of distances across previously inaccessible terrain.

A rotating electronic beam was utilized during World War II in the German navigation system called **sonne** (art. 1206), later further perfected by the British under the name **consol** (art. 1206).

In air navigation electronics was used to develop an automatic direction finder. Four-course **radio ranges** (art. 1207) and the more recent **vortac** (art. 1207) have been used to mark the federal airways. Electronics has various applications to traffic control in congested areas, and in low-visibility approach systems permitting landings under conditions of reduced horizontal and vertical visibility.

Electronics permits measurement of weather conditions at various heights and distances from observing stations, and the transmission of observations from isolated stations to weather centrals. Radar is permitting study of the structure and movement of thunderstorms.

High-speed electronic computers make practicable the modern inspection table, and rapidly perform lengthy computations which make it possible for loran tables and charts to become available to the navigator almost as soon as new stations are operational.

The application of electronics to navigation is almost limitless. Many systems not mentioned have been suggested, and undoubtedly new ones will be operational in the future.

Conclusion

136. Navigation has come a long way, but there is no evidence that it is nearing the end of its development. Progress will continue as long as man remains unsatisfied with the means at his disposal.

Perhaps the best guides to the future are the desires of the present, for a want usually precedes an acquisition. Pytheas and his contemporaries undoubtedly dreamed of devices to indicate direction and distance. The 16th century navigator had these, and wanted a method of determining longitude at sea. The 18th century navigator could determine longitude, but found the task a tedious one, and perhaps longed to be freed from the *drudgery* of navigation. The modern navigator is still seeking further release from the *work* of navigation, and now wants to be freed from the limitations of weather.

There is little probability of further major development in the simplification of tables for celestial navigation. Further release from the work of navigation is more likely to come through another approach—*automation*.

This process might be said to have started with the application of electronics to computation. The direct use of electronics in navigation is more spectacular, but in this it is vulnerable to jamming by an unfriendly power, intentional or accidental mechanical damage, natural failure, propagation limitations in certain areas and at certain times, and accuracy limitations at long ranges.

In the future, it is likely that electronics will be applied increasingly as an additional source of energy to extend the range of usefulness of other methods, rather than to replace them. To date electronics has been related primarily to piloting, extending its range far to sea, and permitting its use in periods of foul weather. In the future it can be expected to play an increasingly important role in the field of dead reckoning and celestial navigation. **Inertial** and **Doppler** systems (art. 809) are under development for use in guided missiles and aircraft, and a **geomagnetic electrokinetograph (GEK)** (art. 611) has been developed to measure the cross component of a current by means of two electrodes towed astern a vessel, utilizing the earth's magnetic field. **Radio astronomy** (art. 1102) may provide a practical means of determining position astronomically through overcast. Star trackers and electronic recorders and computers may further extend the application of electronics to celestial navigation.

It is not inconceivable that a fix may someday be automatically and continuously available, perhaps on latitude and longitude dials. However, when this is accomplished, by one or a combination of systems, it will be but a short additional step to feed this information electronically to a pen which will automatically trace the path of the vessel across a chart. Another short step would be to feed the information electrically to a device to control the movements of the vessel, so that it would automatically follow a predetermined track.

When this has been accomplished, new problems will undoubtedly arise, for it is not likely that the time will ever come when there will be no problems to be solved.

137. The navigator.—It might seem that when complete automation has been achieved, all of the work of the navigator will have been eliminated. However, advance planning of route and schedule will undoubtedly require human intelligence. So will the interpretation of results en route, and the alteration of schedule when circumstances render this desirable. Unless the automatic system can be made 100 percent reliable—a remote prospect for the foreseeable future—it will need checking from time to time, and provision will have to be made for other, perhaps cruder, methods in the event of failure.

Until such time as mechanization may become complete and perfect, the prudent navigator will not permit himself to become wholly dependent upon "black boxes" which may fail at crucial moments, or ready-made solutions that may not be available when most needed. Today and in the future, as in the past, a knowledge of fundamental principles is essential to adequate navigation. If the navigator contents himself with the ability to read dials or look up answers in a book, he will be of questionable value. His future, if he has one, will be in jeopardy.

Human beings who entrust their lives to the skill and knowledge of a navigator are entitled to expect him to be capable of handling any reasonable emergency. When his customary tools or methods are denied him, they have a right to expect him to have the necessary ability to take them safely to their destination, however elementary the knowledge and means available to him.

The wise navigator uses all reliable aids available to him, and seeks to understand their uses and limitations. He learns to evaluate his various aids when he has means for checking their accuracy and reliability, so that he can adequately interpret their indications when his resources are limited. He stores in his mind the fundamental knowledge that may be needed in an emergency. Machines may reflect much of the *science* of navigation, but only a competent human can practice the *art* of navigation.

CHAPTER II

BASIC DEFINITIONS

201. Navigation is the process of directing the movements of a craft from one point to another. The word *navigate* is from the Latin *navigatus*, the past participle of the verb *navigere*, which is derived from the words *navis*, meaning "ship," and *agere*, meaning "to move" or "to direct." Navigation of water craft is called **marine navigation** to distinguish it from navigation of aircraft, called **air navigation.** Navigation of a vessel on the surface is sometimes called **surface navigation** to distinguish it from **underwater navigation** of a submerged vessel. The expression **submarine navigation** is applicable to a submarine, whether submerged or on the surface. Navigation of vehicles across land or ice is called **land navigation.** The expression **lifeboat navigation** is used to refer to navigation of lifeboats or life rafts, generally involving rather crude methods. The expression **polar navigation** refers to navigation in the regions near the geographical poles of the earth, where special techniques are employed.

The principal divisions of navigation are as follows:

Dead reckoning is the determination of position by advancing a known position for courses and distances. A position so determined is called a **dead reckoning position.** It is generally accepted that the course *steered* and the speed *through the water* should be used, but the expression is also used to refer to the determination of position by use of the course and speed expected to be made good over the ground, thus making an estimated allowance for disturbing elements such as current and wind. A position so determined is better called an **estimated position.** The expression "dead reckoning" probably originated from use of the Dutchman's log, a buoyant object thrown overboard, to determine the speed of the vessel relative to the object, which was assumed to be *dead* in the water. Apparently, the expression **deduced reckoning** was used when allowance was made for current and wind. It was often shortened to *ded reckoning* and the similarity of this expression to *dead reckoning* was undoubtedly the source of the confusion that is still associated with these expressions.

Piloting (or **pilotage**) is navigation involving frequent or continuous determination of position or a line of position relative to geographic points, to a high order of accuracy. It is practiced in the vicinity of land, dangers, aids to navigation, etc., and requires good judgment and almost constant attention and alertness on the part of the navigator.

Electronic navigation involves the use of electronic equipment in any way. It may be called **radio navigation** if any form of radio is used. **Sonic navigation,** involving the use of sound waves, becomes part of electronic navigation when electronic equipment is used in the control, production, transmission, reception, or amplification of sound signals. Electronic navigation overlaps piloting, and as electronic equipment is developed to make celestial observations (art. 1102), it becomes intimately associated with celestial navigation.

Celestial navigation is navigation using information obtained from celestial bodies.

202. The earth is approximately an **oblate spheroid** (a sphere flattened at the poles). Its dimensions and the amount of flattening are not known exactly, but the values determined by the English geodesist A. R. Clarke in 1866, as defined by the

U. S. Coast and Geodetic Survey in 1880, are used for charts of North America. According to these dimensions the longer or equatorial radius, a, is 3,443.96 nautical, or 3,963.23 statute, miles and the shorter or polar radius, b, is 3,432.28 nautical, or 3,949.80 statute, miles. The mean radius $\left(\frac{2a+b}{3}\right)$ is 3,440.07 nautical, or 3,958.76 statute, miles. The "oblateness" or amount of flattening is $\frac{a-b}{a}=\frac{11.68}{3443.96}=\frac{1}{295}$, or $\frac{1}{294.98}$ if a and b are computed to additional decimal places. For many navigational purposes the earth is assumed to be a sphere, without intolerable error.

The **axis of rotation** or **polar axis** of the earth is the line connecting the **north pole** and the **south pole.**

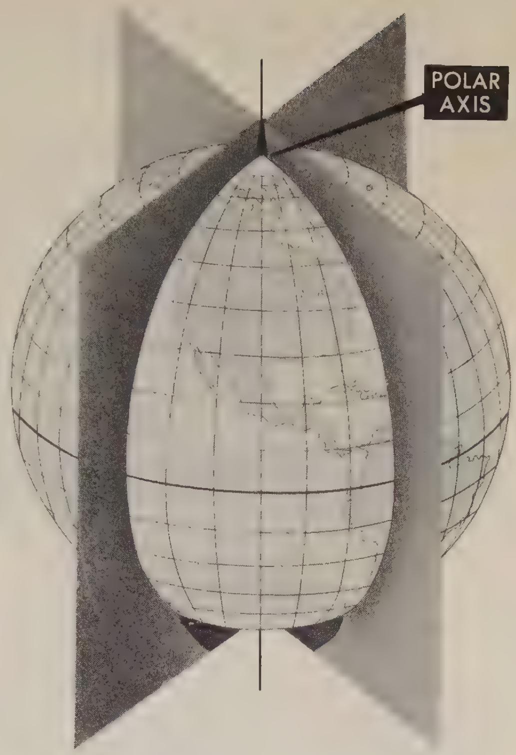

FIGURE 203a.—The planes of the meridians meet at the polar axis.

203. Circles of the earth.—A **great circle** is the line of intersection of a sphere and a plane through the center of the sphere. This is the largest circle that can be drawn on a sphere. The shortest line on the surface of a sphere between two points on that surface is part of a great circle. On the spheroidal earth the shortest line is called a **geodesic.** A great circle is a near enough approximation of a geodesic for most problems of navigation.

A **small circle** is the line of intersection of a sphere and a plane which does not pass through the center of the sphere.

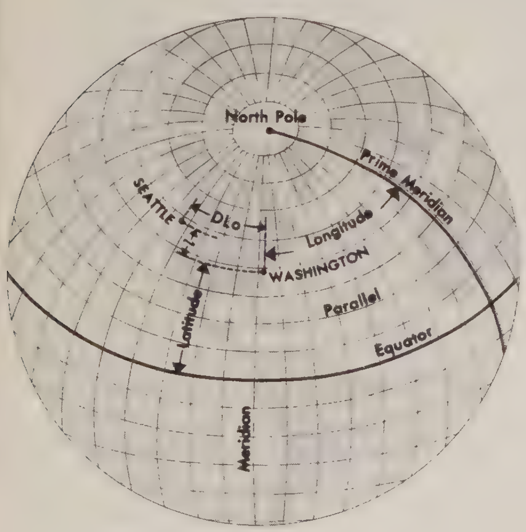

FIGURE 203b.—Circles and coordinates of the earth. All parallels except the equator are small circles; the equator and meridians are great circles.

A **meridian** is a great circle through the geographical poles of the earth. Hence, all meridians meet at the poles, and their planes intersect each other in a line, the **polar axis** (fig. 203a). The term *meridian* is usually applied to the **upper branch** only, that half from pole to pole which passes through a given point. The other half is called the **lower branch.**

The **prime meridian** is that meridian used as the origin for measurement of longitude (fig. 203b). The prime meridian used almost universally is that through the original position of the British Royal Observatory at Greenwich, near London.

The **equator** is the terrestrial great circle whose plane is perpendicular to the polar axis (fig. 203c). It is midway between the poles.

A **parallel** or **parallel of latitude** is a circle on the surface of the earth, parallel to the plane of the equator (fig. 203d). It connects all points of equal latitude. The equator, a great circle, is a limiting case connecting points of 0° latitude. The poles, single points at latitude 90°, are the other limiting case. All other parallels are small circles.

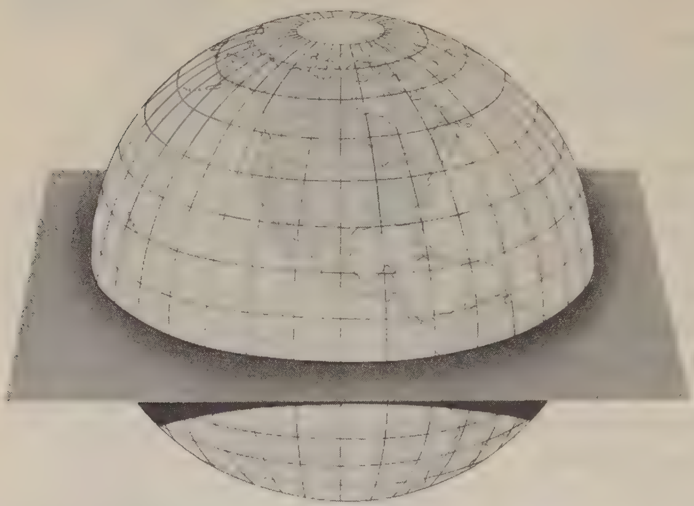

FIGURE 203c.—The equator is a great circle midway between the poles.

204. Position on the earth.—A position on the surface of the earth (except at either of the poles) may be defined by two magnitudes called **coordinates.** Those customarily used are *latitude* and *longitude.* A position may also be expressed in relation to known geographical positions.

Latitude (L, lat.) is angular distance from the equator, measured northward or southward along a meridian from 0° at the equator to 90° at the poles (fig. 203b). It is designated *north* (N) or *south* (S) to indicate the direction of measurement.

The **difference of latitude** (*l*) between two places is the angular length of arc of any meridian between their parallels (fig. 203b). It is the numerical difference of the latitudes if the places are on the same side of the equator, and the sum if they are on opposite sides. It may be designated *north* (N) or *south* (S) when appropriate.

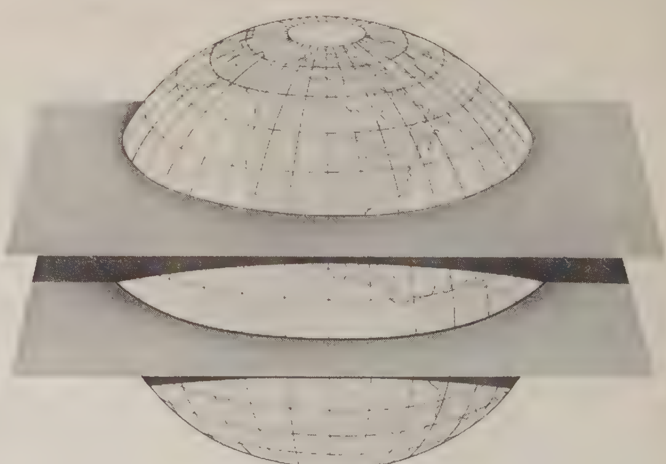

FIGURE 203d.—A parallel of latitude is parallel to the equator.

The **middle** or **mid latitude (Lm)** between two places on the same side of the equator is half the sum of their latitudes. Mid latitude is labeled N or S to indicate whether it is north or south of the equator. The expression is occasionally used with reference to two places on opposite sides of the equator, when it is equal to half the *difference* between the two latitudes, and takes the name of the place farthest from the equator. However, this usage is misleading, as it lacks the significance usually associated with the expression. When the places are on opposite sides of the equator, two mid latitudes are generally used, the average of each latitude and 0°.

Longitude (λ, **long.**) is the arc of a parallel or the angle at the pole between the prime meridian and the meridian of a point on the earth, measured eastward or westward from the prime meridian through 180° (fig. 203b). It is designated *east* (E) or *west* (W) to indicate the direction of measurement.

The **difference of longitude** (**DLo**) between two places is the shorter arc of the parallel or the smaller angle at the pole between the meridians of the two places (fig. 203b). If both places are on the same side (east or west) of Greenwich, DLo is the numerical difference of the longitudes of the two places; if on opposite sides, DLo is the numerical sum unless this exceeds 180°, when it is 360° minus the sum. The distance between two meridians at any parallel of latitude, expressed in distance units, usually nautical miles, is called **departure** (**p**). It represents the distance made good to the east or west as a craft proceeds from one point to another. Its numerical value between any two meridians decreases with increased latitude, while DLo is numerically the same at any latitude. Either DLo or p may be designated *east* (E) or *west* (W) when appropriate.

205. Distance on the earth.—**Distance** (**D, dist.**) is the spatial separation of two points, and is expressed as the length of a line joining them. On the surface of the earth it is usually stated in miles. Navigators customarily use the **nautical mile** (**mi., M**) of 1852 meters exactly. This is the value suggested by the International Hydrographic Bureau in 1929, and since adopted by most maritime nations. It is often called the **international nautical mile** to distinguish it from slightly different values used by some countries. On July 1, 1959, the United States adopted the exact relationship of 1 yard = 0.9144 meter. The length of the international nautical mile is consequently equal to 6,076.11549 U. S. feet (approximately).

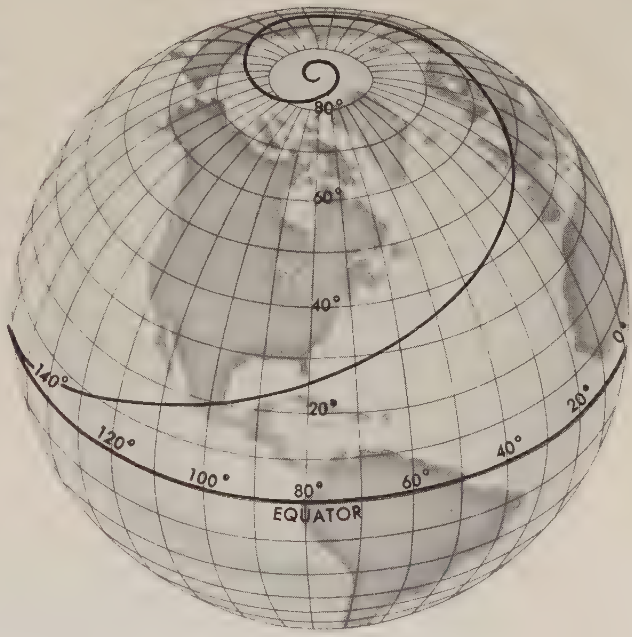

Figure 205.—A rhumb line or loxodrome.

For most navigational purposes the nautical mile is considered the length of one minute of latitude, or of any great circle of the earth, regardless of location. On the Clarke spheroid of 1866, used for mapping North America, the length of one minute of latitude varies from about 6,046 feet at the equator to approximately 6,108 feet at the poles. The length of one minute of a great circle of a sphere having an area equal to that of the earth, as represented by this spheroid, is 6,080.2 United States feet. This was the standard value of the nautical mile in the United States prior to adoption of the international value. A **geographical mile** is the length of one minute of the equator, or about 6,087 feet.

The **land** or **statute mile** (**mi., m**) of 5,280 feet is commonly used for navigation on rivers and lakes, notably the Great Lakes of North America.

The nautical mile is about 38/33 or approximately 1.15 statute miles. A conversion table for nautical and statute miles is given in table 20.

Distance, as customarily used by the navigator, refers to the length of the **rhumb line** connecting two places. This is a line making the same oblique angle with all meridians. Meridians and parallels (including the equator) which also maintain constant true directions, may be considered special cases of the rhumb line. Any other rhumb line spirals toward the pole, forming a **loxodromic curve** or **loxodrome** (fig. 205). Distance along the great circle connecting two points is customarily designated **great-circle distance.**

206. Speed (S) is rate of motion, or distance per unit of time.

A knot (**kn.**), the unit of speed commonly used in navigation, is a rate of one nautical mile per hour. The expression "knots per hour" refers to acceleration, not speed.

Sometimes the expression **speed of advance** (**SOA**) is used to indicate the speed expected to be made good over the ground, and **speed over ground** (**SOG**) the actual speed made good over the ground.

207. Direction on the earth.—Direction is the position of one point relative to another, without reference to the distance between them. In navigation, direction is customarily expressed as the angular difference in degrees from a reference direction, usually north or the ship's head. Compass directions (east, south by west, etc.) or points (of 11¼° or ⅓₂ of a circle) are seldom used by modern navigators for precise directions.

Course (**C, Cn**) is the intended horizontal direction of travel, expressed as angular distance from north, usually from 000° at north, clockwise through 360°. Strictly, the term applies to direction *through the water*, not the direction intended to be made good *over the ground*, but in common American usage it is applied to either. **Course made good** is the single course from the point of departure to point of arrival at any given time. Sometimes the expression **course of advance** (**COA**) is used to indicate the direction expected to be made good over the ground, and **course over ground** (**COG**) the actual direction made good over the ground. **Course line** is a line extending in the direction of a course.

In making computations it is sometimes convenient to express a course as an angle from *either* north or south, through 90° or 180°. In this case it is designated **course angle** (C) and should be properly labeled to indicate the origin (prefix) and direction of measurement (suffix). Thus, C N 35° E = Cn 035° (000°+35°), C N 155° W = Cn 205° (360°−155°), C S 47° E = Cn 133° (180°−47°). But Cn 260° may be either C N 100° W or C S 80° W, depending upon the conditions of the problem.

The symbol C is always used for *course angle*, and is usually used for *course* where there is little or no possibility of confusion.

Track (**TR**) is the path actually followed by a vessel, or the path of proposed travel. It differs from *course* and *course made good* by including the element of distance as well as direction, although the term is occasionally used to refer to direction only. However, the path actually followed is usually a somewhat irregular line. The path of proposed travel consists of one or a series of course lines from the point of departure to the destination, along which it is intended the vessel will proceed. A great circle which a vessel intends to follow approximately is called a **great-circle track.**

Heading (**Hdg., SH**) is the direction in which a vessel is pointed, expressed as angular distance from north, usually from 000° at north, clockwise through 360°. *Heading* should not be confused with *course*. *Heading* is a constantly changing value as a vessel oscillates or yaws back and forth across the course or as the direction of motion is temporarily changed, as in avoiding an obstacle. *Course* is a predetermined value and usually remains constant for a considerable time (fig. 207a).

Bearing (**B, Bn**) is the direction of one terrestrial point from another, expressed as angular distance from a reference direction, usually from 000° at the reference direction, clockwise through 360°. When measured through 90° or 180° from *either*

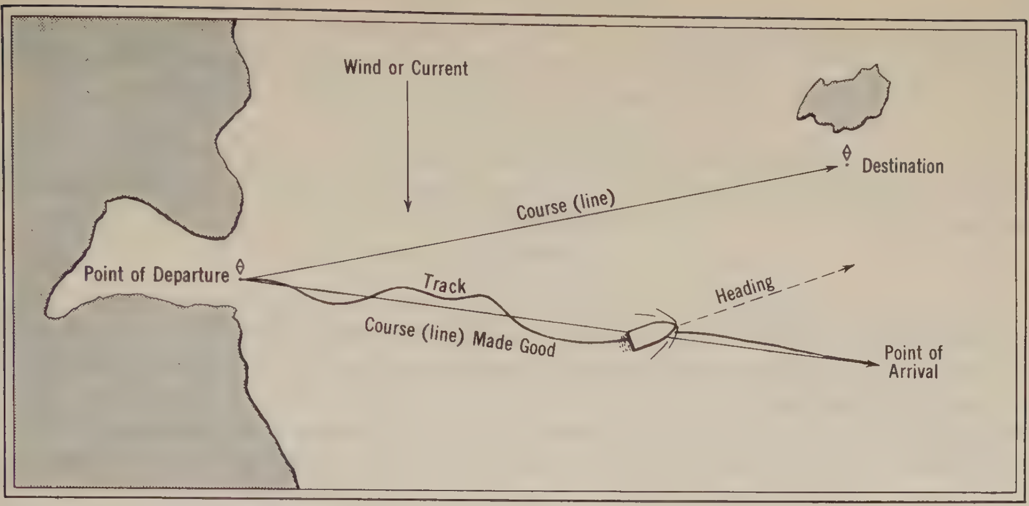

FIGURE 207a.—Course (line), course (line) made good, track, and heading.

north or south, it is called **bearing angle** (**B**), which bears the same relationship to bearing as *course angle* does to *course*. *Bearing* and *azimuth* are sometimes used interchangeably, but the latter is better reserved exclusively for reference to horizontal direction of a point on the celestial sphere from a point on the earth.

A **relative bearing** (**RB**) is one relative to the heading, or to the vessel itself. It is usually measured from 000° at the heading, clockwise through 360°. However, it is sometimes conveniently measured right or left from 0° at the ship's head through 180°. This is particularly true when using table 7. Older methods, such as indicating the number of degrees or points from some part of the vessel (10° forward of the starboard beam, two points on the port quarter, etc.) are seldom used by modern navigators to indicate precise directions, except for bearings dead ahead or astern, or broad on the bow, beam, or quarter.

To convert a relative bearing to a bearing from north (fig. 207b), express the relative bearing in terms of the 0°–360° system and add the heading:

$$Bn = RB + SH$$

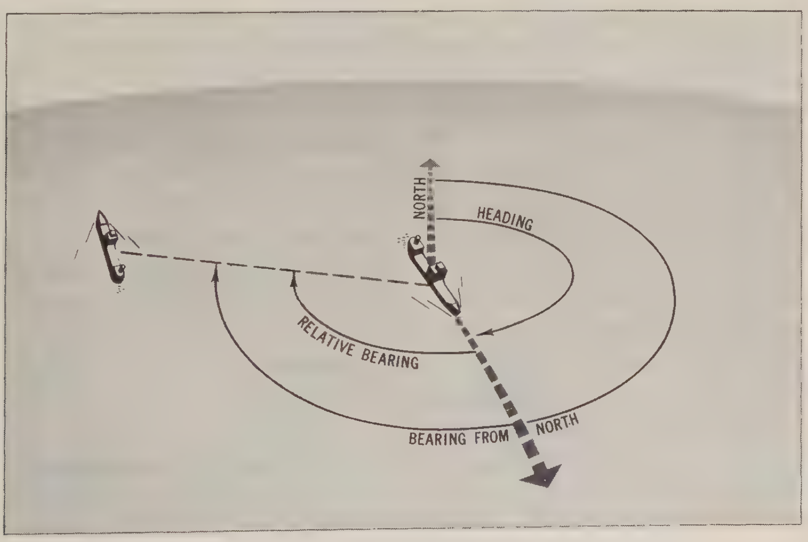

FIGURE 207b.—Relative bearing.

Thus, if another vessel bears 127° relative from a ship whose heading is 150°, the bearing from north is 127°+150°=277°. If the total exceeds 360°, subtract this amount. To convert a bearing from north to a relative bearing, subtract the heading:

$$RB=Bn-SH$$

Thus, a lightship which bears 241° from north bears 241°−137°=104° relative from a ship whose heading is 137°. If SH is larger than Bn, add 360° to Bn before subtracting.

Problems

204. *Given.*—Point *A*: L 37°21′.4 N, λ 143°18′.8 W; Point *B*: L 43°04′.1 N, λ 11°47′.3 E; Point *C*: L 63°24′.4 S, λ 132°06′.9 E; Point *D*: L 2°36′.6 S, λ 168°01′.2 W.

Required.—(1) The difference of latitude between *A* and *B*, between *A* and *C*, and between *C* and *D*.

(2) The difference of longitude between *A* and *B*, *A* and *C*, and *B* and *C*.

Answers.—(1) l_{AB} 5°42′.7 N, l_{AC} 100°45′.8 S, l_{CD} 60°47′.8 N; (2) DLo_{AB} 155°06′.1 E, DLo_{AC} 84°34′.3 W, DLo_{BC} 120°19′.6 E.

205a. The distance between points *E* and *F* is 258.4 nautical miles.

Required.—The distance in statute miles between points *E* and *F* (1) by proportion, using the ratio given in article 205; (2) by conversion factor, using the value given in article 205; (3) by table 20.

Answers.—(1) D 297.6 m, (2) D 297.2 m, (3) D 297.4 m.

205b. The distance between points *G* and *H* is 83.3 statute miles.

Required.—The distance in nautical miles between points *G* and *H* (1) by proportion, using the ratio given in article 205; (2) by conversion factor, using the value given in article 205; (3) by table 20.

Answers.—(1) D 72.3 M, (2) D 72.4 M, (3) D 72.4 M.

206a. A ship is steaming at 18.5 knots.

Required.—The speed in statute miles per hour.

Answer.—S 21.3 mph.

206b. A motorboat is traveling at 30 statute miles per hour.

Required.—The speed in knots.

Answer.—S 26 kn.

207a. *Required.*—Convert the following course angles to courses: (1) N 127° W, (2) S 3° W, (3) N 99° E, (4) S 171° E.

Answers.—(1) Cn 233°, (2) Cn 183°, (3) Cn 099°, (4) Cn 009°.

207b. *Required.*—Convert the following courses to course angles, giving the two possible answers of each: (1) 153°, (2) 257°.

Answers.—(1) C N 153° E or S 27° E, (2) C N 103° W or S 77° W.

207c. A ship is on course 151°. The following relative bearings are observed: (1) 006°, (2) 109°, (3) 255°, (4) broad on the port bow.

Required.—The bearings from north.

Answers.—(1) Bn 157°, (2) Bn 260°, (3) Bn 046°, (4) Bn 106°.

207d. A ship is on course 244°. The following bearings from north are observed: (1) 041°, (2) 188°, (3) 332°.

Required.—The relative bearings.

Answers.—(1) RB 157°, (2) RB 304°, (3) RB 088°.

207e. The captain of a ship on course 055° wishes to change course when a certain lighthouse is broad on the starboard beam.

Required.—The bearing from north when the course is to be changed.

Answer.—Bn 145°.

CHAPTER III

CHART PROJECTIONS

General

301. The navigator's chart.—A **map** is a conventional representation, usually on a plane surface, of all or part of the physical features of the earth's surface or any part of it. A **chart** is such a representation intended primarily for navigation. A **nautical** or **marine chart** is one intended primarily for marine navigation. It generally shows depths of water (by soundings and sometimes also by depth curves), aids to navigation, dangers, and the outline of adjacent land and such land features as are useful to the navigator.

Chart making presents the problem of representing the surface of a spheroid upon a plane surface. The surface of a sphere or spheroid is said to be **undevelopable** because no part of it can be flattened without distortion. A **map projection** or **chart projection** is a method of representing all or part of the surface of a sphere or spheroid upon a plane surface. The process is one of transferring points on the surface of the sphere or spheroid onto a plane, or onto a **developable** surface (one that can be flattened to form a plane) such as a cylinder or cone. If points on the surface of the sphere or spheroid are projected from a single point (including infinity), the projection is said to be **perspective** or **geometric.** Most map projections are not perspective.

302. Selecting a projection.—Each projection has distinctive features which make it preferable for certain uses, no one projection being best for all conditions. These distinctive features are most apparent on charts of large areas. As the area becomes smaller, the differences between various projections become less noticeable until on the largest scale chart, such as of a harbor, all projections become practically identical. Some of the desirable properties are:

1. *True shape* of physical features.
2. *Correct angular relationship.* A projection with this characteristic is said to be **conformal** or **orthomorphic.**
3. *Equal area,* or the representation of areas in their correct relative proportions.
4. *Constant scale* values for measuring distances.
5. *Great circles* represented as straight lines.
6. *Rhumb lines* represented as straight lines.

It is possible to preserve any one and sometimes more than one property in any one projection, but it is impossible to preserve all of them. For instance, a projection cannot be both conformal and equal area, nor can both great circles and rhumb lines be represented as straight lines.

303. Types of projection.—Projections are usually classified primarily as to the type of developable surface to which the spherical or spheroidal surface is transferred. They are sometimes further classified as to whether the projection (but not necessarily the charts made by it) is centered on the equator (**equatorial**), a pole (**polar**), or some point or line between (**oblique**). The name of a projection often indicates its type and sometimes, in addition, its principal feature.

The projection used most frequently by mariners is commonly called **Mercator,** after its inventor (art. 109). Classified according to type this is an **equatorial cy-**

lindrical orthomorphic projection, the cylinder conceived as being tangent along the equator. A similar projection based upon a cylinder tangent along a meridian is called **transverse Mercator** or **transverse cylindrical orthomorphic.** It is sometimes called **inverse Mercator** or **inverse cylindrical orthomorphic.** If the cylinder is tangent along a great circle other than the equator or a meridian, the projection is called **oblique Mercator** or **oblique cylindrical orthomorphic.**

In a **simple conic** projection points on the surface of the earth are conceived as transferred to a tangent cone. In a **Lambert conformal** projection the cone intersects the earth (a **secant** cone) at two small circles. In a **polyconic** projection, a series of tangent cones is used.

An **azimuthal** or **zenithal** projection is one in which points on the earth are transferred directly to a plane. If the origin of the projecting rays is the center of the earth, a **gnomonic** projection results; if it is the point opposite the plane's point of tangency, a **stereographic** projection; and if at infinity (the projecting lines being parallel to each other), an **orthographic** projection (fig. 303). The gnomonic, stereographic, and orthographic are perspective projections. In an **azimuthal equidistant** projection, which is not perspective, the scale of distances is constant along any radial line from the point of tangency.

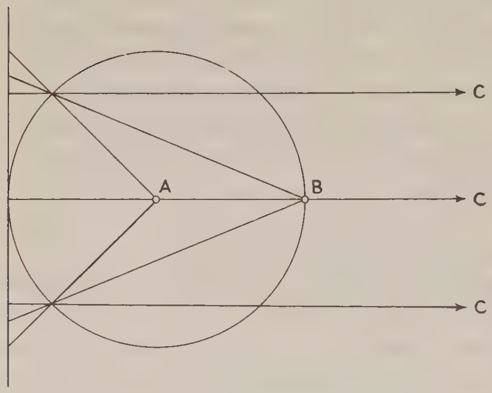

FIGURE 303.—Azimuthal projections: *A*, gnomonic; *B*, stereographic; *C* (at infinity), orthographic.

Cylindrical and plane projections can be considered special cases of conical projections with the heights infinity and zero, respectively.

A **graticule** is the network of latitude and longitude lines laid out in accordance with the principles of any projection.

Cylindrical Projections

304. Features.—If a cylinder is placed around the earth, tangent along the equator, and the planes of the meridians are extended, they intersect the cylinder in a number of vertical lines (fig. 304). These lines, all being vertical, are parallel, or everywhere equidistant from each other, unlike the terrestrial meridians, which become closer together as the latitude increases. On the earth the parallels of latitude are perpendicular to the meridians, forming circles of progressively smaller diameter as the latitude increases. On the cylinder they are shown perpendicular to the projected meridians, but because a cylinder is everywhere of the same diameter, the projected parallels are all the same size.

If the cylinder is cut along a vertical line (a meridian) and spread out flat, the meridians appear as equally spaced, vertical lines, and the parallels as horizontal lines. The spacing of the parallels relative to each other differs in the various types of cylindrical projections.

The cylinder may be tangent along some great circle other than the equator, forming an oblique or transverse cylindrical projection, on which the pattern of latitude and longitude lines appears quite different, since the line of tangency and the equator no longer coincide.

305. Mercator projection.—The only cylindrical projection widely used for navigation is the **Mercator** or **equatorial cylindrical orthomorphic,** named for its inventor Gerhard Kremer (Mercator), a Flemish geographer. It is not perspective and the

parallels cannot be located by geometrical projection, the spacing being derived mathematically. The use of a tangent cylinder to explain the development of the projection has been used, but the relationship of the terrestrial latitude and longitude lines to those on the cylinder is often carried beyond justification, resulting in misleading statements and illustrations.

The distinguishing feature of the Mercator projection (fig. 305) among cylindrical projections is that both the meridians and parallels are expanded at the same ratio with increased latitude. The expansion is equal to the secant of the latitude, with a small correction for the ellipticity of the earth. Since the secant of 90° is infinity, the projection cannot include the poles. Expansion is the same in all directions and angles are correctly shown, the projection being conformal. Rhumb lines appear as straight lines, the directions of which can be measured directly on the chart. Distances can also be measured directly, to practical accuracy, but not by a single distance scale over the entire chart, unless the spread of latitude is small. The latitude scale is customarily used for measuring distances, the expansion of the scale being the same as that of distances at the same latitude. Great circles, except meridians and the equator, appear as curved lines concave to the equator (fig. 310a). Small areas appear in their correct shape but of increased size unless they are near the equator. Plotting of positions by latitude and longitude is done by means of rectangular coordinates, as on any cylindrical projection.

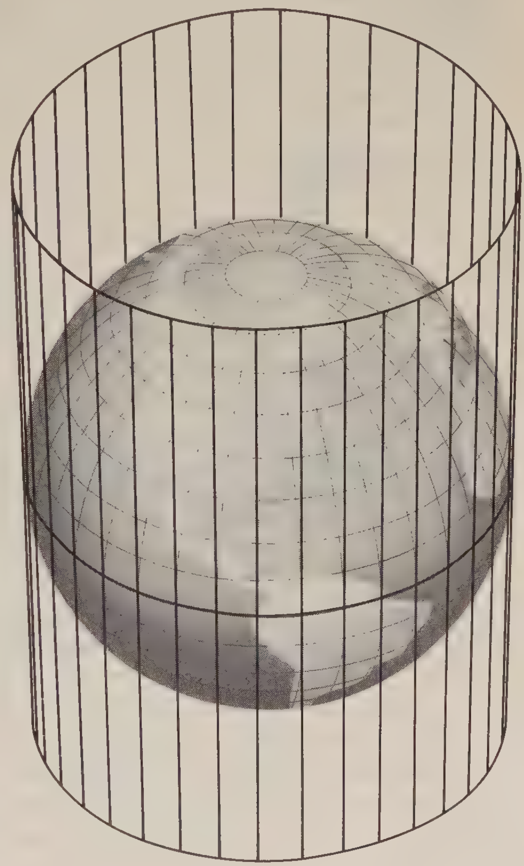

FIGURE 304.—A cylindrical projection.

306. Meridional parts.—At the equator a degree of longitude is approximately equal in length to a degree of latitude. As the distance from the equator increases, degrees of latitude remain approximately the same (not exactly because the earth is not quite a sphere), while degrees of longitude become progressively shorter. Since degrees of longitude appear everywhere the same length in the Mercator projection, it is necessary to increase the length of the meridians if the expansion is to be equal in all directions. Thus, to maintain the correct proportions between degrees of latitude and degrees of longitude, the former are shown progressively longer as the distance from the equator increases (fig. 305).

The length of the meridian, as thus increased between the equator and any given latitude, expressed in minutes of the equator as a unit, constitutes the number of **meridional parts** (**M**) corresponding to that latitude. Meridional parts, given in table 5 for every minute of latitude from the equator to the pole, afford facilities for constructing a Mercator chart and for solving problems in Mercator sailing (art. 817). These values are for the Clarke spheroid of 1866. By means of table 4 they can be converted to the values for certain other spheroids and the sphere.

FIGURE 305.—A Mercator map of the world.

The formula for meridional parts, given in the explanation to table 5, is derived from an integral representing the exact relationship.

307. Mercator chart construction.—To construct a Mercator chart, first select the scale and then proceed as follows:

Draw a series of vertical lines to represent the meridians, spacing them in accordance with the scale selected. If the chart is to include the equator, the distances of the various parallels from the equator are given directly in table 5, although it may be desirable to convert the tabulated values to more convenient units. Thus, if 1°(60′) of longitude is to be shown as one inch, each meridional part will be $\frac{1}{60}$ or 0.01667 inch in length. The distance, in inches, of any parallel from the equator is then determined by dividing its meridional parts by 60 or multiplying them by 0.01667.

If the equator is not to be included, the **meridional difference** (**m**) is used. This is the difference between the meridional parts of the various latitudes and that of the lowest parallel (the one nearest the equator) to be shown. Distances so determined are measured from the lowest parallel.

It is often desired to show a minimum area on a chart of limited size, to the largest possible scale. The scale is then dictated by the limitations.

When the graticule has been completed, the features to be shown are located by means of the latitude and longitude scales.

Example.—A Mercator chart is to be constructed at the maximum scale on a sheet of paper 35 × 46 inches, with a minimum two-inch margin outside the **neat line** limiting

the charted area. The minimum area to be covered is lat. 44°–50° north and long. 56°–68° west.

Solution.—Step one: Determine which dimension to place horizontal. From table 5 the meridional difference is:

$$\begin{array}{lr} M_{50°} & 3456.6 \\ M_{44°} & \underline{2929.6} \\ m & 527.0 \end{array}$$

The chart is to cover at least 12° (68°−56°) of longitude. The longitude is therefore to cover a distance of $12 \times 60 = 720$ meridional parts. Since there are a greater number of meridional parts of longitude to be shown than of latitude, the long dimension is placed horizontal.

Step two: Determine whether the latitude or longitude is the limiting scale factor. The number of inches available for latitude coverage is 31 (35 inches minus a two-inch margin top and bottom). If 527 meridional parts are to be shown in 31 inches, each meridional part will be $\frac{31}{527} = 0.05882$ inch. There are $46-4=42$ inches available for longitude, and therefore the length of each meridional part will be $\frac{42}{720} = 0.05833$ inch. Thus, the longitude is the limiting scale factor, for all of the desired area could not be shown in the available space if the larger scale were to be used. Using the smaller scale, it is found that 30.74 inches (0.05833×527) will be needed to show the desired latitude coverage. The top and bottom margins can be increased slightly, or additional latitude coverage can be shown. If it is desired to include the additional coverage, the amount can be determined by dividing the available space, 31 inches, by the scale, 0.05833. This is 531.5 meridional parts, or 4.5 more than the minimum. By inspection of table 5, it is seen that the latitude can be extended either 3′.3 below 44° or 2′.9 above 50°. Suppose it is decided that the margin will be increased slightly and only the desired minimum coverage shown.

Step three: Determine the spacing of the meridians and parallels. Meridians 1° or 60′ apart will be placed $60 \times 0.05833 = 3.50$ inches apart. Next, determine each degree of latitude separately. First, compute the meridional difference between the lowest parallel and the various parallels to be shown:

$$\begin{array}{lr} M_{45°} & 3013.5 \\ M_{44°} & \underline{2929.6} \\ m & 83.9 \end{array} \quad \begin{array}{lr} M_{46°} & 3098.8 \\ M_{44°} & \underline{2929.6} \\ m & 169.2 \end{array} \quad \begin{array}{lr} M_{47°} & 3185.7 \\ M_{44°} & \underline{2929.6} \\ m & 256.1 \end{array} \quad \begin{array}{lr} M_{48°} & 3274.2 \\ M_{44°} & \underline{2929.6} \\ m & 344.6 \end{array} \quad \begin{array}{lr} M_{49°} & 3364.5 \\ M_{44°} & \underline{2929.6} \\ m & 434.9 \end{array} \quad \begin{array}{lr} M_{50°} & 3456.6 \\ M_{44°} & \underline{2929.6} \\ m & 527.0 \end{array}$$

Next, determine the distance of each parallel from that of L 44° N by multiplying its meridional difference by the scale, 0.05833:

$$\begin{aligned} L\ 44° \text{ to } L\ 45° &= 0.05833 \times 83.9 = 4.89 \text{ in.} \\ L\ 44° \text{ to } L\ 46° &= 0.05833 \times 169.2 = 9.87 \text{ in.} \\ L\ 44° \text{ to } L\ 47° &= 0.05833 \times 256.1 = 14.94 \text{ in.} \\ L\ 44° \text{ to } L\ 48° &= 0.05833 \times 344.6 = 20.10 \text{ in.} \\ L\ 44° \text{ to } L\ 49° &= 0.05833 \times 434.9 = 25.37 \text{ in.} \\ L\ 44° \text{ to } L\ 50° &= 0.05833 \times 527.0 = 30.74 \text{ in.} \end{aligned}$$

Step four: Draw the graticule. Draw a horizontal line 2.13 inches $\left(\frac{35-30.74}{2}\right)$ from the bottom. This is the lower neat line. Label it "44° N." Draw the right-hand neat line two inches from the edge. Label it "56° W." Along the lower parallel measure off distances in units of 3.50 inches from λ 56° W at the right to λ 68° W at the left. Through the points thus located draw vertical lines to represent the meridians.

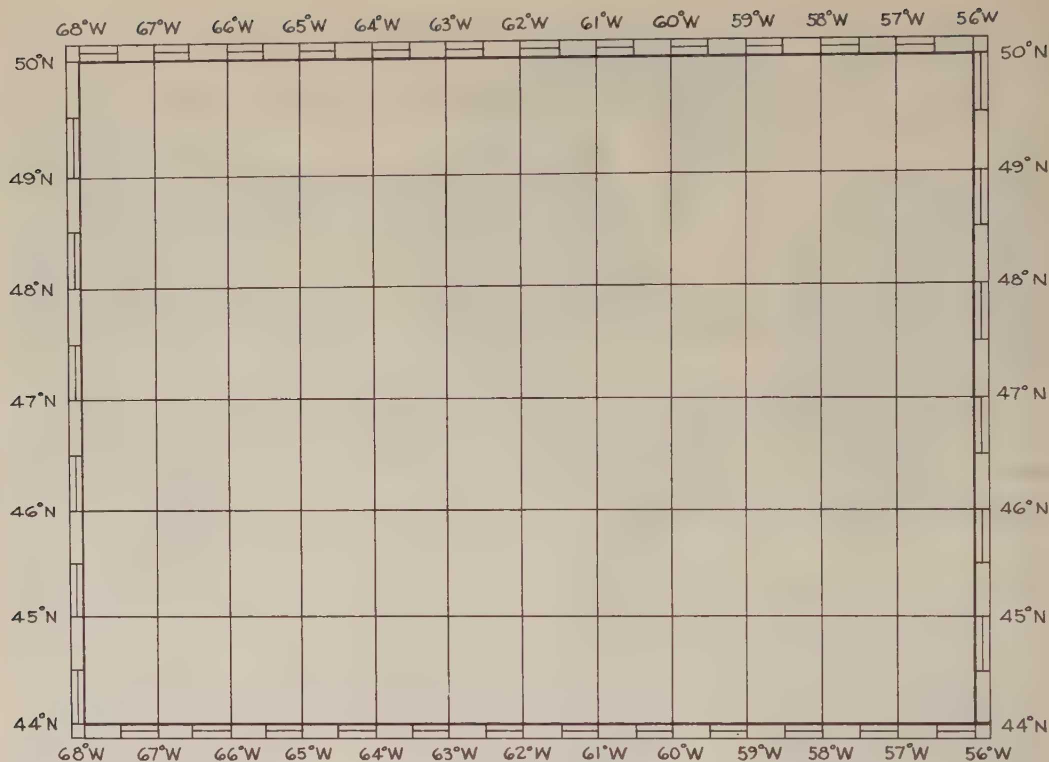

FIGURE 307.—The graticule of a Mercator chart from L 44° N to L 50° N and from λ 56° W to λ 68° W.

Along any meridian measure upward from the horizontal line a series of distances as determined by the calculations above. Through these points draw horizontal lines to represent the parallels. Label the meridians and parallels as shown in figure 307.

Step five: Mark off the latitude and longitude scales around the neat line. The scales can be graduated in units as small as desired. Determine the longitude scale by dividing the degrees into equal parts. Establish the latitude scale by computing each subdivision of a degree in the same manner as described above for whole degrees. In low latitudes degrees of latitude can be divided into equal parts without serious loss of accuracy.

Step six: Fill in the desired detail.

In *south* latitude the distance between consecutive parallels increases toward the *south.* The top parallel is drawn first and distances measured downward from it. Latitude labels increase toward the *south* (down).

In *east* longitude the longitude labels increase toward the *east* (right).

308. Transverse and oblique Mercator projections.—If Mercator principles are used to construct a chart, but with the cylinder tangent along a meridian, a **transverse Mercator** or **transverse cylindrical orthomorphic** projection results. The word "inverse" is sometimes used in place of "transverse" with the same meaning. If the cylinder is tangent at some great circle other than the equator or a meridian (fig. 308a), the projection is called **oblique Mercator** or **oblique cylindrical orthomorphic.** These projections utilize a **fictitious graticule** similar to but offset from the familiar network of meridians and parallels (fig. 308b). The tangent great circle is the **fictitious equator.** Ninety degrees from it are two **fictitious poles.** A group of great circles through these poles and perpendicular to the tangent great circle are the **fictitious**

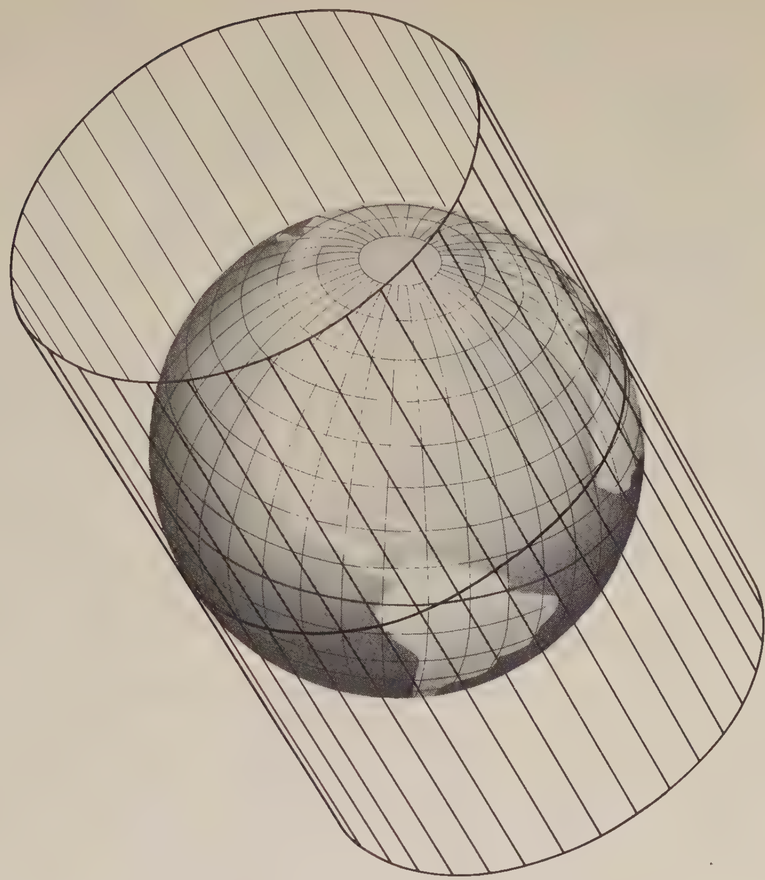

FIGURE 308a.—An oblique Mercator projection.

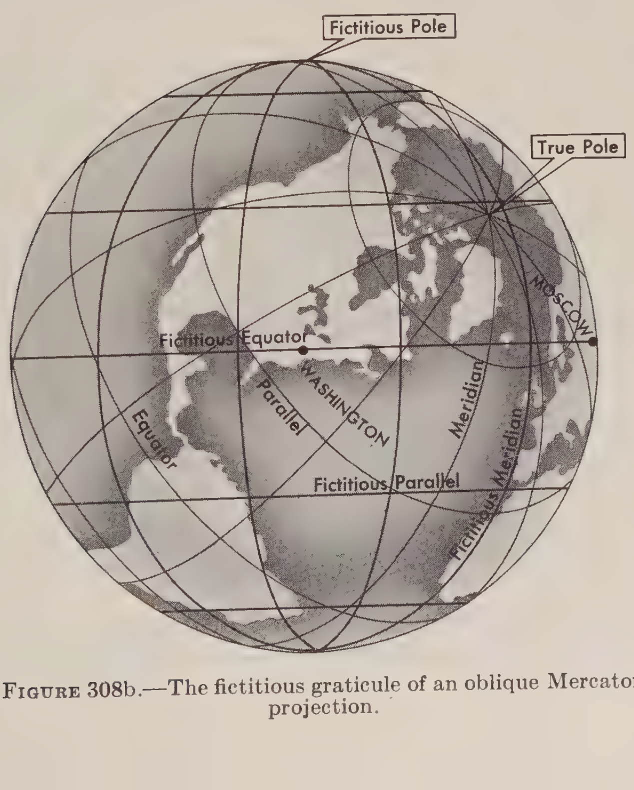

FIGURE 308b.—The fictitious graticule of an oblique Mercator projection.

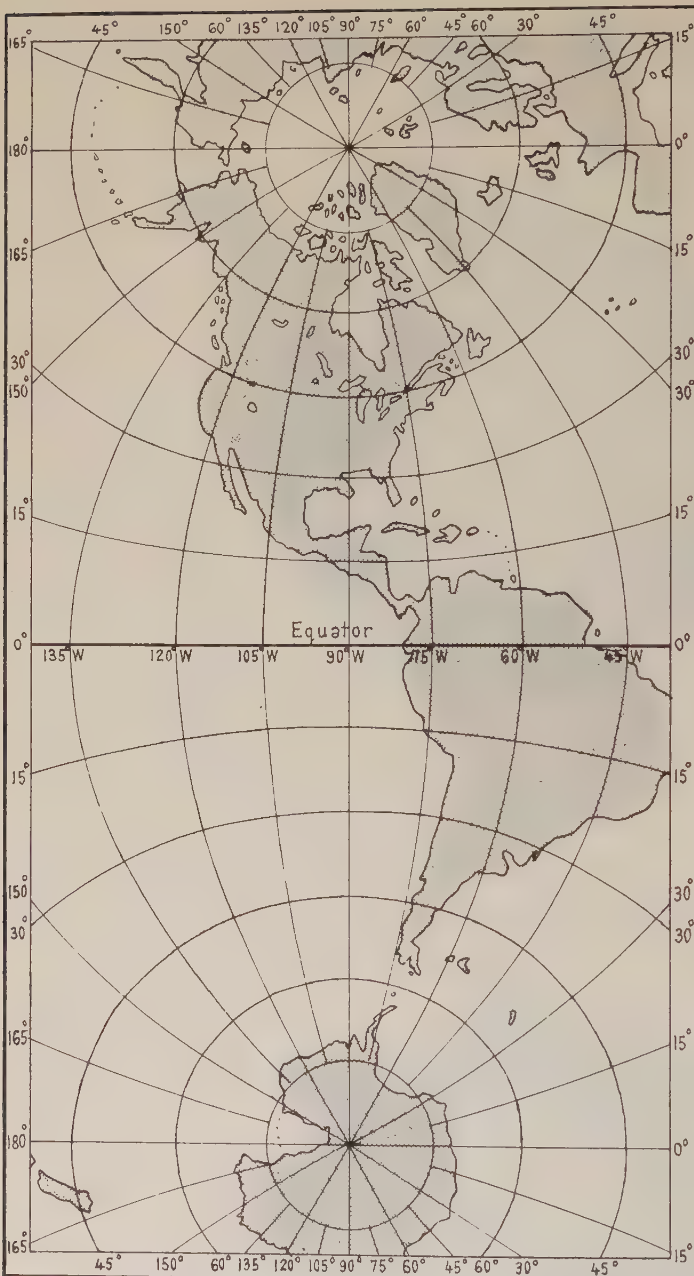

FIGURE 309.—A transverse Mercator map of the western hemisphere.

meridians, while a series of circles parallel to the plane of the tangent great circle form the **fictitious parallels.**

The actual meridians and parallels appear as curved lines (figs. 309, 310b, and 322).

A straight line on the transverse or oblique Mercator projection makes the same angle with all fictitious meridians, but not with the terrestrial meridians. It is therefore a **fictitious rhumb line.** Near the tangent great circle a straight line closely approximates a great circle. It is in this area that the chart is most useful.

The **Universal Transverse Mercator (UTM) grid** is a military grid superimposed upon a transverse Mercator graticule, or the representation of these grid lines upon any graticule.

This grid system and these projections are often used for large-scale (harbor) nautical charts and military charts.

309. Transverse Mercator projection.—A special case of the Mercator projection in which the cylinder is tangent along a meridian is called a **transverse (inverse) Mercator** or **transverse (inverse) cylindrical orthomorphic** projection. Since the area of minimum distortion is near a meridian, this projection is useful for charts covering a large band of latitude and extending a relatively short distance on each side of the tangent meridian (fig. 309) or for charts of the polar regions (fig. 322). It is sometimes used for star charts showing the evening sky at various seasons of the year (figs. 2205–2208).

310. Oblique Mercator projection.—The Mercator projection in which the cylinder is tangent along a great circle other than the equator or a meridian is called an **oblique**

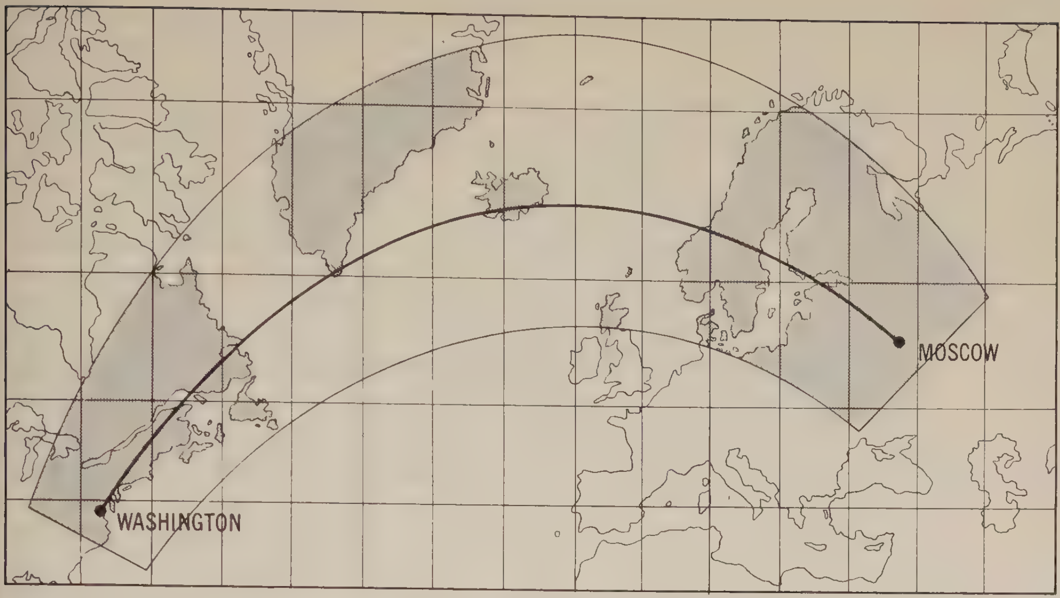

FIGURE 310a.—The great circle between Washington and Moscow as it appears on a Mercator map. See figures 308b and 310b.

Mercator or **oblique cylindrical orthomorphic** projection. This projection is used principally where it is desired to depict an area in the near vicinity of an oblique great circle, as, for instance, along the great-circle route between two important, widely separated centers. Figure 310a is a Mercator map showing Washington and Moscow and the great circle joining them. Figure 310b is an oblique Mercator map with the great circle between these two centers as the tangent great circle or fictitious equator (as in fig. 308b). The limits of the chart of figure 310b are indicated in figure 310a. Note the large variation in scale as the latitude changes.

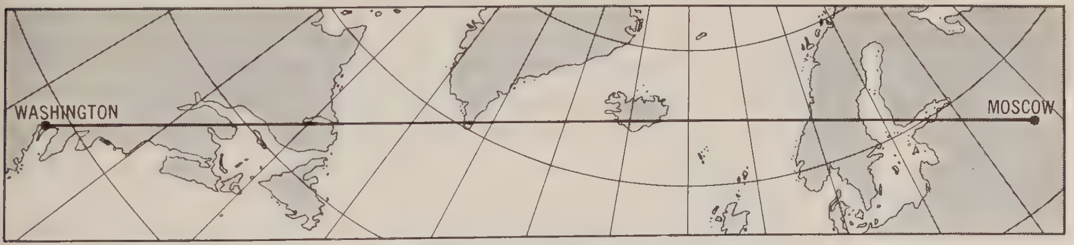

FIGURE 310b.—An oblique Mercator map based upon a cylinder tangent along the great circle through Washington and Moscow. The map includes an area 500 miles on each side of the great circle. The limits of this map are indicated on the Mercator map of figure 310a.

311. Rectangular projection.—A cylindrical projection similar to the Mercator but with uniform spacing of the parallels is called a **rectangular** projection (fig. 311). It is convenient for graphically depicting information where distortion is not important. The principal navigational use of this projection is for the star chart of the *Air Almanac* (art. 2204), where positions of stars are plotted by rectangular coordinates representing declination (ordinate) and sidereal hour angle (abscissa). Since the meridians are parallel, the parallels of latitude (including the equator and the poles) are all represented by lines of equal length.

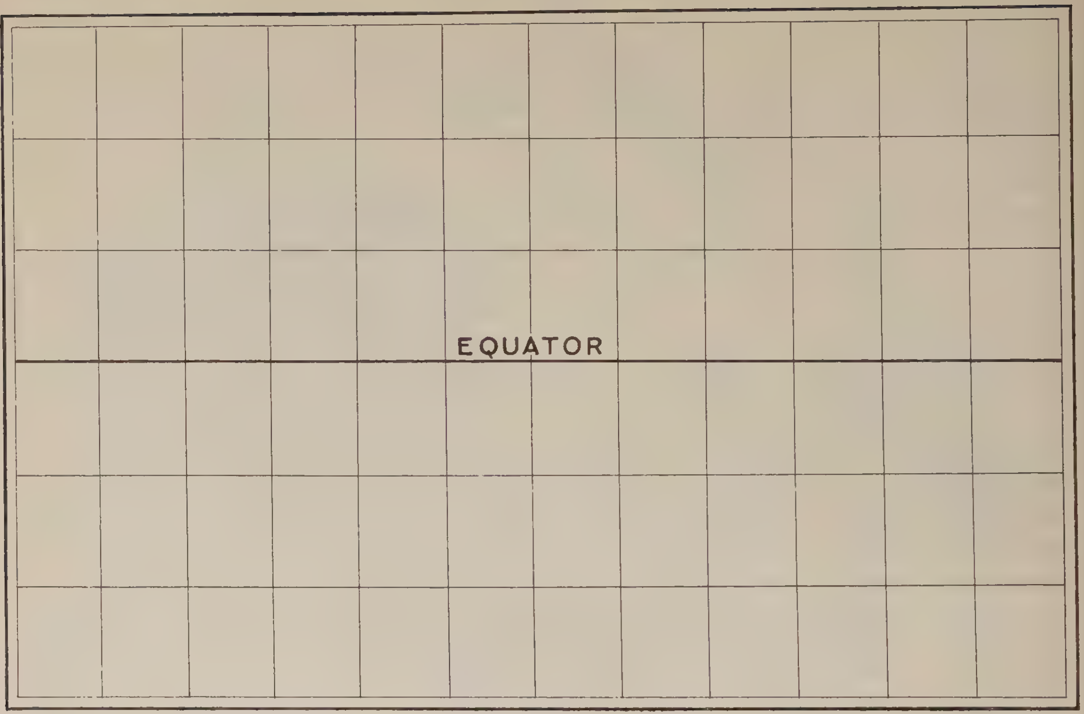

FIGURE 311.—A rectangular graticule. Compare with figure 305.

Conic Projections

312. Features.—A conic projection is produced by transferring points from the surface of the earth to a cone or series of cones which are then cut along an element and spread out flat to form the chart. If the axis of the cone coincides with the axis of the earth, the usual situation, the parallels appear as arcs of circles and the meridians as either straight or curved lines converging toward the nearer pole. Excessive distortion is usually avoided by limiting the area covered to that part of the cone near the surface of the earth. A parallel along which there is no distortion is called a **standard parallel.** Neither the **transverse conic** projection, in which the axis of the cone is in the equatorial plane, nor the **oblique conic** projection, in which the axis of the cone is oblique to the plane of the equator, are ordinarily used for navigation, their chief use being for illustrative maps.

The appearance and features of conic projections are varied by using cones tangent at various parallels, using a secant (intersecting) cone, or by using a series of cones.

313. Simple conic projection.—A conic projection using a single tangent cone is called a **simple conic** projection (fig. 313a). The height of the cone increases as the latitude of the tangent parallel decreases. At the equator the height reaches infinity and the cone becomes a cylinder. At the pole its height is zero and it becomes a plane. As in the Mercator projection, the simple conic projection is not perspective, as only the meridians are projected geometrically, each becoming an element of the cone. When this is spread out flat to form a map, the meridians appear as straight lines converging at the apex of the cone. The standard parallel, or that at which the cone is tangent to the earth, appears as the arc of a circle with its center at the apex of the cone, or the common point of intersection of all the meridians. The other parallels are concentric circles, the distance along any meridian between consecutive parallels being in correct relation to the distance on the earth, and hence derived

mathematically. The pole is represented by a circle (fig. 313b). The scale is correct along any meridian and along the standard parallel. All other parallels are too great in length, the error increasing with increased distance from the standard parallel. Since the scale is not the same in all directions about every point, the projection is not conformal, its principal disadvantage for navigation. Neither is it an equal-area projection.

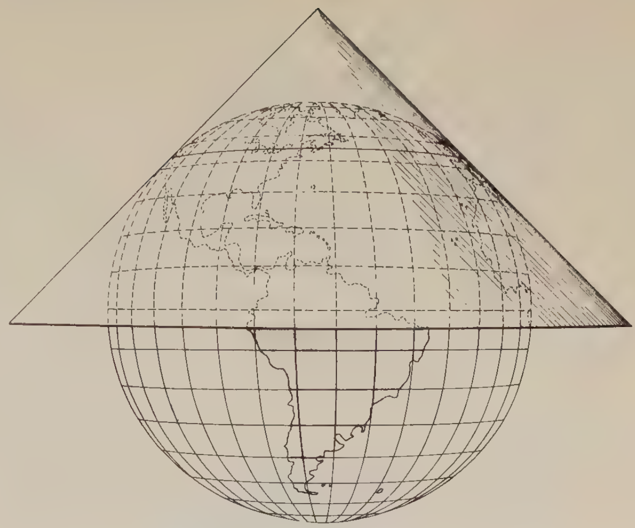

Figure 313a.—A simple conic projection.

Since the scale is correct along the standard parallel and varies uniformly on each side, with comparatively little distortion near the standard parallel, this projection is useful for mapping an area covering a large spread of longitude and a comparatively narrow band of latitude. It was developed by Claudius Ptolemy in the second century after Christ to map just such an area, the Mediterranean.

314. Lambert conformal projection.—The useful latitude range of the simple conic projection can be increased by using a secant cone intersecting the earth at two

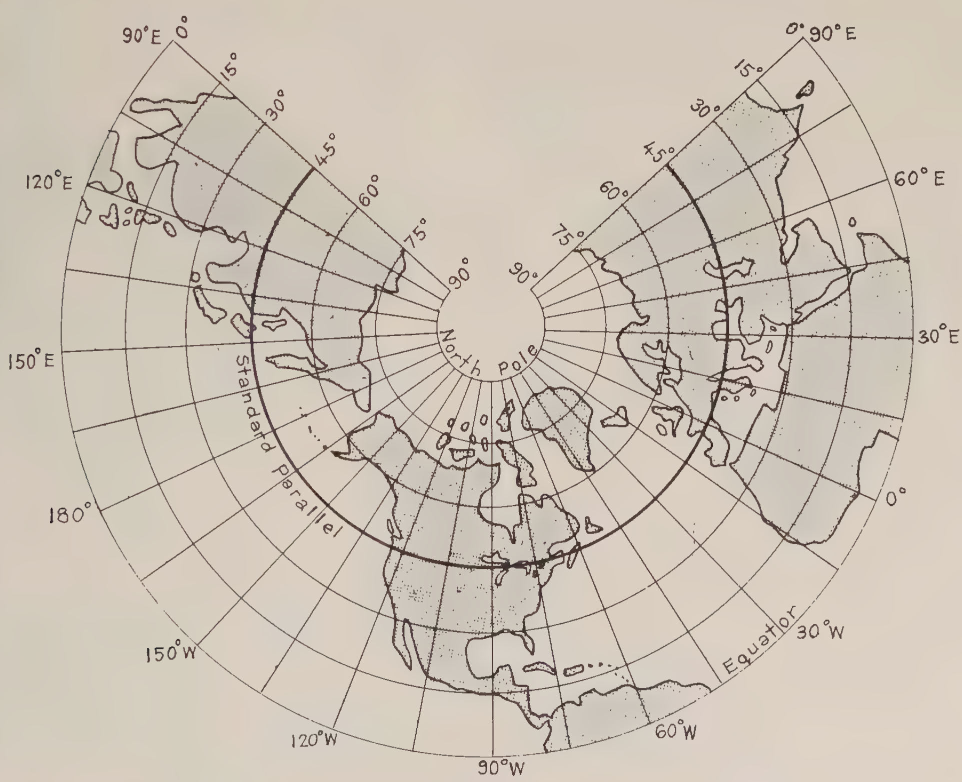

Figure 313b.—A simple conic map of the northern hemisphere.

FIGURE 314.—A secant cone for a conic projection with two standard parallels.

standard parallels (fig. 314). The area between the two standard parallels is compressed, and that beyond is expanded. Such a projection is called a **secant conic** or **conic projection with two standard parallels.**

If, in such a projection, the spacing of the parallels is altered so that the distortion is the same along them as along the meridians, the projection becomes conformal. This is known as the **Lambert conformal** projection, after its eighteenth century Alsatian inventor, Johann Heinrich Lambert. It is the most widely used conic projection for navigation, though its use is more common among aviators than mariners. Its appearance is very much the same as that of the simple conic projection. If the chart is not carried far beyond the standard parallels, and if these are not a great distance apart, the distortion over the entire chart is small. A straight line on this projection so nearly approximates a great circle that the two can be considered identical for many purposes of navigation. Radio bearings, from signals which are considered to travel great circles, can be plotted on this projection without the correction needed when they are plotted on a Mercator chart. This feature, gained without sacrificing conformality, has made this projection popular for aeronautical charts, since aircraft make wide use of radio aids to navigation. It has made little progress in replacing the Mercator projection for marine navigation, except in high latitudes. In a slightly modified form this projection has been used for polar charts (art. 321).

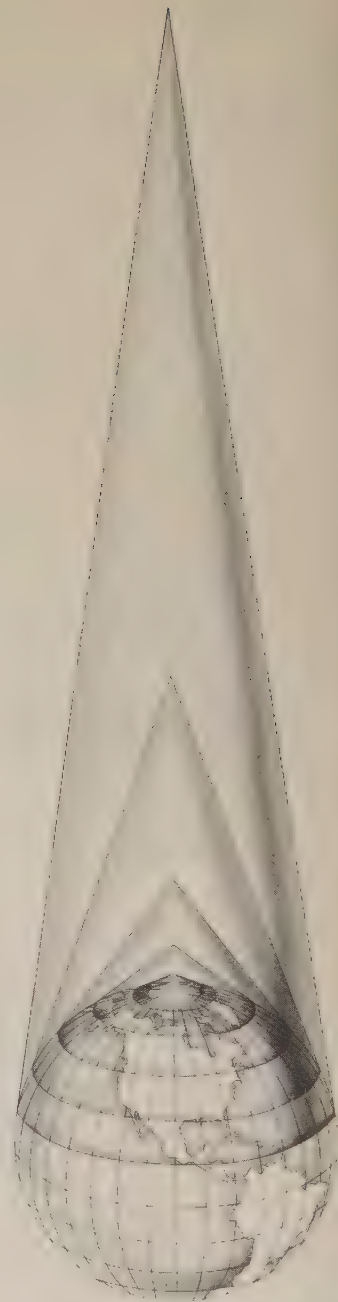

FIGURE 315a.—A polyconic projection.

315. Polyconic projection.—The latitude limitations of the secant conic projection can be essentially eliminated by the use of a series of cones, resulting in a **polyconic** projection. In this projection each parallel is the base of a tangent cone (fig. 315a). At the edges of the chart the area between parallels is expanded to eliminate gaps. The scale is correct along any parallel and along the central meridian of the projection. Along other meridians the scale increases with increased difference of longitude from the central meridian. Parallels appear as nonconcentric circles and meridians as curved lines converging toward the pole and concave to the central meridian.

The polyconic projection is widely used in atlases, particularly for areas of large range in latitude and reasonably large range in longitude, as for a continent such as North America (fig. 315b). However, since it is not conformal, this projection is not customarily used in navigation, except for **boat sheets** used in hydrographic surveying (art. 4118).

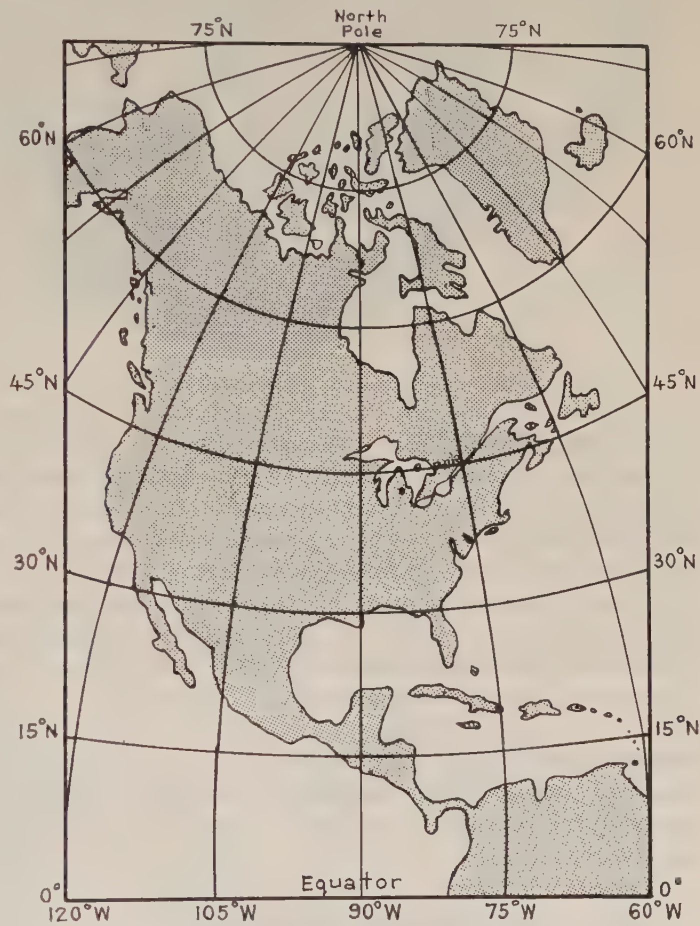

FIGURE 315b.—A polyconic map of North America.

Azimuthal Projections

316. Features.—If points on the earth are projected directly to a plane surface, a map is formed at once, without cutting and flattening, or "developing." This can be considered a special case of a conic projection in which the cone has zero height.

The simplest case of the azimuthal projection is one in which the plane is tangent at one of the poles. The meridians are straight lines intersecting at the pole, and the parallels are concentric circles with their common center at the pole. Their spacing depends upon the method of transferring points from the earth to the plane.

If the plane is tangent at some point other than a pole, straight lines through the point of tangency are great circles, and concentric circles with their common center at the point of tangency connect points of equal distance from that point. Distortion, which is zero at the point of tangency, increases along any great circle through this point. Along any circle whose center is the point of tangency, the distortion is constant. The bearing of any point from the point of tangency is correctly represented. It is for this reason that these projections are called **azimuthal.** They are also called **zenithal.** Several of the common azimuthal projections are perspective.

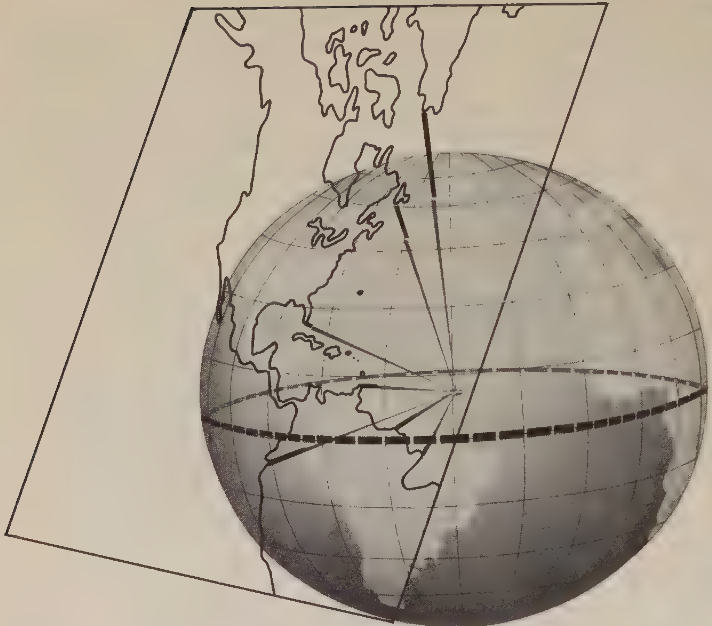

FIGURE 317a.—An oblique gnomonic projection.

317. Gnomonic projection.—If a plane is tangent to the earth, and points are projected geometrically from the center of the earth, the result is a **gnomonic** projection (fig. 317a). This is probably the oldest of the projections, believed to have been developed by Thales about 600 BC. Since the projection is perspective, it can be demonstrated by placing a light at the center of a transparent terrestrial globe and holding a flat surface tangent to the sphere.

For the oblique case the meridians appear as straight lines converging toward the nearer pole. The parallels, except the equator, appear as curves (fig. 317b). As in all azimuthal projections, bearings from the point of tangency are correctly represented. The distance scale, however, changes rapidly. The projection is neither conformal nor equal area. Distortion is so great that shapes, as well as distances and areas, are very poorly represented, except near the point of tangency.

The usefulness of the projection rests upon the one feature that *any* great circle appears on the map as a straight line. This is apparent when it is realized that a great circle is the line of intersection of a sphere and a plane through the center of the sphere, this center being the origin of the projecting rays for the map. This plane intersects any other nonparallel plane, including the tangent plane, in a straight line. It is this one useful feature that gives charts made on this projection the common name **great-circle charts.**

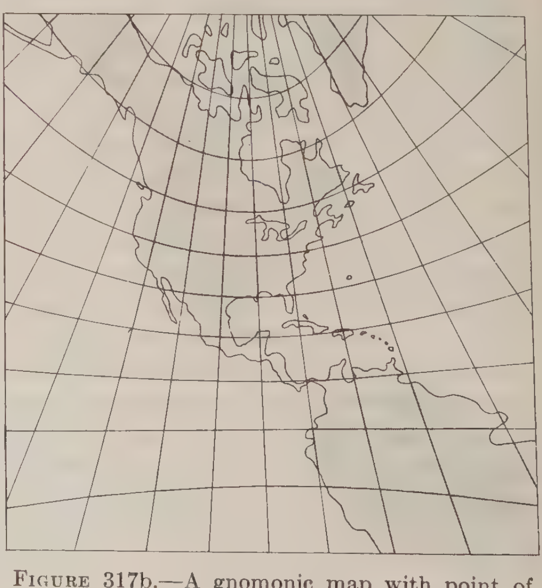

FIGURE 317b.—A gnomonic map with point of tangency at latitude 30° N, longitude 90° W.

Gnomonic charts published by the U. S. Navy Hydrographic Office bear instructions for determining direction and distance on the charts. The principal navigational use of such charts is for plotting the great-circle track between points, for planning purposes. Points along the track are then transferred, by latitude and longitude, to the navigational chart, usually one on the Mercator projection. The great circle is then followed approximately by following the rhumb line from one point to the next (art. 820).

318. Stereographic projection.—If points on the surface of the earth are pro-

jected geometrically onto a tangent plane, from a point on the surface of the earth opposite the point of tangency, a **stereographic** projection results (fig. 318a). It is also called an **azimuthal orthomorphic** projection.

The scale of the stereographic projection increases with distance from the point of tangency, but more slowly than in the gnomonic projection. An entire hemisphere can be shown on the stereographic projection without excessive distortion (fig. 318b). As in other azimuthal projections, great circles through the point of tangency appear as straight lines. All other circles, including meridians and parallels, appear as circles or arcs of circles.

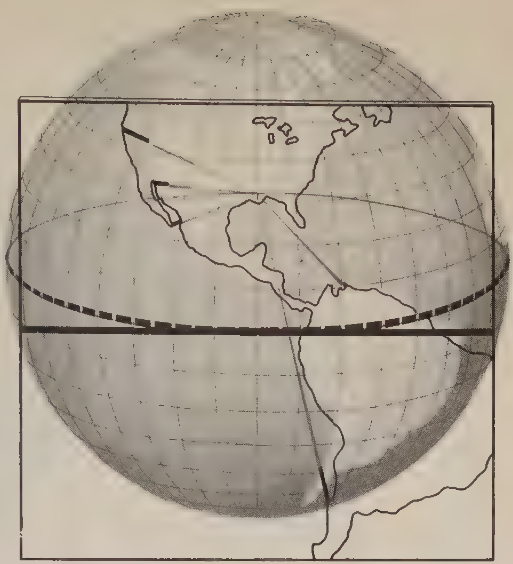

FIGURE 318a.—An equatorial stereographic projection.

The principal navigational use of the stereographic projection is for charts of the polar regions and devices for mechanical or graphical solution of the navigational triangle (art. 2122).

319. Orthographic projection.—If terrestrial points are projected geometrically from infinity (projecting lines parallel) to a tangent plane, an **orthographic** projection results (fig. 319a). This projection is neither conformal nor equal area and has no advantages as a map projection. Its principal navigational use is in the field of navigational astronomy, where it is useful for illustrating or graphically solving the navigational triangle and for illustrating celestial coordinates. If the plane is tangent at a point on the equator, the usual case, the parallels (including the equator) appear as straight lines and the meridians as ellipses, except that the meridian through the point of tangency appears as a straight line and the one 90° away as a circle (fig. 319b).

FIGURE 318b.—A stereographic map of the western hemisphere.

320. Azimuthal equidistant projection.—An azimuthal projection in which the distance scale along any great circle through the point of tangency is constant is called an **azimuthal equidistant** projection. If a pole is the point of tangency, the meridians appear as straight radial lines and the parallels as concentric circles, equally spaced. If the plane is tangent at some point other than a pole, the concentric circles represent distance from the point of tangency. In this case meridians and parallels appear as curves. The projection can be used to portray the entire earth, the

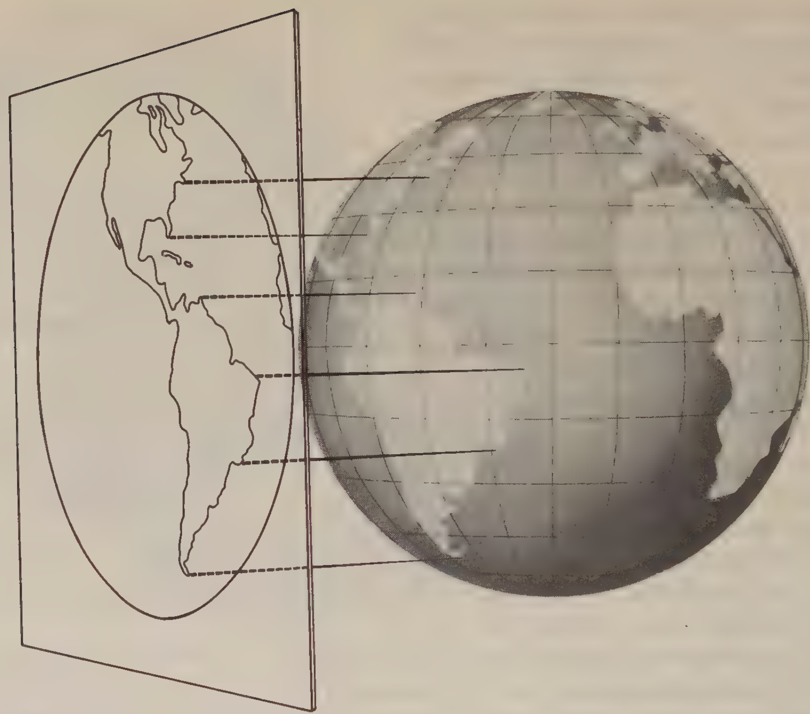

FIGURE 319a.—An equatorial orthographic projection.

point 180° from the point of tangency appearing as the largest of the concentric circles. The projection is neither conformal nor equal area, nor is it perspective. Near the point of tangency the distortion is small, but it increases with distance until shapes near the opposite side of the earth are unrecognizable (fig. 320).

FIGURE 319b.—An orthographic map of the western hemisphere.

The projection is useful because it combines the three features of being azimuthal, having a constant distance scale from the point of tangency, and permitting the entire earth to be shown on one map. Thus, if an important harbor or airport is selected as the point of tangency, the great-circle course, distance, and track from that point to any other point on the earth are quickly and accurately determined. For communication work at a fixed point, the point of tangency, the path of an incoming signal is at once apparent if the direction of arrival has been determined. The direction to train a directional antenna for desired results can

FIGURE 320.—An azimuthal equidistant map of the world with the point of tangency at latitude 40° N, longitude 100° W.

be determined easily. The projection is also used for polar charts and for the familiar star finder and identifier, H. O. 2102–D (art. 2210).

Polar Charts

321. Polar projections.—Special consideration is given to the selection of projections for polar charts, principally because the familiar projections become special cases with unique features.

In the case of cylindrical projections in which the axis of the cylinder is parallel to the polar axis of the earth, distortion becomes excessive and the scale changes rapidly. Such projections cannot be carried to the poles. However, both the transverse and oblique Mercator projections are used.

Conic projections with their axes parallel to the earth's polar axis are limited in their usefulness for polar charts because parallels of latitude extending through a full 360° of longitude appear as arcs of circles rather than full circles. This is because a

cone, when cut along an element and flattened, does not extend through a full 360° without stretching or resuming its former conical shape. The usefulness of such projections is also limited by the fact that the pole appears as an arc of a circle instead of a point. However, by using a parallel very near the pole as the higher standard parallel, a conic projection with two standard parallels can be made which requires little stretching to complete the circles of the parallels and eliminate that of the pole. Such a projection, called the **modified Lambert conformal** or **Ney's** projection, is useful for polar charts. It is particularly acceptable to those accustomed to using the ordinary Lambert conformal charts in lower latitudes.

Azimuthal projections are in their simplest form when tangent at a pole, since the meridians are straight lines intersecting at the pole, and parallels are concentric circles with their common center at the pole. Within a few degrees of latitude of the pole they all look essentially alike, but as the distance becomes greater, the spacing of the parallels becomes distinctive in each projection. In the polar azimuthal equidistant it is uniform; in the polar stereographic it increases with distance from the pole until the equator is shown at a distance from the pole equal to twice the length of the radius of the earth, or about 27% too much; in the polar gnomonic the increase is considerably greater, becoming infinity at the equator; in the polar orthographic it decreases with distance from the pole (fig. 321). All of these but the last are used for polar charts.

322. Selection of a polar projection.—The principal considerations in the choice of a suitable projection for polar navigation are:

1. *Conformality.* It is desirable that angles be correctly represented so that plotting can be done directly on the chart, without annoying corrections.

2. *Great-circle representation.* Since great circles are more useful than rhumb lines in high latitudes, it is desirable that great circles be represented by straight lines.

3. *Scale variation.* Constant scale over an entire chart is desirable.

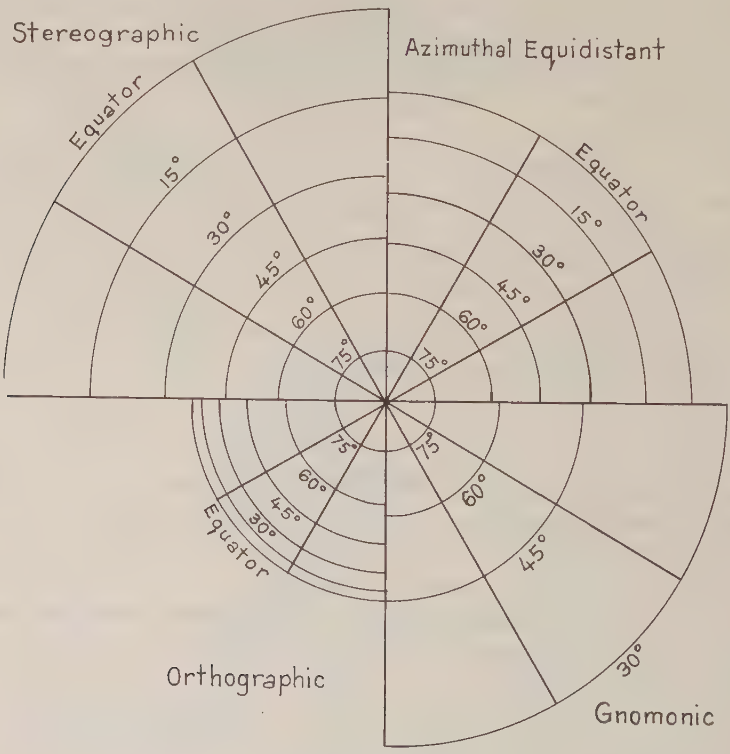

FIGURE 321.—Expansion of polar azimuthal projections.

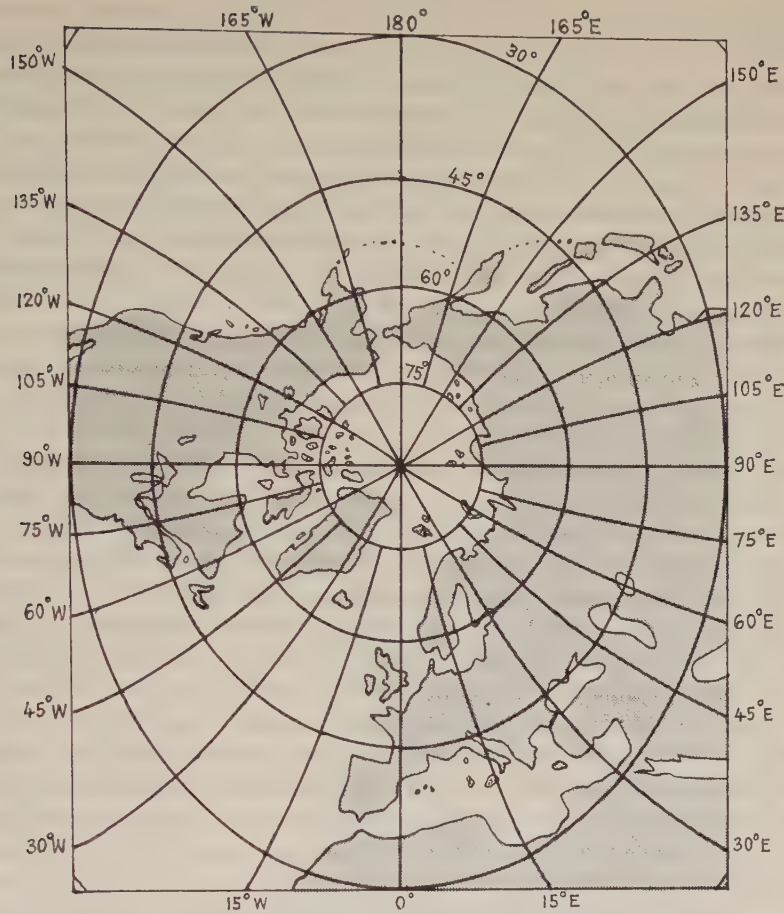

FIGURE 322.—A polar transverse Mercator map with the cylinder tangent at the 90° E-90° W meridian.

4. *Meridian representation.* Straight meridians are desirable for convenience and accuracy of plotting, and for grid navigation (art. 2510).

5. *Limits of utility.* Wide limits are desirable to reduce to a minimum the number of projections needed. The ideal would be a single projection for world coverage.

The projections commonly used for polar charts are the transverse Mercator, modified Lambert conformal, gnomonic, stereographic, and azimuthal equidistant. Near the pole there is little to choose between them. Within the limits of practical navigation all are essentially conformal and on all a great circle is nearly a straight line.

As the distance from the pole increases, however, the distinctive features of each projection become a consideration. The transverse Mercator is conformal and its type of distortion is familiar to one accustomed to using a Mercator chart. Distances can be measured in the same manner as on any Mercator chart. The tangent meridian and all straight lines perpendicular to it are great circles. All other great circles, including the meridians, are curves. The departure of a great circle from a straight line becomes a maximum at the outer edges parallel to the tangent meridian, where the straight lines are nearer the pole than the arcs of great circles between the same points. A slight inconvenience in measurement of angles may result from the curvature of the meridians (fig. 322). The projection is excellent for a narrow band along the tangent meridian and for use with automatic navigation equipment generating transverse latitude and transverse longitude.

The modified Lambert conformal projection is virtually conformal over its entire extent, and the amount of its scale distortion is comparatively little if it is carried only to about 25° or 30° from the pole. Beyond this, the distortion increases rapidly. A great circle is very nearly a straight line anywhere on the chart. Distances and directions can be measured directly on the chart in the same manner as on a Lambert conformal chart. However, for highly accurate work this projection is not suitable, for it is not strictly conformal, and great circles are not exactly straight lines.

The polar gnomonic projection is the one polar projection on which great circles are exactly straight lines. The excessive distortion and lack of conformality of this projection make it unsuitable for ordinary navigation.

The polar stereographic projection is conformal over its entire extent, and a great circle differs but little from a straight line. The scale distortion is not excessive for a considerable distance from the pole, but is greater than that of the modified Lambert conformal projection.

The polar azimuthal equidistant projection is useful for showing a large area such as a hemisphere, because there is no expansion along the meridians. However, the projection is not conformal, and distances cannot be measured accurately in any but a north-south direction. Great circles other than the meridians differ somewhat from straight lines. The equator is a circle centered at the pole.

The three projections most commonly used for charts for ordinary navigation near the poles are the transverse Mercator, modified Lambert conformal, and the polar stereographic. The transverse Mercator permits use of automatic dead reckoning equipment designed for use on a Mercator projection, transverse coordinates being substituted for geographical coordinates. However, for accuracy, it requires input of a constant transverse rhumb direction, which no present instrument provides. When a directional gyro is used as a directional reference, as in many aircraft, the track of the craft is approximately a great circle. A desirable chart is one on which a great circle is represented as a straight line with a constant scale and with angles correctly represented. These requirements are not met entirely by any single projection, but they are approximated by both the modified Lambert conformal and the polar stereographic. The scale is more nearly constant on the former, but the projection is not strictly conformal. The polar stereographic is conformal, and its maximum scale variation can be reduced by using a plane which intersects the earth at some parallel intermediate between the pole and the lowest parallel, so that that portion within this standard parallel is compressed, and that portion outside is expanded.

The selection of a suitable projection for use in polar regions, as in other areas, depends upon the requirements, which establish relative importance of the various features. For a relatively small area, any of several projections is suitable. For a large area, however, the choice is more critical. If grid directions (art. 2510) are to be used, it is important that all units in related operations use charts on the same projection, with the same standard parallels, so that a single grid direction exists between any two points. Nuclear powered submarine operations under the polar icecap have increased the need for grid directions in marine navigation. Increasing installations of gyro compasses with directional gyro modes in surface ships should increase the need for grid directions further.

Plotting Sheets

323. Definition and use.—A **plotting sheet** is a blank or incomplete chart. It has the latitude and longitude lines, and it may have one or more *compass roses* (art. 516) for measuring direction, but little or no additional information. The meridians are

usually unlabeled by the publisher so the plotting sheet can be used for any longitude. If it is suitable for use in any latitude, the parallels, also, may be unlabeled.

Plotting sheets are less expensive to produce than charts and are equally suitable or superior for some purposes. They are used primarily for plotting lines of position from celestial observations and for dead reckoning, particularly when land, aids to navigation, and depth of water are not important.

Any projection can be used for constructing a plotting sheet, but that used for the navigator's charts is customarily employed also for his plotting sheets.

324. Small area plotting sheets.—A Mercator plotting sheet can be constructed by the method explained in article 307. For a relatively small area a good approximation can be more quickly constructed by the navigator by either of two alternative methods based upon a graphical solution of the secant of the latitude, which approximates the expansion.

First method (fig. 324a). *Step one.* Draw a series of equally spaced, vertical lines at any spacing desired. These are the meridians; label them at any desired interval, as 1′, 2′, 5′, 10′, 30′, 1°, etc.

Step two. Through the center of the sheet draw a horizontal line to represent the parallel of the mid latitude of the area to be covered, and label it.

Step three. Through any convenient point, such as the intersection of the central meridian and the parallel of the mid latitude, draw a line making an angle with the *horizontal* equal to the mid latitude. In figure 324a this angle is 35°.

Step four. Draw in and label additional parallels. The length of the oblique line between consecutive meridians is the perpendicular distance between consecutive parallels, as shown by the dashed arc. The number of minutes of arc between consecutive parallels thus drawn is the same as that between the meridians shown.

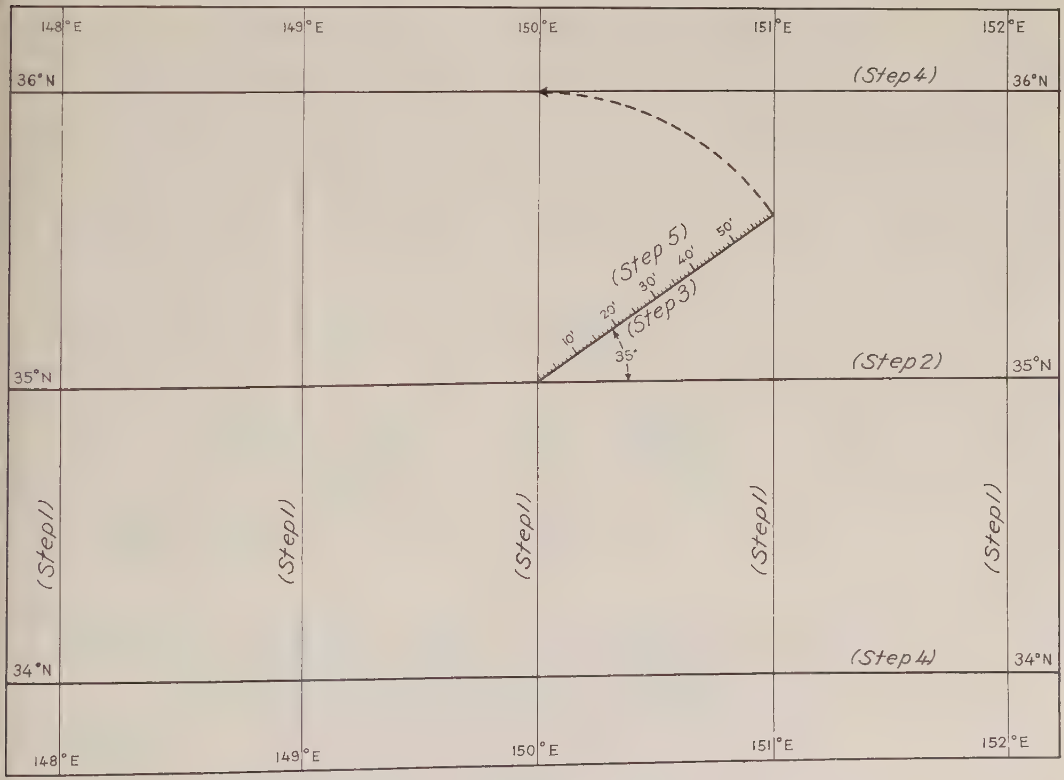

FIGURE 324a.—Small area plotting sheet with selected longitude scale.

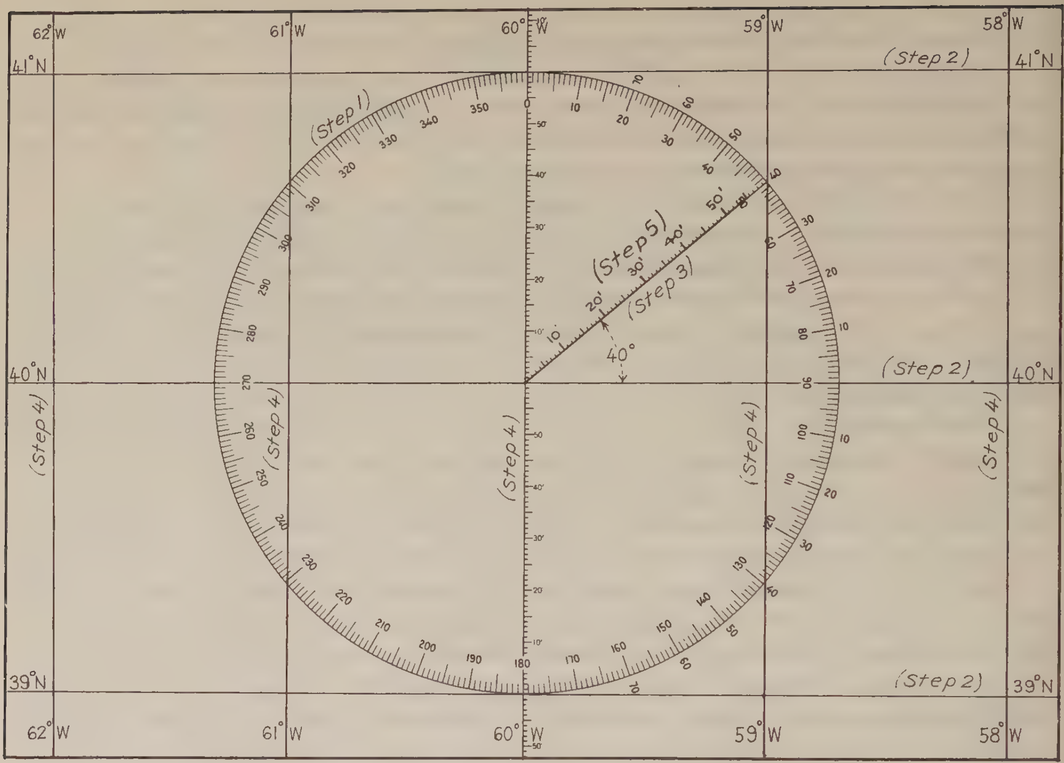

FIGURE 324b.—Small area plotting sheet with selected latitude scale.

Step five. Graduate the oblique line into convenient units. If 1′ is selected, this scale serves as both a latitude and mile scale. It can also be used as a longitude scale by measuring horizontally from a meridian instead of obliquely along the line.

Second method (fig. 324b). *Step one.* At the center of the sheet draw a circle with a radius equal to 1° (or any other convenient unit) of latitude at the desired scale. If a sheet with a compass rose is available, as in figure 324b, the compass rose can be used as the circle and will prove useful for measuring directions. It need not limit the scale of the chart, as an additional concentric circle can be drawn and desired graduations extended to it.

Step two. Draw horizontal lines through the center of the circle and tangent at the top and bottom. These are parallels of latitude; label them accordingly, at the selected interval (as every 1°, 30′, etc.).

Step three. Through the center of the circle draw a line making an angle with the *horizontal* equal to the mid latitude. In figure 324b this angle is 40°.

Step four. Draw in and label the meridians. The first is a vertical line through the center of the circle. The second is a vertical line through the intersection of the oblique line and the circle. Additional meridians are drawn the same distance apart as the first two.

Step five. Graduate the oblique line into convenient units. If 1′ is selected, this scale serves as a latitude and mile scale. It can also be used as a longitude scale by measuring horizontally from a meridian instead of obliquely along the line.

The same end result is produced by either method. The first method, starting with the selection of the longitude scale, is particularly useful when the longitude limits of the plotting sheet determine the scale. When the latitude coverage is more important, the second method may be preferable. If a standard size is desired, part

of the sheet can be printed in advance, forming what is called a **universal plotting sheet.** This is done by the U. S. Navy Hydrographic Office (art. 431). In either method a central compass rose might be printed. In the first method the meridians may be shown at the desired interval and the mid parallel may be printed and graduated in units of longitude. In using the sheet it is necessary only to label the meridians and draw the oblique line and from it determine the interval and draw in and label additional parallels. If the central meridian is graduated, the oblique line need not be. In the second method the parallels may be shown at the desired interval, and the central meridian may be printed and graduated in units of latitude. In using the sheet it is necessary only to label the parallels, draw the oblique line and from it determine the interval and draw in and label additional meridians. If the central meridian is graduated, as shown in figure 324b, the oblique line need not be.

Both methods use a constant relationship of latitude to longitude over the entire sheet and both fail to allow for the ellipticity of the earth. For practical navigation these are not important considerations for a small area. If a larger area is to be shown or if more precise results are desired, the method of article 307 should be used.

Grids

325. Purpose and definition of grid.—No system has been devised for showing the surface of the earth *on a flat surface,* without distortion. Moreover, the appearance of any portion of the surface varies with the projection and, in many cases, with the location of the portion with respect to the point or line of tangency. For some purposes (particularly military) it is desirable to be able to identify a location or area by rectangular coordinates, using numbers or letters, or a combination of numbers and letters, without the necessity of indicating the units used or assigning a name (north, south, east, or west), thus reducing the possibility of a mistake. This is accomplished by means of a **grid.** In its usual form this consists of two series of lines which are mutually perpendicular *on the chart,* with suitable designators. The grid used in **grid navigation** (art. 2510) is a similar network, or a single series of parallel lines, used to provide a uniform directional reference, particularly in polar regions. In any system the difference in direction between true north at any point and grid north at that same point is called **grid declination.**

326. Types of grids.—A grid may use the rectangular graticule of the Mercator projection, or a set of arbitrary lines on a particular projection. The most widely used system of the first is called the **World Geographic Referencing System (Georef).** It is merely a method of designating latitude and longitude by a system of letters and numbers instead of by angular measure, and therefore is not strictly a grid, except on a Mercator projection. It is particularly useful for operations extending over a wide area. Examples of the second type of grid are the **Universal Transverse Mercator (UTM) grid,** the **Universal Polar Stereographic (UPS) grid,** and the **Temporary Geographic Grid (TGG).** Since these systems are used primarily by military forces, they are sometimes called **military grids.**

CHAPTER IV

CHARTS AND PUBLICATIONS

Sources

401. Introduction.—Charts and publications are important navigational aids. It is desirable that the navigator have a knowledge of what is available in this field, how he can obtain the various items, how he can be sure they are accurate and up-to-date, and what information he can expect to get from each. Instructions for the use of a number of these items are given elsewhere in this book.

402. Sources of charts and publications.—There is no central government office from which the navigator can satisfy all of his chart and publication requirements. The principal sources are the U. S. Navy Hydrographic Office, U. S. Coast and Geodetic Survey, U. S. Coast Guard, and U. S. Naval Observatory. Other sources include the U. S. Geological Survey, Mississippi River Commission, U. S. Engineer Office of the Department of the Army, U. S. Weather Bureau, USAF Aeronautical Chart and Information Center, Federal Aviation Agency, and various commercial sources.

403. The U. S. Navy Hydrographic Office maintains liaison with foreign hydrographic departments; makes hydrographic, topographic, oceanographic, and geomagnetic surveys in international waters and along foreign coasts; conducts research in oceanography and in navigational methods (both marine and air); systematically collects data in these fields from public and private institutions and persons in all parts of the world; prepares, prints, and distributes nautical and aeronautical charts; and prepares and issues publications and timely advice, including radio broadcasts, for the safe navigation of surface and subsurface vessels and of aircraft.

The products of the U. S. Navy Hydrographic Office include nautical and aeronautical charts of the high seas and foreign waters, sailing directions for foreign shores, light lists, various navigational manuals and tables, weather summaries, various oceanographic charts and publications, pilot charts, loran and radar charts, plotting sheets, a number of special charts, and several periodical publications to notify navigators of changes to their charts and publications.

404. The U. S. Coast and Geodetic Survey, of the Department of Commerce, conducts research in hydrography, cartography, tides, currents, geodesy, geomagnetism, and seismology. It publishes coast and harbor charts of the United States and its possessions and aeronautical charts of the United States, tide and tidal current tables for both United States and foreign waters, coast pilots (sailing directions) for coasts of the United States and its possessions (including the intracoastal waterway) and a number of special publications covering results of its research.

405. The U. S. Coast Guard has charge of the inspection of merchant marine vessels, licensing of merchant marine officers, and the installation and maintenance of aids to marine navigation (lighthouses, beacons, buoys, etc.). It publishes light lists for the waters of the United States and its possessions, and international and inland rules of the road and pilot rules.

406. The U. S. Naval Observatory conducts research in various branches of astronomy, including measurement and dissemination of time. It furnishes time sig-

nals, publishes nautical and air almanacs and an ephemeris, as well as tables of sunrise, sunset, and twilight.

407. Miscellaneous sources.—The U. S. Geological Survey, Department of the Interior, publishes topographic maps of the United States. The Mississippi River Commission publishes charts of the Mississippi River from Cairo, Illinois, to the delta. District offices of the U. S. Corps of Engineers, Department of the Army, publish charts of the Ohio River and other United States rivers, Illinois Waterway system, the Great Lakes (but not Canadian harbor charts nor charts of Georgian Bay), Lake Champlain, Oneida Lake, New York canals, and the St. Lawrence River above St. Regis and Cornwall. The U. S. Weather Bureau, Department of Commerce, publishes a chart and booklet showing principal types of clouds, instructions for marine meteorological observers, a glossary of weather terms, and other meteorological publications. The USAF Aeronautical Chart and Information Center produces aeronautical charts and publications. The Federal Aviation Agency produces a number of publications of interest chiefly to aviators. Various other publications and their sources are listed in appendix N.

408. Obtaining charts and publications.—In most instances charts and publications are distributed directly by the publishing agency. A notable exception is the U. S. Navy Hydrographic Office, which, except for official distribution, distributes its charts and publications through authorized sales agents throughout the world. These agents are listed in (H.O.) Pub. No. 1–N, Part I. Publications of the U.S. Coast Guard, U.S. Naval Observatory, and the U.S. Weather Bureau are sold by the Superintendent of Documents, U.S. Government Printing Office. Some of the publications of other agencies are sold both by this office and the publisher (or its agents).

The U. S. Navy Hydrographic Office, U. S. Coast and Geodetic Survey, and the Superintendent of Documents have sales agents in various United States and foreign ports. In addition, the U. S. Navy Hydrographic Office maintains a number of branch offices at major ports to collect, compile, and distribute timely information to afford the maximum safety and facility of operation to vessels of the Navy and the merchant marine. These branch offices issue pilot charts, the *Daily Memorandum*, and *Notice to Mariners*. The U. S. Coast and Geodetic Survey maintains district offices at which their charts and publications can be purchased.

Appendix N lists sources of charts and publications of interest to the navigator.

409. Numbering of charts.—Each chart is given a number by its publishing agency. Vessels of the U. S. Navy use charts of various publishers, with some duplication of numbers. To avoid confusion, charts issued to these vessels are given a **consecutive number** and arranged in convenient groups in **chart portfolios.** This system is not available to commercial or private users.

410. Terminology.—The following terminology applies generally to charts and publications of government agencies:

A **new chart** or **publication** is the first edition.

A **new edition** is a revision that supersedes previous issues, containing changes of such importance that earlier issues are obsolete.

A **corrected (new) print** is a revision that does not supersede previous issues, containing minor changes and corrections, principally those published in the *Notice to Mariners* since the preceding edition.

A **reprint** is a reproduction without change.

A **supplement** contains corrections and additions to an existing publication.

A **change** consists of corrections and additions to a loose-leaf publication.

A **summary** is a collection in one publication of related items of a specified class.

Oceanographic and Meteorological Charts and Publications

411. Tide tables are published annually by the U. S. Coast and Geodetic Survey. In them are tabulated the predicted times and heights of high and low waters for every day in the year for a number of **reference stations,** and differences for obtaining similar predictions for numerous other places. They also give other useful information such as a method for obtaining the height of the tide at any time, local mean time of sunrise and sunset for various latitudes, reduction of local mean time to standard time, zone time of moonrise and moonset for certain ports, and other astronomical data. The use of these tables is explained in chapter IX.

Tide tables are available in separate volumes for (1) east coast of North and South America, including Greenland, (2) west coast of North and South America, including the Hawaiian Islands, (3) Europe and west coast of Africa, including the Mediterranean Sea, and (4) central and western Pacific Ocean and Indian Ocean.

412. Tidal current tables, published annually by the U. S. Coast and Geodetic Survey, tabulate daily predictions of the times of slack water and the times and speeds of maximum flood and ebb currents for a number of waterways, together with differences for obtaining predictions at numerous other places. They also include other useful information on tidal currents, such as a method for obtaining the speed of current at any time and one for determining the duration of slack water, coastal tidal currents, the combination of currents, and current diagrams. Information on the Gulf Stream is included in the tidal current tables for the Atlantic coast of North America. The use of these tables is explained in chapter IX.

Tidal current tables are available in separate volumes for (1) Atlantic coast of North America, and (2) Pacific coast of North America and Asia. For places not covered by these tables the navigator must rely upon notes, tables, and arrows on charts, special current charts, sailing directions, and any other available sources.

413. Tidal current charts for various United States harbors are published by the U.S. Coast and Geodetic Survey. Each of the nine sets consists of about 12 charts which depict the direction and speed of the tidal current for each hour of the tidal cycle, thus presenting a comprehensive view of the tidal current movement in the respective waterways as a whole, and supplying a means for readily determining for any time the direction and speed of the current at various localities throughout the areas covered. The charts are intended for use in connection with the tidal current tables for the same areas, except for New York Harbor, where the tide tables are to be used.

414. Pilot charts are published by the U.S. Navy Hydrographic Office for each month for (1) the North Atlantic Ocean, and (2) the North Pacific Ocean. Pilot charts are published in atlas form for (1) the Northern North Atlantic Ocean, (2) the South Atlantic Ocean and Central American Waters, and (3) the South Pacific and Indian Oceans.

These charts present in graphical form the available facts or conclusions obtained from many years of research in navigation, oceanography, and meteorology, to assist the mariner in selecting the safest and quickest routes and avoiding dangers. Their principal features are monthly averages for: prevailing winds and currents; percentage of gales, calms, and fog; lines of equal air and water temperature, and atmospheric pressure; and limits of the drift of both field ice and icebergs. Also presented are lines of equal magnetic variation, location of ocean station vessels, and recommended routes or steamer tracks. Timely articles are printed on the backs of many pilot charts.

Pilot charts of the North Atlantic and North Pacific are furnished without charge to cooperating observers.

415. Miscellaneous oceanographic publications.—The U. S. Navy Hydrographic Office promotes basic oceanographic research and collects and codifies data which it makes available in the form of charts, manuals, and special reports. Charts in this category include those showing bottom sediment, surface temperature, currents, sea and swell, bathymetric charts (showing bottom gradient tints), as well as the pilot charts (art. 414). Representative books are *Breakers and Surf, Principles in Forecasting* (H.O. Pub. No. 234); *Oceanographic Atlas of the Polar Seas* (Pub. No. 705), Part I, Antarctica and Part II, Arctic; *Wind, Sea, and Swell: Theory of Relations for Forecasting* (H.O. Pub. No. 601). This Office also publishes several instruction manuals of use to the navigator. These include *Manual of Ice Seamanship* (Pub. No. 551), *Sonic Soundings* (H.O. Pub. No. 606–b), *Bathythermograph Observations* (H.O. Pub. No. 606–c), *Ice Observations* (H.O. Pub. No. 606–d), and *Sea and Swell Observations* (H.O. Pub. No. 606–e). The U.S. Navy Hydrographic Office *Catalog of Nautical Charts and Publications* (Pub. No. 1–N series) lists the various oceanographic charts and publications available.

The U.S. Coast and Geodetic Survey conducts research in tides and currents and makes available several publications relating to them.

Electronic Navigation Charts and Publications

416. Loran.—Tables for plotting loran lines of position are published by the U.S. Navy Hydrographic Office as H.O. Pub. No. 221, in a number of volumes. Loran lines of position are printed on certain nautical and aeronautical charts by the U.S. Navy Hydrographic Office and the Coast and Geodetic Survey. Information on loran charts and publications is contained in H.O. Pub. 1–N, *Catalog of Nautical Charts and Publications*, the *Catalog of U.S. Navy Aeronautical Charts and Related Publications*, the *Coast and Geodetic Survey catalog of Aeronautical Charts and Related Publications*, and the *DOD Catalog of Aeronautical Charts and Flight Information Publications* which is available only to military users. H.O. Pub. No. 1–V, *Catalog of Aeronautical Charts and Publications*, has been canceled.

417. Radar.—The U.S. Coast and Geodetic Survey has published several experimental nautical charts showing a great number of land contours and gradient tints, for use with radar.

418. Miscellaneous.—The U.S. Navy Hydrographic Office publications entitled *Radio Navigational Aids* (H.O. Pubs. Nos. 117–A, Atlantic and Mediterranean Area and 117–B, Pacific and Indian Oceans Area) contain detailed information on radiobeacons and other aids to navigation. The light lists includes some details of radiobeacons. Volume II of *International Code of Signals* (H.O. Pub. No. 104) deals with radio communication. Various other publications relating to radio navigation are listed in appendix N.

419. Information by radio.—H.O. Pubs. Nos. 117–A and 117–B, *Radio Navigational Aids*, contain complete lists of the radio stations that perform services of value to the mariner, and give general and detailed information concerning these services, and present the regulations of various nations on this subject.

In addition to its information on radiobeacons and radio direction finder stations, H.O. Pub. No. 117 gives full information on time signals, navigational warnings, distress signals, medical advice, quarantine report stations, long-range navigational aids, wartime emergency procedures for U. S. merchant vessels, and plain language weather reports and storm and hurricane warnings. For information concerning radio traffic stations, the mariner should consult the lists published by the Bureau of the International Telecommunication Union, Berne, Switzerland.

H.O. Pubs. Nos. 118–A and 118–B, *Radio Weather Aids*, contain general information, marine broadcasts, synoptic broadcasts, facsimile broadcasts, weather codes and code forms, and miscellaneous conversion tables.

H.O. Pub. No. 119, *Weather Station Index*, contains a complete list of international index numbers with locations of stations, key groups, and call signs, and includes a supplemental listing of U.S. meteorological reporting stations.

Corrections to these volumes are published in *Notice to Mariners*. The publications themselves are corrected by "Changes" which are issued quarterly for H.O. Pubs. Nos. 117–A, 117–B, 118–A, and 118–B.

Navigational Publications

420. Sailing Directions or **pilots** are books containing descriptions of coast lines, harbors, dangers, aids to navigation, winds, currents, and tides; instructions for navigating narrow waterways and for approaching and entering harbors; information on port facilities, signal systems, and pilotage services; and other data that cannot be conveniently shown on charts. Those covering the coasts of the United States and its possessions, including the Intracoastal Waterway, are called **coast pilots,** and are published by the U. S. Coast and Geodetic Survey. Those covering foreign coasts, called **sailing directions,** are published in looseleaf form by the U. S. Navy Hydrographic Office.

Supplements to coast pilots are published annually, and change pages to sailing directions are published periodically. The more important changes are published in *Notice to Mariners*.

421. Light lists for the United States and its possessions, including the Intracoastal Waterway, the Great Lakes (both United States and Canadian shores), and the Mississippi River and its navigable tributaries, are published annually by the U. S. Coast Guard. Similar publications covering foreign coasts are published in looseleaf form by the U.S. Navy Hydrographic Office in seven volumes (H.O. Pubs. Nos. 111–A, 111–B and 112 through 116). "Changes" are published at appropriate intervals. Light lists give detailed information regarding navigational lights, light structures, radiobeacons, and fog signals. Corrections to both sets of light lists are published weekly in the *Notice to Mariners*. Coast Guard light lists also give unlighted buoys.

422. Navigational tables.—Many types of navigational tables are published. While many of these appear as parts of other books, such as those at the back of this volume, a number of separate books of tables are available. Nearly all of these are published by the U. S. Navy Hydrographic Office. The ones of principal interest to the navigator are:

H.O. Pub. No. 260, *Azimuth Tables*, lists the azimuth angle of the sun at intervals of 10^m between sunrise and sunset for each degree of latitude between the equator and 70° (north or south). It is also applicable to other bodies having declinations of 0° to 23°. Azimuth angles are tabulated to a precision of 1′. These are popularly known as the "Red Azimuth Tables" to distinguish them from H.O. Pub. No. 261. The use of these tables is explained in article 2126.

H.O. Pub. No. 151, *Table of Distances between Ports*, tabulates about 40,000 distances between various ports throughout the world.

Distances between United States Ports, published by the U. S. Coast and Geodetic Survey, tabulates approximately 10,000 distances along the shortest routes marked by aids to navigation between various United States ports. It also includes conversion tables similar to table 20 and parts of table 21 of this volume.

H.O. Pub. No. 261, *Azimuths of Celestial Bodies*, is similar to H.O. Pub. No. 260, but for declinations of 24° to 70°. These are popularly known as the "Blue Azimuth Tables." Their use is explained in article 2126.

H.O. Pub. No. 208, *Navigation Tables for Mariners and Aviators*, is a set of trigonometric tables arranged in convenient form for solving the navigational triangle by the formulas of Dreisonstok (art. 2110).

H.O. Pub. No. 211, *Dead Reckoning Altitude and Azimuth Table*, is a trigonometric table arranged in convenient form for solving the navigational triangle by the formulas of Ageton (art. 2111).

H.O. Pub. No. 214, *Tables of Computed Altitude and Azimuth*, tabulates the solution of the navigational triangle for each 1° of latitude from the equator to 89° (north or south), each 1° of meridian angle where the altitude is 5° or more, and each 0°5 of declination from 0° to 29° with selected values above 29°. Altitude is given to the nearest 0'1 and azimuth angle to the nearest 0°1. There are nine volumes, each covering 10° of latitude, with separate tabulations for same and contrary names of declination and latitude. These are the basic tables for marine celestial navigation, and are explained fully in chapter XX.

H.O. Pub. No. 218, *Astronomical Navigation Tables*, is somewhat similar to H.O. Pub. No. 214, but designed primarily for aviators. Altitudes are tabulated to the nearest 1' and azimuth angles to the nearest 1°. Altitudes are corrected for refraction at a height of eye of 5,000 feet. In addition to the tabulation for same and contrary names of declination and latitude there is a section giving altitude and azimuth of 22 selected stars, the name of the star being given as one of the entering arguments to eliminate interpolation for declination. There are 14 volumes, each covering 5° of latitude, the total coverage extending from the equator to latitude 69° (north or south). These tables have been largely superseded by H.O. Pub. No. 249.

H.O. Pub. No. 221, *Loran Tables*, is discussed in article 416.

H.O. Pub. No. 249, *Sight Reduction Tables*, is intended primarily for air navigation. Volume I tabulates the altitude to the nearest 1', and *azimuth* (not azimuth angle) to the nearest 1°, for seven selected stars. Entries are given for each 1° (2° beyond latitude 69°) of local hour angle of the vernal equinox for each 1° of latitude from 89° N to 89° S, in a single volume.

Volumes II and III tabulate the altitude to the nearest 1' and *azimuth angle* to the nearest 1°, for each 1° of meridian angle (2° beyond 69°) and 1° of declination, from 0° to 29° (with separate tabulations for same and contrary name), for each 1° of latitude from 89° N to 89° S. Volume II covers latitudes 0° to 39°, and volume III covers latitudes 40° to 89°. Altitudes extend to negative values to provide for observation of bodies near the horizon from aircraft in flight.

423. Almanacs.—The positions of celestial bodies on the celestial sphere; times of sunrise, sunset, moonrise, moonset, and beginning and ending of twilight; sextant altitude corrections; and other astronomical information of particular interest to navigators are published by the U. S. Naval Observatory in books called "almanacs." *The Nautical Almanac*, published annually, tabulates the basic information to the nearest 0'1 at hourly intervals. *The Air Almanac*, published three times a year, tabulates essentially the same information to the nearest 1' at time intervals of ten minutes. Since 1960, *The American Ephemeris and Nautical Almanac* and *The Astronomical Ephemeris* have also been unified. Published annually, they tabulate a great amount

of astronomical information of interest primarily to astronomers. The information is generally tabulated to a precision much greater than needed by either marine or air navigators. All of these publications are published jointly by the United States and Great Britain.

424. Manuals.—Reference or instruction books are published by many sources, both governmental and commercial. Some of these are general, such as the present volume, and others are limited to particular aspects of the subject, such as H.O. Pub. No. 257, *Radar Plotting Manual*, H.O. Pub. No. 217, *Maneuvering Board Manual*, and H.O. Pub. No. 226, *Handbook of Magnetic Compass Adjustment and Compensation*. There are a great number and variety of such books. In general, they can be obtained from stores handling nautical publications, government agencies having cognizance over the subjects of the manuals, or instrument makers (in the case of manuals describing specific instruments). The U.S. Government Printing Office publishes lists of publications on a number of subjects and most other government agencies and commercial publishing companies have similar lists for distribution.

Periodical Publications and Broadcasts

425. *Notice to Mariners,* published weekly by the U.S. Navy Hydrographic Office, lists changes in aids to navigation throughout the world, newly reported dangers such as wrecks, important new soundings, and official regulations affecting navigation. It is the official publication for the correction of charts, sailing directions, light lists, etc. It also carries announcements of new charts, new editions of charts, and new publications. Two editions are published, one for the Atlantic and Mediterranean, and one for the Pacific and Indian Oceans. *Notice to Mariners* is distributed without charge to qualified users. It can be consulted at offices of sales agents for products of the U. S. Navy Hydrographic Office, U. S. Coast and Geodetic Survey, and U. S. Coast Guard; Branch Hydrographic Offices; District Offices of the Coast Guard; United States consulates abroad; and Centralization Offices in various ports of the world.

426. *Daily Memorandum,* published each working day by the U.S. Navy Hydrographic Office, gives a synopsis of late information relating to aids to navigation and dangers to vessels, including reports of ice, derelicts, etc. The urgent items are also broadcast by radio (art. 427). It also contains advance information of the more important material that will appear in the *Notice to Mariners*. This publication is distributed locally by the Branch Hydrographic Offices. An East Coast edition is published at Washington, a West Coast edition by the Branch Hydrographic Office in San Francisco, a Pacific edition by the Branch Hydrographic Office in Honolulu, a Far East edition by the Branch Hydrographic Office in Yokosuka, and a Canal Zone edition by the Branch Hydrographic Office in Cristobal, C. Z.

427. Radio broadcasts.—Nearly all maritime nations broadcast radio navigational warnings. In general, such broadcasts contain information of importance to the safety of vessels at sea, such as the position of ice and derelicts, inadequacy and changes in aids to navigation, mine fields, etc. Most of the information is furnished by cooperating observers at sea.

As a general rule, each nation broadcasts only those navigational warnings affecting its own coasts. In the United States the broadcasts are made by Navy and Coast Guard radio stations. The information is compiled by the U. S. Navy Hydrographic Office and the U. S. Coast Guard. Frequently, broadcasts include warnings from both agencies. The major items affecting the Atlantic and Gulf coasts and, occasionally, important Pacific and foreign notices are broadcast daily by station NSS, Washington. The major Pacific items are broadcast daily by station NPG, San Francisco. Usually the information contained in these general broadcasts is adequate for offshore

navigation, but before nearing the coast, vessels should obtain the information available in local broadcasts from the area to be entered. In general, the information contained in a local broadcast affects only the area in which the broadcasting station is located and, occasionally, adjacent areas.

Urgent messages, such as those concerning tsunamis (art. 3310), hurricanes, etc., are broadcast immediately upon receipt and at frequent intervals thereafter as long as they are applicable. In some countries provision is made whereby navigational warnings can be obtained upon request. In the majority of cases this information is a repetition of scheduled broadcasts.

Urgent messages pertaining to the Atlantic area are called **hydrolants** and those pertaining to the Pacific **hydropacs.** These terms refer to messages broadcast by the United States. Urgent messages pertaining to the Eastern Atlantic and Mediterranean and broadcast by the British Admiralty are called **naveams.**

In addition to navigational warnings, radio services include time signals, weather and ice reports and predictions, distress information, and medical advice. Full information on navigational radio broadcasts, including the times, stations, frequencies, and instructions for utilizing this service, is given in H.O. Pubs. Nos. 117–A and 117–B, *Radio Navigational Aids,* and H.O. Pubs. Nos. 118–A and 118–B, *Radio Weather Aids.*

Miscellaneous Charts and Publications

428. Isomagnetic charts.—The U. S. Navy Hydrographic Office publishes a series of charts of magnetic information. There are five groups, each consisting of one chart for each polar region and one for the remainder of the world, plus grid variation charts for each polar region. There is one group each showing lines of equal dip (inclination), horizontal intensity, vertical intensity, total intensity, and variation of the compass (magnetic declination). In addition to these charts, the Hydrographic Office publishes a 12-sheet series of charts showing world coverage of magnetic variation of the compass. The U. S. Coast and Geodetic Survey publishes charts showing lines of equal variation for the United States and Alaska, and other isomagnetic charts.

Variation is also shown on the navigator's regular nautical charts.

429. Great-circle charts.—The U. S. Navy Hydrographic Office publishes a number of charts on the gnomonic projection with the points of tangency selected so as to make the charts suitable for planning ocean voyages. These charts are customarily used in connection with regular nautical charts, the desired great circle being plotted as a straight line on the gnomonic chart and various points along the line being transferred by means of its geographical coordinates (latitude and longitude) to the nautical chart to mark the ends of a series of rhumb lines. Points along any desired great circle can also be established by computation (art. 822).

430. Aeronautical charts, although designed primarily for air navigation, are sometimes useful to the marine navigator as well. They often show more details of adjacent land than do nautical charts, and they show aeronautical beacons (lighted and radio) which can be of value to the marine navigator who understands their use. Such charts are published principally by the Aeronautical Chart and Information Center of the U. S. Air Force, the U. S. Coast and Geodetic Survey, and the U. S. Navy Hydrographic Office. These agencies publish catalogs listing their aeronautical charts and publications.

431. Plotting charts and plotting sheets are published by the U. S. Navy Hydrographic Office.

Plotting charts show the land area in outline. Soundings, aids to navigation, and other information customarily shown on nautical charts are not given. The charts are used principally for planning.

Plotting sheets are blank charts showing only the graticule of latitude and longitude lines, at a specified range of latitude, and compass roses. The meridians are not labeled, permitting the plotting sheet to be used at any longitude. A **universal plotting sheet** (art. 324) shows only the parallels of latitude, a central compass rose, and a single mid meridian. The user draws in the meridians at the correct interval, depending upon the latitude. In addition to the universal plotting sheet, there are four series of ordinary plotting sheets, each series of a different size. Details are given in Pub. No. 1–N, Introduction Part I (*Catalog of Nautical Charts and Publications*). Plotting sheets are used primarily for plotting celestial fixes and dead reckoning at sea. The navigator customarily uses a chart when near land.

432. Miscellaneous charts.—Both the U. S. Navy Hydrographic Office and the U. S. Coast and Geodetic Survey publish a number of special charts listed in their catalogs. Some of the H.O. charts are listed in Pub. No. 1–N. Among these are track charts, an air route chart of the world, an airline distance map of the United States, a time zone chart of the world, outline charts and maps, azimuthal equidistant charts centered on certain strategic cities, star charts, special charts for the fishing industry, and others.

433. Miscellaneous publications.—There are numerous other publications of greater or less interest to navigators. Among these are:

Chart No. 1, *Nautical Chart Symbols and Abbreviations.* A pamphlet showing the standard symbols in color and the various abbreviations which have been approved for use on nautical charts published by the United States of America. Much of this information is reproduced in appendix K.

H.O. Pub. No. 103, *International Code of Signals,* Vol. I (visual).

H.O. Pub. No. 110, *DAPAC* (Danger Areas in the Pacific).

Nemedri. A publication giving routing instructions for areas in northern European, Mediterranean, and Black Sea waters declared dangerous because of mines. This publication is distributed by the British Admiralty for the International Routing and Reporting Authority. A United States reprint is distributed without cost by the U. S. Navy Hydrographic Office.

H.O. Pub. No. 150, *World Port Index.*

H.O. Pub. No. 216, *Air Navigation.*

H.O. Pub. No. 220, *Navigation Dictionary.*

Weather maps and reports, available from the U. S. Weather Bureau.

H.O. Pub. No. 606–a, *Navigational Observations.* An instruction manual for the various observations on which the U. S. Navy Hydrographic Office desires reports.

H.O. Pub. No. 609, *A Functional Glossary of Ice Terminology.*

H.O. 2102–D, *Star Finder and Identifier.*

H.O. Misc. 10578, *Eskimo Place Names and Aids to Conversation,* compiled by Commander Donald B. MacMillan, USNR.

Rules of the Road—International—Inland. A pamphlet giving the international and inland rules of the road in parallel columns, followed by pilot rules for certain inland waters, published by the U.S. Coast Guard. Additional pamphlets or individual sheets published by the same agency give the specific rules applying to U.S. waterways. An example is the booklet entitled *Rules of the Road—Western Rivers.*

Aids to Marine Navigation of the United States, published by the U.S. Coast Guard.

CHAPTER V

THE NAUTICAL CHART

General Information

501. Introduction.—A nautical chart is a conventional graphic representation, on a plane surface, of a navigable portion of the surface of the earth. It shows the depth of water by numerous soundings, and sometimes by depth curves, the shore line of adjacent land, topographic features that may serve as landmarks, aids to navigation, dangers, and other information of interest to navigators. It is designed as a work sheet on which courses may be plotted, and positions ascertained. It assists the navigator in avoiding dangers and arriving safely at his destination. The nautical chart is one of the most essential and reliable aids available to the navigator.

502. Projections.—Nearly all nautical charts used for ordinary purposes of navigation are constructed on the Mercator projection (art. 305). Large-scale harbor charts on standard scales (1:12,500, 1:25,000, 1:50,000) are often constructed on the transverse Mercator projection. Charts for special purposes, such as great-circle sailing or polar navigation, often are on some other projection. Many aeronautical charts are constructed on the Lambert conformal projection (art. 314). The principal projections, with their navigational uses, are discussed in chapter III.

503. Scale.—The *scale* of a chart is the ratio of a given distance on the chart to the actual distance which it represents on the earth. It may be expressed in various ways. The most common are:

Natural scale, expressed as a simple ratio or fraction. For example, 1:80,000 or $\frac{1}{80,000}$ means that one unit (such as an inch) on the chart represents 80,000 of the same unit on the surface of the earth.

Numerical scale, or a statement of that distance on the earth shown in one unit (usually an inch) on the chart, or vice versa. For example, "30 miles to the inch" means that one inch on the chart represents 30 miles of the earth's surface. Similarly, "2 inches to a mile" indicates that 2 inches on the chart represent 1 mile on the earth.

Graphic scale. A line or bar may be drawn at a convenient place on the chart and subdivided into nautical miles, yards, etc. All charts vary somewhat in scale from point to point, and in some projections the scale is not the same in all directions about a single point. A single subdivided line or bar for use over an entire chart is shown only when the chart is of such scale and projection that the scale varies a negligible amount over the chart, usually one of about 1:50,000 or larger. Since one minute of latitude is very nearly equal to one nautical mile, the latitude scale serves as an approximate graphical scale. On most nautical charts the east and west borders are subdivided to indicate the latitude scale.

On a Mercator chart the scale varies with the latitude. This is noticeable on a chart covering a relatively large distance in a north-south direction. On such a chart the scale at the latitude in question should be used for measuring distances.

Of the various methods of indicating scale, the graphical method is normally available in some form on the chart. In addition, the natural scale is customarily stated on charts on which the scale does not change appreciably over the chart.

The natural and numerical scales of a chart are readily interchangeable. For instance, in a nautical mile there are about 6,076.11549 feet or $6{,}076.11549\times 12=72{,}913.39$ inches. If the natural scale of a chart is 1:80,000, one inch of the chart represents 80,000 inches of the earth, or a little more than a mile. To find the exact amount, divide the scale by the number of inches in a mile, or $\frac{80{,}000}{72{,}913.39}=1.097$. Thus, a natural scale of 1:80,000 is the same as a numerical scale of 1.097 (or approximately 1.1) miles to an inch. Stated another way, there are $\frac{72{,}913.39}{80{,}000}=0.911$ (approximately 0.9) inch to a mile. Similarly, if the numerical scale is 60 nautical miles to an inch, the natural scale is $1{:}(60\times 72{,}913.39)=1{:}4{,}374{,}803$.

It should be clearly understood that scale, as discussed above, refers to *distances*, not *areas*. If the area scale is desired, it is found by squaring the natural scale. Thus, if the natural scale of a chart is 1:50,000, the corresponding area scale is $1{:}(50{,}000\times 50{,}000)=1{:}2{,}500{,}000{,}000$ or one square inch on the chart represents 2,500,000,000 square inches on the earth, or a square 50,000 inches on a side.

A chart covering a relatively large area is called a *small-scale* chart and one covering a relatively small area is called a *large-scale* chart. Since the terms are relative, there is no sharp division between the two. Thus, a chart of scale 1:100,000 is large scale when compared with a chart of 1:1,000,000 but small scale when compared with one of 1:25,000.

504. Chart classification by scale.—Charts are constructed on many different scales, ranging from about 1:2,500 to 1:14,000,000 (and even smaller for some world charts). Small-scale charts covering large areas are used for planning and for offshore navigation. Charts of larger scale, covering smaller areas, should be used as the vessel approaches pilot waters. Several methods of classifying charts according to scale are in use in various nations. The following classifications of nautical charts are those used by the U. S. Navy Hydrographic Office and the U. S. Coast and Geodetic Survey:

Sailing charts are the smallest scale charts used for planning, fixing position at sea, and for plotting the dead reckoning while proceeding on a long voyage. The scale is generally 1:600,000 or smaller. The shore line and topography are generalized and only offshore soundings, the principal navigational lights, outer buoys, and landmarks visible at considerable distances are shown.

General charts are intended for coastwise navigation outside of outlying reefs and shoals. The scales range from about 1:100,000 to 1:600,000.

Coast charts are intended for inshore coastwise navigation where the course may lie inside outlying reefs and shoals, for entering or leaving bays and harbors of considerable width, and for navigating large inland waterways. The scales range from about 1:50,000 to 1:100,000.

Harbor charts are intended for navigation and anchorage in harbors and small waterways. The scale is generally larger than 1:50,000.

In addition, there are special series of charts, such as the 1:40,000 U. S. Coast and Geodetic Survey charts of the Intracoastal Waterway (inside route) and various series of river and canal charts.

505. Accuracy.—The accuracy of a chart depends upon:

1. *Thoroughness and up-to-dateness of the survey and other navigational information.* Some estimate of the accuracy of the survey can be formed by an examination of the source notes given in the title of the chart. If the chart is based upon very old surveys, it should be used with caution. Many of the earlier surveys were made under

conditions that were not conducive to great accuracy. It is safest to question every chart based upon surveys of doubtful accuracy.

The number of soundings and their spacing is some indication of the completeness of the survey. Only a small fraction of the soundings taken in a thorough survey are shown on the chart, but sparse or unevenly distributed soundings indicate that the survey was probably not made in detail. Large or irregular blank areas, or absence of depth curves, generally indicate lack of soundings in the area. If the water surrounding such a blank area is deep, there is generally considerable depth in the blank; conversely, shallow water surrounding such an area indicates the strong possibility of shoal water. If neighboring areas abound in rocks or are particularly uneven, the blank area should be regarded with additional suspicion. However, it should be kept in mind that relatively few soundings are shown when there is a large number of depth curves or where the bottom is flat or gently and evenly sloping. Additional soundings are shown when they are helpful in indicating the uneven character of a rough bottom (figs. 505a and 505b).

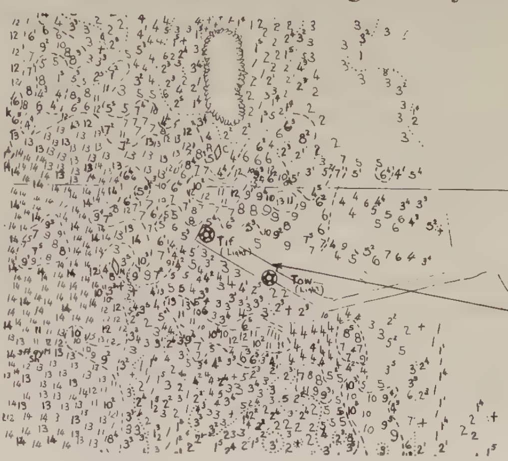

Figure 505a.—Part of a boat sheet, showing the soundings obtained in a survey.

Even a detailed survey may fail to locate every rock or pinnacle, and in waters where their existence is suspected, the best methods for determining their presence are wire drag surveys or use of electronic underwater obstacle detection gear. Areas that have been dragged may be indicated on the chart and a note added to show the effective depth at which the drag was operated.

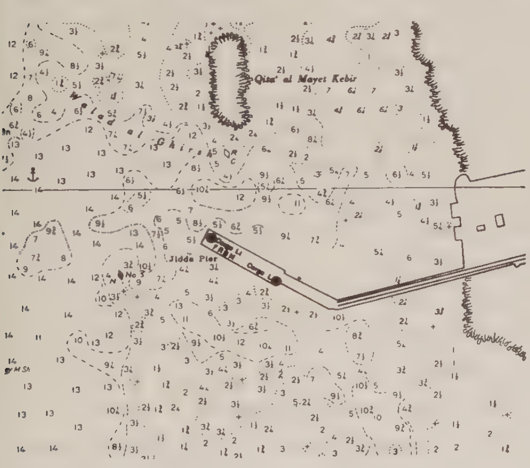

Figure 505b.—Part of a nautical chart made from the boat sheet of figure 505a. Compare the number of soundings in the two figures.

Changes in the contour of the bottom are relatively rapid in areas where there are strong currents or heavy surf, particularly when the bottom is composed principally of soft mud or sand. The entrances to bar harbors are especially to be regarded with suspicion. Similarly, there is sometimes a strong tendency for dredged channels to shoal, especially if they are surrounded by sand or mud, and cross currents exist. Notes are sometimes shown on the chart when the bottom contours are known to change rapidly. However, the absence of such a note should not be regarded as evidence that rapid change does not occur.

Changes in aids to navigation, structures, etc., are more easily determined, and charts are generally corrected in this regard to the date of distribution. However, there is always the possibility of a change having occurred since the chart was mailed or received. The date to which the chart was corrected is stamped on it

before distribution. All issues of *Notice to Mariners* printed after that date should be checked to ensure accuracy in this respect.

2. *Suitability of the scale for the design and intended navigational use.* The same detail cannot be shown on a small-scale chart as on one of a larger scale. For this reason it is good practice to use the largest scale chart available when in the vicinity of shoals or other dangers.

3. *Presentation and adequacy of data.* The amount and kind of detail to be shown, and the method of presentation, are continually under study by charting agencies. Development of a new navigational aid may render many previous charts inadequate. An example is radar. Many of the charts produced before radar became available lack the detail needed for confident identification of targets.

Part of the responsibility for the continuing accuracy of charts lies with the user. If charts are to remain reliable, they must be corrected as indicated by the *Notice to Mariners*. In addition, the user's reports of errors and changes and his suggestions often are useful to the publishing agencies in correcting and improving their charts. Navigators and maritime activities have contributed much to the reliability and usefulness of the modern nautical chart. If a chart becomes wet, the expansion and subsequent shrinkage when the chart dries are likely to cause distortion.

506. Dates on charts.—The system of dates now used on charts published by the U. S. Coast and Geodetic Survey and the U. S. Navy Hydrographic Office is as follows:

First edition. The original date of issue of a new chart is shown at the lower left-hand corner and at the top center margin, thus:

1st Ed., Sept. 1901

New edition. A new edition is made when, at the time of printing, the corrections are too numerous or too extensive to be reported in *Notice to Mariners*, making previous printings obsolete. The date of the first edition is retained at the top margin. At the lower left-hand corner it is replaced by the number and date of the new edition, thus:

5th Ed., July 11, 1955

Corrected (New) print. A corrected print contains corrections which have been published in the *Notice to Mariners*, and other information which is not of sufficient importance to justify a new edition. The date of a corrected print is the date on which the last check is made to see that all important corrections have been applied. Normally, this date is the Monday following the date of the last *Notice to Mariners* used. It is added at the lower left-hand corner of the chart, thus:

5th Ed., July 11, 1955; Revised 2/4/57

For any subsequent corrected prints the date is replaced by the later one, thus:

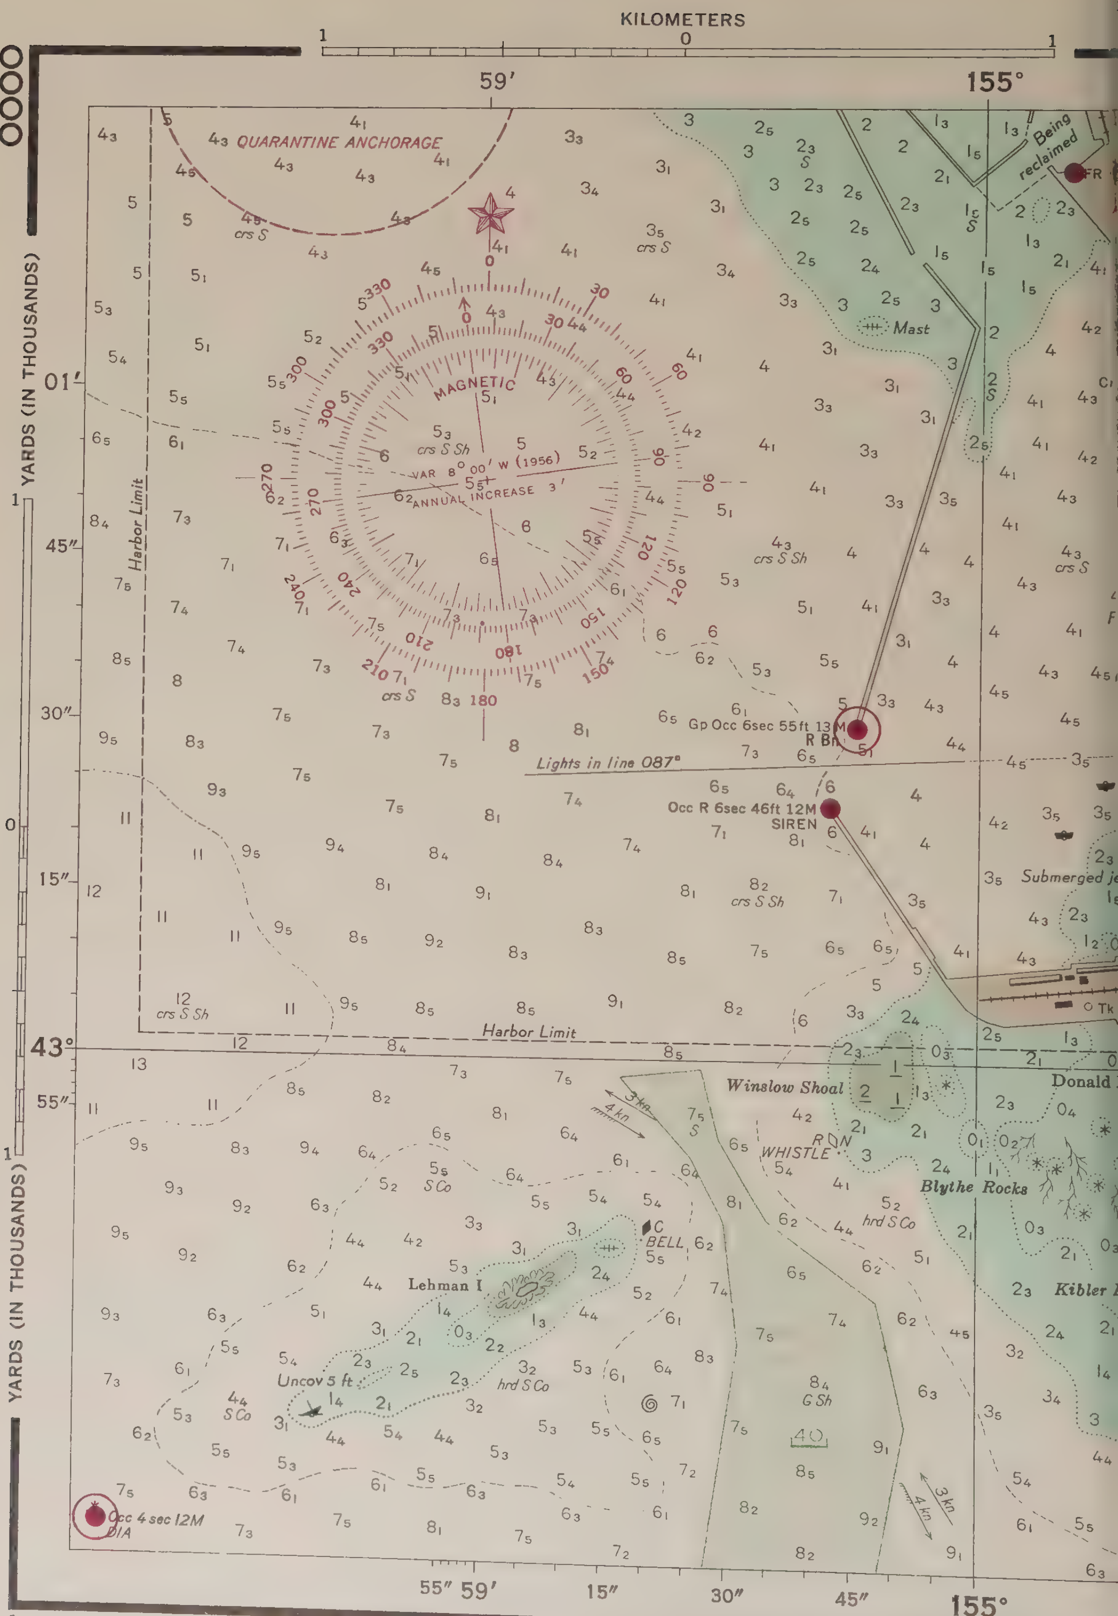
5th Ed., July 11, 1955; Revised 2/17/58

Hydrographic Office chart terminology is discussed in article 4406.

Hand-correction date. Stocks of charts kept on hand by the publishing agencies or their distribution centers are hand corrected for changes shown in *Notice to Mariners* published prior to the date of distribution. The date of the latest issue for which hand corrections have been made is stamped in the margin. This is the most important date shown on the chart. Important changes after the date of the latest hand-corrected change are published in the weekly *Notice to Mariners* and should be applied immediately by the user.

Chart Reading

507. Chart symbols.—Much of the information contained on charts is shown by conventional symbols which make no attempt at accuracy in scale or detail, but are



1st Ed., June 18, 1956

0000 PRICE 00 CENTS

STANDARD NAUTICAL CHART
(Area Fictitious)

Published a
by the U. S. NAVY
under the authority of t

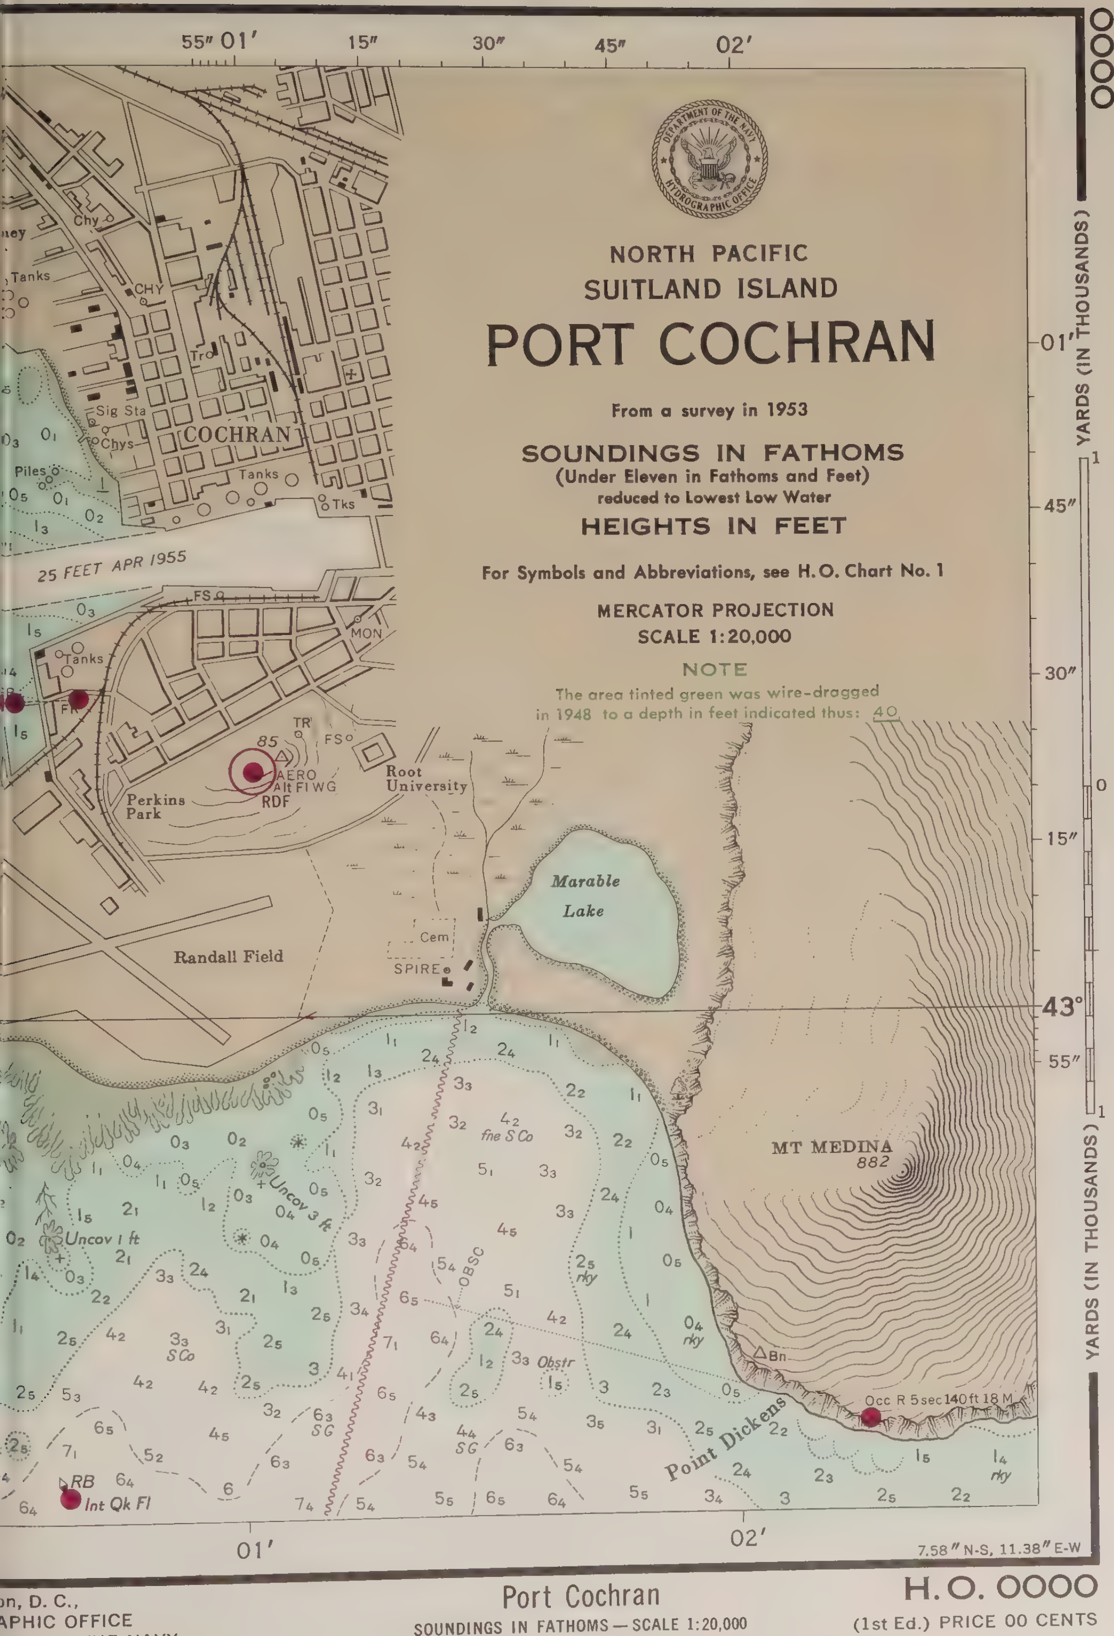


FIGURE 507.— A fictitious sample nautical chart.

shown at the correct location and make possible the showing of a large amount of information without congestion or confusion. The standard symbols and abbreviations which have been approved for use on regular nautical charts published by the United States of America are shown in appendix K. A knowledge of the meanings of these symbols is essential to a full understanding of charts. A fictitious sample chart showing a number of these symbols is given in figure 507.

Most of the symbols and abbreviations shown in appendix K are in agreement with those recommended by the International Hydrographic Bureau. Where there is disagreement, the number of the symbol or abbreviation is in leaning figures. Vertical figures enclosed in parentheses indicate that the symbol or abbreviation is an addition to those recommended by the International Hydrographic Bureau.

The symbols and abbreviations on any given chart may differ somewhat from those shown in appendix K because of a change in the standards since printing of the chart or because the chart was published by an agency having a different set of standards.

508. Lettering.—Certain standards regarding lettering have been adopted, except on charts made from reproducibles furnished by foreign nations.

Vertical type is used for features which are dry at high water and not affected by movement of the water, except for heights above water.

Leaning type is used for water, underwater, and floating features, except soundings.

The type of lettering used may be the only means of determining whether a feature may be visible at high tide. For instance, a rock might bear the title "________ Rock" whether or not it extends above the surface. If the name is given in vertical letters, the rock constitutes a small islet; if in leaning type, the rock constitutes a reef.

509. The shore line shown on nautical charts is the boundary between water and land at high tide (usually mean high water). A broken line indicates that the charted position is approximate only. The nature of the shore may be indicated, as shown by the symbols in part A of appendix K.

Where the low-water line differs considerably from the high-water line, the low-water line may be indicated by dots in the case of mud, sand, gravel, or stones, with the kind of material indicated, and by a characteristic symbol in the case of rock or coral. The area alternately covered and uncovered may be shown by a tint which is a combination of the land tint and a blue water tint.

In marsh or mangrove areas, the outer edge of vegetation is used as the shore line. The inner edge is marked by a broken line when no other symbol (such as a cliff, levee, etc.) furnishes such a limit. The area between inner and outer limits may be given the combined land-water tint or the land tint.

510. Water areas.—Soundings or depths of water are shown in several ways. Individual soundings are shown by numbers. These do not follow the general rule for lettering. They may be either vertical or leaning, or both may be used on the same chart to distinguish between the data based upon different surveys, different datums, or furnished by different authorities.

On all charts produced from surveys by United States vessels, soundings are shown in English units (feet or fathoms). The unit used is shown in the chart legend. Foreign charts may show depths in meters, and occasionally in other units. The units used on charts of various nations are shown in appendix L.

"No bottom" soundings are indicated by a number with a line over the top and a dot over the line, thus: $\dot{\overline{45}}$. This indicates that the spot was sounded to the depth indicated without reaching the bottom. Areas which have been wire dragged are shown by a limiting line, and the clear effective depth is indicated, with a characteristic symbol under the numbers, thus: $\llcorner\underline{24}\lrcorner$.

The soundings are supplemented by a series of bottom contours or *depth curves* connecting points of equal depth. These lines present a graphic indication of the configuration of the bottom. The types of lines used for various depths are shown in part R of appendix K. On some of the recent charts of the U. S. Coast and Geodetic Survey an increased number of depth curves have been shown in solid blue or black lines, the depth represented by each being shown by numbers placed in breaks in the lines, as with land contours. This type chart, presenting a more detailed indication of the bottom configuration with fewer numerical soundings, is particularly useful to the vessel equipped with an echo sounder permitting continuous determination of a profile of the bottom. Such a chart, to be reliable, can be made only for areas which have been surveyed in great detail.

Areas which uncover at low tide are tinted as indicated in article 509. Those areas out to a given depth, usually one, two, or three fathoms, often are given a blue tint, and occasionally a lighter blue is carried to some greater depth, usually five fathoms. On older charts the one-, two-, and three-fathom curves have stippled edges. Charts designed to give maximum emphasis to the configuration of the bottom show depths over the entire chart by a series of blue gradient tints similar to the tints sometimes shown on land areas to indicate graduations in height. These are called *bathymetric* charts.

The side limits of dredged channels are indicated by broken lines. The controlling depth and the date it was determined, if known, are shown by a statement in or along the channel. The *controlling* depth is not necessarily an indication of the *least* depth in the channel on the date of determination. For channels less than 100 feet in width, at least 80 percent at the center is clear to the charted (controlling) depth. For channels more than 100 feet in width, at least the 50 percent at the center is clear to the charted depth. The possibility of shoaling since the controlling depth was determined should be considered.

The chart scale is generally too small to permit all soundings to be shown. In the selection of soundings to be shown, *least* depths are generally chosen first and a sounding pattern worked out to provide safety, a practical presentation of the bottom configuration, and a neat appearance. Depths greater than those indicated may be found close to charted depths, but steep changes in depth are given every consideration in sounding selection. Also, the state of the tide affects the depth at any given moment. An isolated shoal sounding should be approached with caution, or avoided, unless it is known that the area has been wire dragged, for there is always the possibility that a depth less than the least shown may have escaped detection. Also, the shoal area near a coast little frequented by vessels is sometimes not surveyed with the same thoroughness as other areas. Such areas and those where rocks, coral, etc., are known to exist should be entered with caution, or avoided.

The substance forming the bottom is shown by abbreviations, as listed in part S of appendix K. The meaning of some of the less-well-known terms is given below:

Ooze is a soft, slimy, organic sediment composed principally of shells or other hard parts of minute organisms.

Marl is a crumbling, earthy deposit, particularly one of clay mixed with sand, lime, decomposed shells, etc. A layer of marl may become quite compact.

Shingle consists of small, rounded, waterworn stones. It is similar to gravel but with the average size of stone generally larger.

Schist is crystalline rock of a finely laminated nature.

Madrepore is a stony coral which often forms an important building material for reefs.

Lava is rock in the fluid state, or such material after it has solidified. It is formed at very high temperature and issues from the earth through volcanoes.

Pumice is cooled volcanic glass with a great number of minute cavities caused by the expulsion of water vapor at high temperature, resulting in a very light material.

Tufa is a porous rocky deposit sometimes formed in streams and in the ocean near the mouths of rivers.

Scoria (plural *scoriae*) is rough, cinderlike lava.

Seatangle is any of several species of seaweed, especially those of large size.

Spicules are the small skeletons of various marine animals such as sponges.

Foraminifera (plural) are small marine animals with hard shells of from one to many chambers.

Globigerina is a very small marine animal of the foraminifera order, with a chambered shell, or the shell of such an animal. In large areas of the ocean the calcareous shells of these animals are very numerous, being the principal constituent of a soft mud or **globigerina ooze,** forming part of the ocean bed.

Diatom is a microscopic animal with external skeletons of silica, often found in both fresh and salt water. Part of the ocean bed is composed of a sedimentary ooze consisting principally of large collections of the skeletal remains of diatoms.

Radiolaria (plural) are minute sea animals with a siliceous outer shell. The skeletons of these animals are very numerous, especially in the tropics.

Pteropod is a small marine animal with or without a shell and having two thin, winglike feet. These animals are often so numerous they cover the surface of the sea for miles. In some areas their shells cover the bottom.

Polyzoa (plural) are very small marine animals which reproduce by budding, many generations often being permanently connected by branchlike structures.

Cirripeda (plural) are barnacles and certain other parasitic marine animals.

Fucus is a coarse seaweed growing attached to rocks.

Matte is a dense, twisted growth of a sea plant such as grass.

"Calcareous" is an adjective meaning "containing or composed of calcium or one of its compounds."

511. Chart datum.—*Depths.* All depths indicated on charts are reckoned from some selected level of the water, called the *chart datum.* The various chart datums are explained in chapter XXXI. On charts made from surveys conducted by the United States the chart datum is selected with regard to the tides of the region, so that depths might be shown in their least favorable aspect. On charts based upon those of other nations the datum is that of the original authority. When it is known, the datum used is stated on the chart. In some cases where the chart is based upon old surveys, particularly in areas where the range of tide is not great, the actual chart datum may not be known.

For U. S. Coast and Geodetic Survey charts of the Atlantic and Gulf coasts of the United States and Puerto Rico the chart datum is *mean low water.* For charts of the Pacific coast of the United States, including Alaska, it is *mean lower low water.* Most U. S. Navy Hydrographic Office charts are based upon *mean low water, mean lower low water,* or *mean low water springs.* The chart datum for British Admiralty charts based upon British surveys is *mean low water springs* in areas where the daily inequality is small, and *Indian spring low water* where the daily inequality is large. The chart datum for charts published by other countries varies greatly, but is usually lower than mean low water. On charts of the Baltic Sea, Black Sea, the Great Lakes, and other areas where tidal effects are small or without significance, the datum adopted is an arbitrary height approximating the mean water level. Chart datums used in various areas are shown in appendix M.

The chart datum of the largest-scale charts of an area is generally the same as the reference level from which height of tide is tabulated in the tide tables.

The height of a chart datum is usually only an approximation of the actual mean value specified, for determination of the actual mean height usually requires a longer series of tidal observations than is available to the cartographer, and the height changes somewhat over a period of time.

Since the chart datum is generally a computed mean or average height at some state of the tide, the depth of water at any particular moment may be less than shown on the chart. For example, if the chart datum is *mean lower low water*, the depth of water at *lower low water* will be less than the charted depth about as often as it is greater. A lower depth is indicated in the tide tables by a minus sign (—).

Heights. The shore line shown on charts is the high-water line, generally the level of mean high water. The heights of lights, rocks, islets, etc., are generally reckoned from this level. However, heights of islands, especially those at some distance from the coast, are often taken from sources other than hydrographic surveys, and may be reckoned from some other level, often mean sea level. The plane of reference for topographic detail is frequently not stated on the chart.

Since heights are usually reckoned from high water and depths from some form of low water, the reference levels are seldom the same. This is generally of little practical significance, but it might be of interest under some conditions, particularly where the range of tide is large.

512. Dangers are shown by appropriate symbols, as indicated in part O of appendix K.

A rock which is uncovered at mean high water is shown as an islet enclosed by a dotted line to make it more prominent. If an isolated, offlying rock is known to uncover at the chart datum but to be covered at high water, the appropriate symbol is shown and the height above the chart datum, if known, is usually given, either by statement such as "*Uncov 2 ft*" or by the figure indicating the number of feet above the chart datum underlined and usually enclosed in parentheses, thus: ($\underline{2}$). This is illustrated in figure 512a. A rock which does not uncover is shown by the appropriate symbol. If it is considered a danger to surface vessels, the symbol is enclosed by a dotted curve.

A distinctive symbol is used to show a detached coral reef which uncovers at the chart datum. For a coral or rocky reef which is submerged at chart datum, the sunken rock symbol or an appropriate statement is used, enclosed by a dotted or dashed line if the limits have been determined.

Several different symbols are used for wrecks, depending upon the nature of the wreck or scale of the chart. The usual symbol for a visible wreck is shown in figure 512b. A sunken wreck with less than ten fathoms of water over it is considered dangerous and its symbol is surrounded by a dotted curve. The safe clearance depth found over a wreck is indicated by a standard sounding number placed at the wreck. If this depth is determined by a wire drag, the sounding is underscored by the wire drag symbol (art. 510).

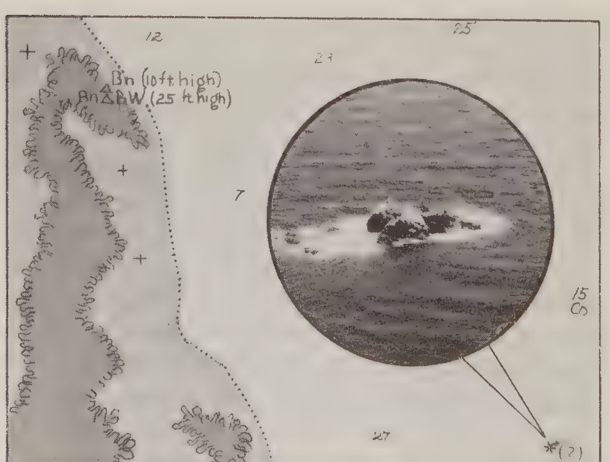

FIGURE 512a.—A rock awash.

Tide rips, eddies, and kelp are shown by symbol or lettering.

Piles, dolphins (clusters of piles), snags, stumps, etc., are shown by small circles and a label

identifying the type of obstruction. If such dangers are submerged, the letters "Subm" precede the label.

513. Aids to navigation are shown by symbol, as given in appendix K, usually supplemented by abbreviations and sometimes by additional descriptive text. In order to render the symbols conspicuous it is necessary to show them in greatly exaggerated size relative to the scale of the chart. It is therefore important that the navigator know which part of the symbol represents the actual position of the aid. For floating aids (lightships and buoys), the position part of the symbol marks the location of the anchor or sinker, the aid swinging in an orbit around this position.

FIGURE 512b.—A visible wreck.

The principal charted aids to navigation are lighthouses, beacons, lightships, radiobeacons, and buoys. The number of aids shown and the amount of information concerning them varies with the scale of the chart. Wherever distance of visibility is given, it is computed for a height of eye of the observer of 15 feet. Unless otherwise indicated, lights which do not alternate in color are white, and alternating lights are red and white. Light lists give complete navigational information concerning them.

Lighthouses and *lighted beacons* are shown as black dots surrounded by magenta disks. The disks for primary lighthouses are a little larger than those for beacons. In either case, the center of the black dot within the magenta disk is the position of the light. On older charts a six-pointed star symbol was used for primary lighthouses and a five-pointed star symbol for beacons. The center of the star symbol marks the position of the light.

On large-scale charts the characteristics of lights are shown in the following order:

Characteristic	*Example*	*Meaning*
1. Character	Gp. Fl.	group flashing
2. Color	R	red
3. Period	(2) 10 sec.	two flashes every 10 seconds
4. Height	160 ft.	160 feet
5. Visibility	19M	visible 19 nautical miles (15 ft. height of eye)
6. Number	"6"	light number 6

The legend for this light would appear on the chart:

Gp. Fl. R (2) 10 sec. 160 ft. 19 M "6"

On older charts this form is varied slightly. As the chart scale becomes smaller the six items listed above are omitted in the following order: first, height; second, period (seconds); third, number (of flashes, etc.) in group; fourth, light number; fifth, visibility. Names of unnumbered lights are shown when space permits.

Daybeacons (unlighted beacons) are shown by small triangles, the center of the triangle marking the position of the aid. Except on Intracoastal Waterway charts the abbreviation Bn is shown beside the symbol, with the appropriate abbreviation for color. For black beacons the triangle is solid black and there is no color abbreviation. All

beacon abbreviations are in vertical lettering, as appropriate for fixed aids (fig. 513a).

Lightships are shown by ship symbol, the center of the small circle at the base of the symbol indicating the position of the lightship's anchor. On recent charts the circle is overprinted by a small magenta disk as shown in figure 513b. As a floating aid, the light characteristics and the name of the lightship are given in leaning letters.

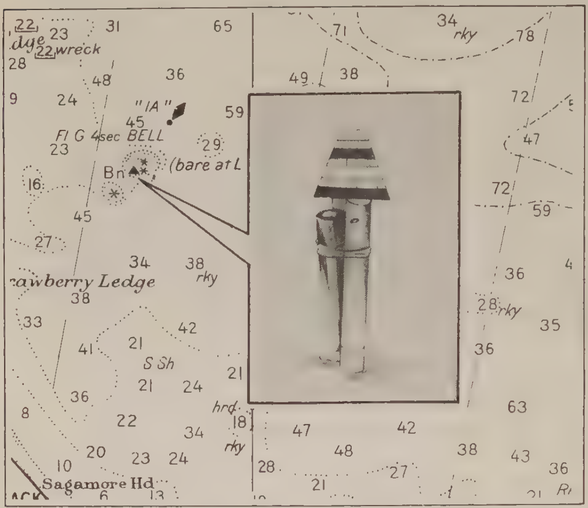

FIGURE 513a.—A daybeacon.

Radiobeacons are indicated on the chart by a small magenta circle, as shown in figure 513b, accompanied by the appropriate abbreviation to indicate whether an ordinary radiobeacon (R Bn) or a radar beacon (Racon). The same symbol is used for a radio direction finder station with the abbreviation "RDF" and a coast radar station with the abbreviation Ra. Other radio stations are indicated by a small black circle with a dot in the center, or a smaller circle without a dot, and the appropriate abbreviation. In every case the center of the circle marks the position of the aid.

Buoys, except mooring buoys, are shown by a diamond-shaped symbol and a small dot outside the diamond and near one of its points (at one of its acute angles). The dot indicates the position of the buoy's sinker. A mooring buoy is shown by a distinctive symbol as indicated at number 22 of part L, appendix K. The small circle interrupting the symbol's base line indicates the position of the sinker.

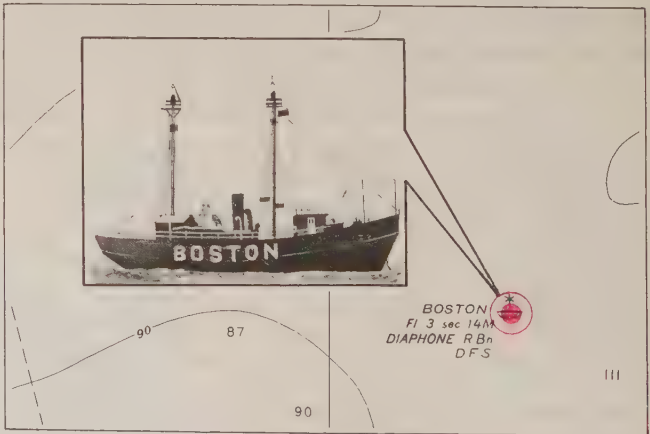

FIGURE 513b.—A lightship with a radiobeacon.

A black buoy is shown by a solid black diamond symbol, without abbreviation. For all other buoys, color is indicated by an abbreviation, or in full by a note on the chart. In addition, the diamond shape of symbols of red buoys are colored magenta. A buoy symbol with a line connecting the side points (shorter axis), half of the symbol being magenta or open and the other half black, indicates horizontal bands. A line connecting the upper and lower points (longer axis) represents vertical stripes. Two lines connecting the opposite *sides* of the symbol indicate a checkered buoy.

There is no significance to the angle at which the diamond-shape appears on the chart. The symbol is placed so as to avoid interference with other features of the chart.

Lighted bouys are indicated by a small magenta disk centered on the dot or small

circle indicating the position of the buoy's sinker, as shown in figure 513c. On older charts a series of radiating lines representing light rays was drawn about the dot or circle, and no magenta disk was given.

Abbreviations for light characteristics, type and color of buoy, number of the buoy, and any other pertinent information given near the symbol are in leaning letters. The letter C, N, or S, indicates a can, nun, or spar, respectively (art. 917). The words "bell," "gong," and "whistle," are shown as BELL, GONG, and WHIS, respectively. The number or letter designation of the buoy is given in quotation marks on small-scale charts. On large-scale charts they are given without quotation marks or punctuation, thus: No 1, No 2, etc.

Station buoys are not shown on small-scale charts, but are given on some large-scale charts.

Aeronautical lights included in the light lists are shown by the lighthouse symbol, accompanied by the abbreviation "AERO". The completeness to which the characteristics are shown depends principally upon the effective range of other navigational lights in the vicinity, and the usefulness of the light for marine navigation.

Ranges are indicated by a dashed or solid line. If the direction is given, it is expressed in degrees clockwise from true north.

Fog signal apparatus is indicated by the appropriate word in capital letters (HORN, BELL, GONG, etc.) or an abbreviation indicating the type of sound. The letters "D.F.S." indicate a **distance finding station** having synchronized sound and radio signals. The location of a fog signal which does not accompany a visual aid, either lighted or unlighted, is shown by a small circle and the appropriate word in vertical block letters.

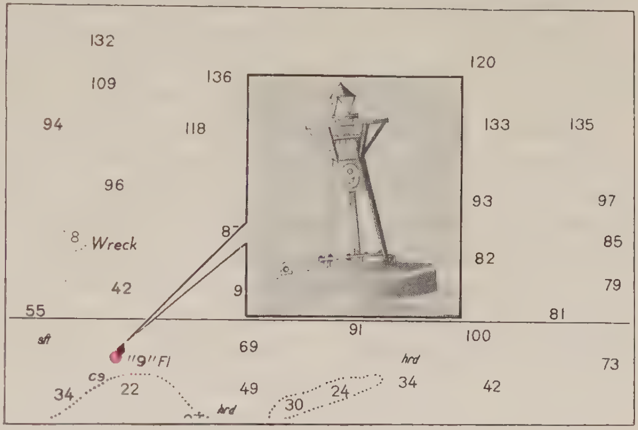

FIGURE 513c.—A lighted buoy.

Private aids are not indicated on the chart except in special cases. When they are shown, they are marked "Privately maintained" or "Priv. maintd." Any privately maintained unlighted aid is indicated by a small circle accompanied by the word "Marker," or a larger circle with a dot in the center and the word "MARKER," the symbols for any landmark or conspicuous object not having a distinctive symbol. The center of the circle indicates the position of the aid. A privately maintained lighted aid has the light symbol and is accompanied by the characteristics and the usual indication of its private nature.

Floats are indicated by the open buoy symbol accompanied by the word "FLOAT." Either the lighted or unlighted symbol is used, as appropriate, to indicate whether or not the float displays a light.

A *light sector* is the sector or area bounded by two radii and the arc of a circle in which a light is visible or in which it has a distinctive color different from that of adjoining sectors. The limiting radii are indicated on the chart by dotted lines.

Colors of the sectors are indicated by words spelled out if space permits, or by abbreviation (W, R, etc.) if it does not.

Limits of light sectors and arcs of visibility *as observed from a vessel* are given in the light lists, in clockwise order.

514. Land areas.—The amount of detail shown on the land areas of nautical charts depends upon the scale, the intended purpose of the chart, and available information. Since the advent of radar, topographical details have increased and have been extended farther inland, where this information has been available.

Relief is shown by contours, form lines, hachures, or tint shading. Tint shading is used principally to stress those terrain features affecting surface radar returns. It may be shown with or without contours and spot elevations.

Contours are lines connecting points of equal elevation. The heights represented by the contours are indicated in leaning figures at suitable places along the lines. Heights are usually expressed in feet (or in meters with means for conversion to feet on certain special charts). The interval between contours is uniform over any one chart, except that certain intermediate contours are sometimes shown by dashed line. When contours are broken, their locations are approximate.

Form lines are approximations of contours used for the purpose of indicating relative elevations. They are used in areas where accurate information is not available in sufficient detail to permit exact location of contours. Elevations of individual form lines are not indicated on the chart.

Hachures are short lines, or groups of lines, indicating the direction and extent of steep slopes. The lines generally follow the direction of the slope, the length of the lines indicating the height of the slope. Distinctive symbols somewhat resembling hachures are used for cliffs or other steep slopes on or near the coast line, where contours or form lines, being virtually over each other, would be difficult to interpret or would fail to give a true indication of the nature of the terrain.

Spot elevations are generally given only for summits or for tops of conspicuous landmarks. The heights of spot elevations and contours are given with reference to mean high water when this information is available.

When there is insufficient space to show the heights of islets or rocks, they are indicated by leaning figures enclosed in parentheses in the water area nearby.

Cities and roads. Except on the smaller scale charts, cities are usually represented by their street systems or a conventional system of intersecting lines. The symbol for large cities approximates their extent and shape. Street names are generally not charted except those along the waterfront on the largest scale charts. Only the more important streets are shown on smaller scale charts. In general, only the important through highways and roads leading from them to the waterfront are shown. Occasionally, highway numbers are given. When shown, trails are indicated by a light broken line. Buildings along the waterfront or individual ones back from the waterfront but of special interest to the mariner are shown on large-scale charts. Special symbols are used for certain kinds of buildings, as indicated in part I of appendix K. Both single and double track railroads are indicated by a single line with cross marks. In general, city electric railways are not charted. A fence or sewer extending into the water is shown by a broken line, usually labeled. Airports are shown on small-scale charts by symbol and on large-scale charts by shape and extent of runways. Breakwaters and jetties are shown by single or double lines depending upon the scale of the chart. A submerged portion and the limits of the submerged base are shown by broken lines.

515. Landmarks are shown by symbols, as given in appendix K. Some of the accompanying labels encountered on a chart are interpreted as follows:

Building or **house.** One of these terms, as appropriate, is used when the entire structure is the landmark, rather than an individual feature of it.

A **spire** is a slender pointed structure extending above a building. It is seldom less than two-thirds of the entire height of the structure, and its lines are rarely broken by stages or other features. The term is not applied to a short pyramid-shaped structure rising from a tower or belfry.

A **cupola** (kū′pō·lȧ) is a small dome-shaped tower or turret rising from a building (fig. 515).

A **dome** is a large, rounded, hemispherical structure rising above a building, or a roof of the same shape. A prominent example is that of the Capitol of the United States, in Washington.

A **chimney** is a relatively small, upright structure projecting above a building for the conveyance of smoke.

A **stack** is a tall smokestack or chimney. The term is used when the stack is more prominent as a landmark than accompanying buildings.

FIGURE 515.—A cupola.

A **flagpole** is a single staff from which flags are displayed. The term is used when the pole is not attached to a building.

The term **flagstaff** is used for a flagpole rising from a building.

A **flag tower** is a scaffold-like tower from which flags are displayed.

A **radio tower** is a tall pole or structure for elevating radio antennas.

A **radio mast** is a relatively short pole or slender structure for elevating radio antennas, usually found in groups.

A **tower** is any structure with its base on the ground and high in proportion to its base, or that part of a structure higher than the rest, but having essentially vertical sides for the greater part of its height.

A **lookout station** or **watch tower** is a tower surmounted by a small house from which a watch is kept regularly.

A **water tower** is a structure enclosing a tank or standpipe so that the presence of the tank or standpipe may not be apparent.

A **standpipe** is a tall cylindrical structure, in a waterworks system, the height of which is several times the diameter.

The term **tank** is used for a water tank elevated high above the ground by a tall skeleton framework.

The expression **gas tank** or **oil tank** is used for the distinctive structures described by these words.

516. Miscellaneous.—*Measured mile.* A measured nautical mile indicated on a chart is accurate to within six feet of the correct length. Most measurements in the United States were made before 1959, when the United States adopted the international nautical mile. The new value is within six feet of the previous standard length of 6,080.20 feet, adjustments not having been made. If the measured distance differs from the standard value by more than six feet, the actual measured distance is stated and the words "measured mile" are omitted.

Periods after abbreviations in water areas are omitted, as these might be mistaken for rocks. However, a lower case *i* or *j* is dotted.

Courses shown on charts are given in true directions, to the nearest minute of arc.

Bearings shown are in true directions *toward* (not from) the objects.

Commercial radio broadcasting stations are shown on charts when they are of value to the mariner either for obtaining radio bearings or as landmarks.

Rules of the road. Lines of demarcation between the areas in which international and inland rules apply are shown only when they cannot be adequately described in notes on the chart.

Compass roses are placed at convenient locations on Mercator charts to facilitate the plotting of bearings and courses. The outer circle is graduated in degrees with zero at true north. The inner circle is graduated in points and degrees with the arrow indicating magnetic north.

Magnetic information. On many charts magnetic variation is given to the nearest 15′ by notes in the centers of compass roses. When this is done, the annual change is given to the nearest 1′ to permit correction of the given value at a later date. However, since the annual change is a variable quantity, and since the values given are rounded off, as well as for other reasons, it is wise to use a chart of recent date. On other charts the variation is given by a series of **isogonic lines** connecting points of equal variation, usually a separate line being given for each degree of variation. The line of zero variation is called the **agonic line.** Many plans and insets show neither compass roses nor isogonic lines, but indicate magnetic information by note. A local magnetic disturbance of sufficient force to cause noticeable deflection of the magnetic compass, called **local attraction,** is indicated by a note on the chart.

Currents are sometimes shown on charts by means of arrows giving the directions, and figures giving the speeds. The information thus given refers to the usual or average conditions, sometimes based upon very few observations. It is not safe to assume that conditions at any given time will not differ considerably from those shown.

Longitudes are reckoned eastward and westward from the meridian of Greenwich, England, unless otherwise stated. Nearly all modern charts use Greenwich.

Notes on charts should be read with care, as they may give important information not graphically presented. Several types of notes are used. First, those in the margin give such information as the chart number and (sometimes) price, publication and edition notes, identification of adjoining charts, etc. Second, notes in connection with the chart title include such information as scale, sources of charted data, tidal information, the unit in which soundings are given, cautions, etc. A third class of notes is that given in proximity to the detail to which it refers. Examples of this type of note are those referring to local magnetic disturbance, controlling depths of channels, measured miles, dangers, dumping grounds, anchorages, etc.

Title. The chart title may be at any convenient location, usually in some area not important to navigation. It is composed of several distinctive parts as shown in figure 516.

Use of Charts

517. Advance preparation.—Before a chart is to be used, it should be studied carefully. All notes should be read and understood. There should be no question of the meanings of symbols or the unit in which depths are given, for there may not be time to determine such things when the ship is underway, particularly if an emergency should arise. Since the graduations of the latitude and longitude scales differ considerably on various charts, those of the chart to be used should be noted carefully. Dangers and abnormal conditions of any kind should be noted.

SCALE → SCALE 1:150,000 AT LAT. 27°

FIGURE 516.—A chart title.

Particular attention should be given to soundings. It is good practice to select a realistic danger sounding (art. 911) and mark this prominently with a colored pencil.

It may be desirable to place additional information on the chart. Arcs of circles might be drawn around navigational lights to indicate the limit of visibility at the height of eye of an observer on the bridge. Notes regarding the appearance of light structures, tidal information, prominent ranges, or other information from the light lists, tide tables, tidal current tables, and sailing directions might prove helpful.

The particular preparation to be made depends upon the requirements and the personal preferences and experience of the individual navigator. The specific information selected is not important. But it *is* important that the navigator familiarize himself with his chart so that in an emergency the information needed will be available and there will be no question of its meaning.

518. Maintaining charts.—When a chart is received, the date to which it has been hand corrected will be found stamped in the margin. Responsibility for maintaining it after this date lies with the user. *An uncorrected chart is a menace.* The various issues of *Notice to Mariners* subsequent to the stamped hand correction date contain all the information needed for maintaining charts. The more urgent items are also given in advance in the *Daily Memorandum* or by radio broadcast. A convenient way of keeping a record of the *Notice to Mariners* corrections made to each chart on hand is by means of 5×8-inch chart correction record cards (PRNC–NHO–5610/2, formerly form N.H.O. 1278), which can be purchased for a nominal sum.

When a new edition of a chart is published, it should be obtained and the old one retired from use. The very fact that a new edition has been prepared generally indicates that there have been changes that cannot adequately be shown by hand correction.

519. Use and stowage of charts.—Charts are among the most important aids of the navigator, and should be treated as such. When in use they should be spread out flat on a suitable chart table or desk, and properly secured to prevent loss or

damage. Every effort should be made to keep charts dry, for a wet chart stretches and may not return to the original dimensions after drying. The distortion thus introduced may cause inaccurate results when measurements are made on the chart. If a chart does become wet, the distortion may be minimized by ironing the chart with a warm iron until it is dry.

Permanent corrections to charts should be made in ink so that they will not be inadvertently erased. All other lines should be drawn lightly in pencil so that they can be easily erased without removing permanent information or otherwise damaging the chart. To avoid possible confusion, lines should be drawn no longer than necessary, and adequately labeled. When a voyage is completed, the charts should be carefully and thoroughly erased unless there has been an unusual incident such as a grounding or collision, when they should be preserved without change, as they will undoubtedly be requested by the investigating authority. After a chart has been erased, it should be inspected carefully for possible damage and for incompletely erased or overlooked marks that might prove confusing when the chart is next used.

When not in use charts should be stowed flat in their proper drawers or portfolios, with a minimum of folding. The stowed charts should be properly indexed so that any desired one can be found when needed. In removing or replacing a chart, care should be exercised to avoid damage to it or other charts.

A chart that is given proper care in use and stowage can have a long and useful life.

520. Chart lighting.—In the use of charts it is important that adequate lighting be provided. However, the light on the bridge of a ship underway at night should be such as to cause the least interference with the darkness-adaptation of the eyes of bridge personnel who watch for navigational lights, running lights, dangers, etc. Experiments by the Department of the Navy have indicated that red light is least disturbing to eyes which have been adapted to maximum vision during darkness. In some instances red lights, filters, or goggles have been provided on the bridges or in chartrooms of vessels. However, the use of such light seriously affects the appearance of a chart. Red, orange, and buff disappear. Other colors may appear changed. This has led to the substitution of magenta or purple for red and orange, and gray for buff on some charts. However, before a chart is used in any light except white, a preliminary test should be made and the effect noted carefully. If a glass or plastic top is provided for the chart table or desk, a dim white light *below* the chart may provide sufficient illumination to permit chart reading, without objectionable disturbance of night vision.

PART TWO

PILOTING AND DEAD RECKONING

PART TWO

PILOTING AND DEAD RECKONING

CHAPTER VI

INSTRUMENTS FOR PILOTING AND DEAD RECKONING

Introduction

601. Kinds of instruments.—The word "instrument" has several meanings, at least two of which apply to navigation: (1) an implement or tool, and (2) a device by which the present value of a quantity is measured. Thus, a straightedge and a mechanical log are both instruments, the first serving as a tool, and the second as a measuring device. This chapter is concerned with the navigational instruments used for plotting, and those for measuring distance or speed, depth, and direction. Instruments for measuring time are discussed in chapter XV. These quantities are the basic data in dead reckoning (ch. VIII) and piloting (ch. IX). Other instruments are discussed in chapters XI, XV, XXXVII, and XL.

In addition to the instruments discussed, several others are important to the navigator. Binoculars are helpful in observing landmarks. A flashlight has many uses, the principal one being to illuminate the scales of instruments when they are to be read at night. Erasers should be soft, and pencils should not be so hard that they damage the surface of the chart. The navigator's chart is discussed in chapter V.

Plotting Instruments

602. Dividers and compasses.—**Dividers,** or "pair of dividers," is an instrument originally used for dividing a line into equal segments. The instrument consists essentially of two hinged legs with pointed ends which can be separated to any distance from zero to the maximum imposed by physical limitations. The setting is retained either by friction at the hinge, as in the usual navigational dividers, or by means of a screw acting against a spring.

If one of the legs carries a pencil or ruling pen, the instrument is called **compasses.** The two legs may be attached to a bar of metal or wood instead of being hinged, thus permitting greater separation of the points. Such an instrument is called **beam compasses** or **beam dividers** (fig. 4011b).

The principal use of dividers in navigation is to measure or transfer distances on a chart, as described in article 804. Compasses are used for drawing distance circles (art. 905), circles of visibility (art. 916), or any plotting requiring an arc of a circle.

The friction at the hinge of most dividers and compasses can be varied, and should be adjusted so that the instrument can be manipulated easily with one hand, but will retain the separation of the points in normal handling. A drop of oil on the hinge may be required occasionally. The points should be sharp, and should have equal length, permitting them to be brought close together for the measurement of very short distances.

For navigation, it is desirable to have dividers and compasses with comparatively long legs, to provide adequate range for most requirements. It is desirable to learn to manipulate dividers or compasses with one hand.

603. Parallel rulers are an instrument for transferring a line parallel to itself. In its most common form it consists of two parallel bars or rulers, connected in such a manner that when one is held in place on a flat surface, the other can be moved, remain-

ing parallel to its original direction. Firm pressure is required on one ruler while the other is being moved, to prevent slippage. The principal use of parallel rulers in navigation is to transfer the direction of a charted line to a compass rose, and vice versa.

The edges of the rulers should be truly straight; and in the case of double-edged rulers, should be parallel to each other in order that either edge can be used. Parallelism can be tested by comparison of all edges with the same straight line, as a meridian or parallel of a Mercator chart. The linkage can be tested for looseness and lack of parallelism by "walking" the rulers between parallel lines on opposite sides of the chart and back again.

Some metal parallel rulers have a protractor engraved on the upper surface to permit orientation of the ruler at any convenient meridian.

In one type of instrument, parallelism during transfer is obtained by supporting a single ruler on two knurled rollers. Both rollers have the same diameter, and the motion of one is transmitted to the other by an axle having a cover which provides a convenient handle. This type of ruler is convenient and accurate, and is less likely to slip than the linked double-ruler type. However, care is necessary to prevent its rolling off the chart table when the vessel is rolling or pitching.

Directions can also be transferred by means of two triangles such as are used in drafting, or by one triangle and a straightedge. One edge of a triangle is aligned in the desired direction and the triangle is then moved along a straightedge held firmly against one of its other edges until the first edge is at the desired place on the chart. Some triangles have protractors (art. 604) engraved on them to assist in transferring lines. Such a triangle becomes a form of plotter (art. 605).

604. Protractor.—A **protractor** is a device for measuring angles on a chart or other surface. It consists essentially of a graduated arc, usually of 180°, on suitable material such as metal or plastic.

A **three-arm protractor** consists essentially of a circular protractor with three radial arms attached. This instrument, discussed in greater detail in article 4011, is used primarily in hydrographic surveying.

605. Plotters.—The increased popularity of graphical methods in practical navigation during recent decades has resulted in the development of a wide variety of devices to facilitate plotting. In its most common form, such a device consists essentially of a protractor combined with a straightedge. There are two general types, one having no movable parts, and

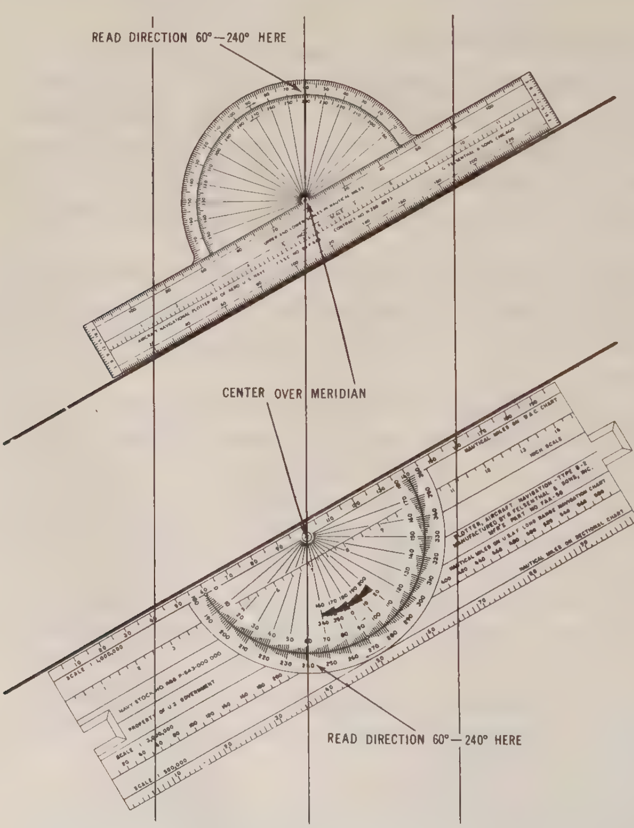

FIGURE 605.—Two plotters having no movable parts.

the other having a pivot at the center of the arc of the protractor, to permit rotation of the straightedge around the protractor. Examples of the fixed type are illustrated in figure 605. Those shown were designed for air navigation, but are applicable to many processes of marine navigation. The direction of the straightedge is controlled by placing the center of the protractor arc and the desired scale graduation on the same reference line. If the reference line is a meridian, the directions shown by the straightedge are true geographic directions. If, as in some processes of celestial navigation, it is desired to plot a line perpendicular to another line, the direction may be measured from a parallel of latitude or its equivalent, instead of adding or subtract-

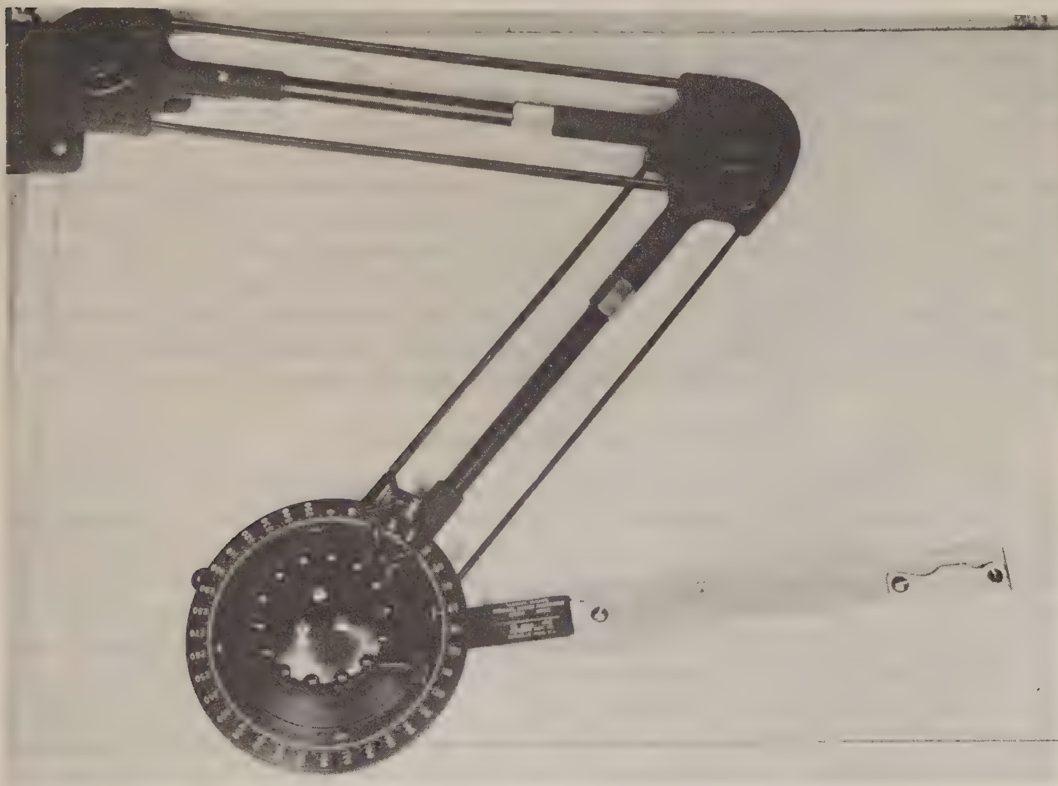

FIGURE 606.—Drafting machine.

ing 90° from the value and measuring from a meridian. Some fixed-type plotters have auxiliary scales labeled to indicate true direction if a parallel is used as the reference.

Most plotters also provide linear distance scales, as shown in figure 605. In the movable-arm type of plotter, a protractor is aligned with a meridian, and the movable arm is rotated until it is in the desired direction.

606. Drafting machine.—If a chart table of sufficient size is available, a **drafting machine** (fig. 606) is probably the most desirable plotting instrument. The straightedge of this instrument can be clamped so as to retain its direction during movement over the entire plotting area. Straightedges of various lengths and linear scales are interchangeable. Some models make provision for mounting two straightedges perpendicular to each other. However, for most purposes of navigation, the perpendicular is more conveniently obtained by the use of a triangle with a single straightedge. The movable protractor also retains its orientation, and can be adjusted to conform to the

compass rose of a chart secured in any position on the chart table. Directions of the straightedge can then be read or set on the protractor without reference to charted compass roses. Use of the clamped protractor requires that charted meridians be straight and parallel, as on a Mercator chart (art. 305). Its use is restricted with projections such as the Lambert conformal (art. 314), on which meridians converge.

When a drafting machine is used, the chart or plotting sheet is first secured to the chart table. The straightedge is aligned with a meridian (or parallel) and clamped in position. The protractor is then adjusted so that 000° and 180° (090° and 270° if a parallel is used) are at the ruler indices, and clamped. With this setting, any subsequent position of the ruler is indicated as a true direction. If the protractor is offset by the amount of the compass error (ch. VII), true directions can be plotted by setting the straightedge at the compass direction on the protractor, without need for applying compass error arithmetically. However, it is generally preferable to keep it set to true directions, and apply compass error mentally.

If accurate results are to be obtained, the anchor base must be rigidly fastened to the chart table. This should be checked from time to time, as the base may be loosened by vibration or normal use. The pivots in the anchor base should be firm without binding. The endless belts of the parallel motion mechanism should be taut if rigidity of the ruler is to be preserved. Provision is usually made for adjusting each of the various rulers to uniformity of alignment so that any other ruler can be substituted without changing the setting. As with parallel rulers, the device can be checked for parallelism by means of meridians or parallels on opposite sides of a Mercator chart.

Distance and Speed Measurement

607. Units of measurement.—Mariners generally measure horizontal distances in nautical miles (art. 205), but occasionally in yards or feet. Either feet or fathoms are used for measuring depth of water, and feet for measuring height above water. The British yard is now equal to that of the United States (art. 205). However, the difference was never significant in the ordinary practice of navigation. Nations which have adopted the metric system use meters in place of yards, feet, and fathoms, and for some purposes they use kilometers in place of nautical miles. Conversion factors for these and other units are given in appendix D. Nautical miles of 6,076.11549 feet (approximately) and land or statute miles of 5,280 feet can be interconverted by means of table 20. Meters, feet, and fathoms can be interconverted by means of table 21.

Speed is customarily expressed in knots (art. 206), or for some purposes, in kilometers per hour, or yards or feet per minute. For short distances, a nautical mile can be considered equal to 2,000 yards or 6,000 feet. This is a useful relationship because $\frac{6{,}000 \text{ feet}}{60 \text{ minutes}}=100$ feet per minute. Thus, speed in knots is equal approximately to hundreds of feet per minute or, hundreds of yards per 3-minute interval.

608. Distance, speed, and time are related by the formula

$$\text{distance}=\text{speed}\times\text{time}.$$

Therefore, if any two of the three quantities are known, the third can be found. The units, of course, must be consistent. Thus, if speed is measured in knots, and time in hours, the answer is in nautical miles. Similarly, if distance is measured in yards, and time in minutes, the answer is in yards per minute.

Table 19 is a speed, time, and distance table which supplies one of the three values if the other two are known. It is intended primarily for use in finding the distance steamed in a given time at a known speed. Table 18 is for use in determining speed by measuring the time needed to steam exactly one mile.

The solution of problems involving distance, speed, and time can easily be accomplished by means of a slide rule (art. O15). If the index of scale C is set opposite speed in knots on scale D, the distance in nautical miles appears on scale D opposite time in hours on scale C. If 60 of scale C is set opposite speed in knots on scale D, the distance covered in any number of *minutes* is shown on scale D opposite the minutes on scale C. Several circular slide rules particularly adapted for solution of distance, speed, and

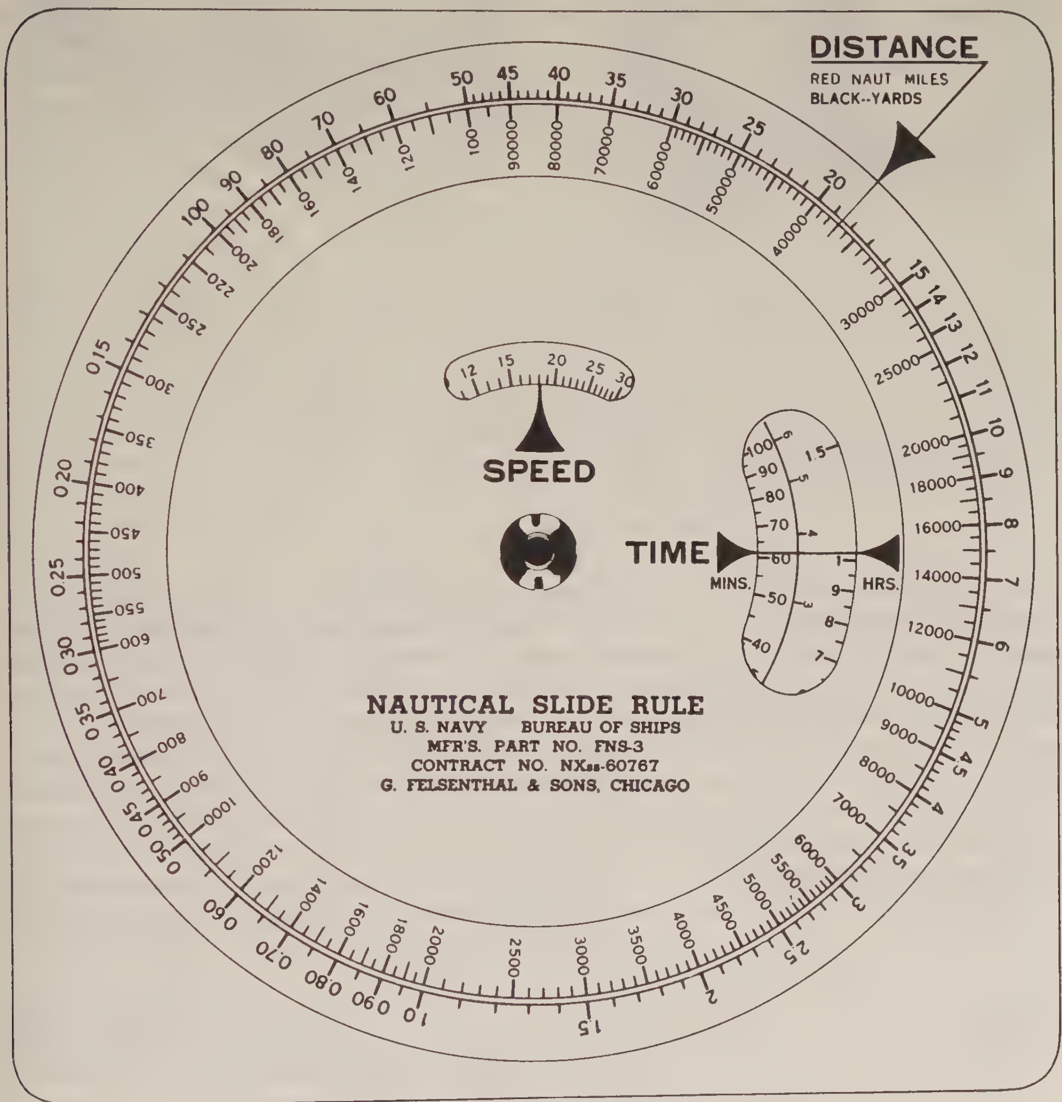

FIGURE 608.—The nautical slide rule.

time problems have been devised. One of these, called the "Nautical Slide Rule" is shown in figure 608.

609. Measurement of distance to an object can be made in a variety of ways, as by radar (art. 1208), sonar (art. 1103), RAR beacon (art. 1205), distance finding station (art. 1205), sextant angle (art. 905), range finder, or by several indirect methods. Another method used principally for measuring distance between ships in formation, but useful in measuring other distances, is by means of a small, hand-held instrument called a **stadimeter.**

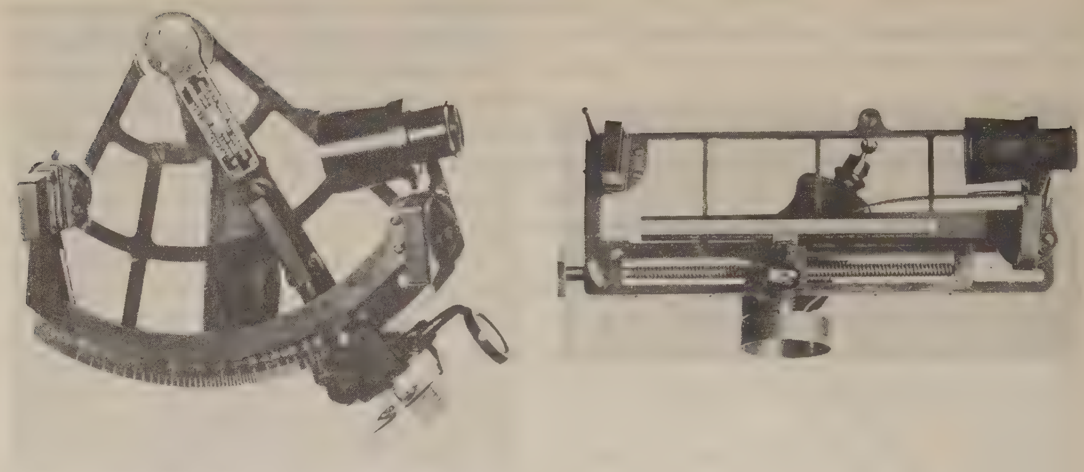

FIGURE 609a.—Stadimeters. Brandon (sextant) type at left; Fisk type at right.

Two types of stadimeters are illustrated in figure 609a. Both the Brandon or sextant type and the Fisk type operate on the principle used in table 9:

In a plane right triangle, *ABC*, having opposite sides *a*, *b*, and *c*,

$$\tan A = \frac{a}{b}, \text{ and } b = a \cot A.$$

This is applied to the stadimeter as shown in figure 609b. The height of the object is set on the height scale of the instrument, and the measured subtended angle is expressed in yards on the distance (range) scale. To measure the angle, one directs the line of sight through the instrument to the water line of the object observed, and adjusts the range index until the reflection of the top of the object is seen in coincidence with the water line. If the readings are not within the scale of the instrument, some fraction or multiple of the height can be used and a corresponding adjustment made to the answer. Thus, if *half* the height is set on the instrument, the distance indicated is *half* the correct value.

Since the observer's eye is not at the water level, a right angle is not necessarily formed between the line of sight and the top of the observed object. However, the

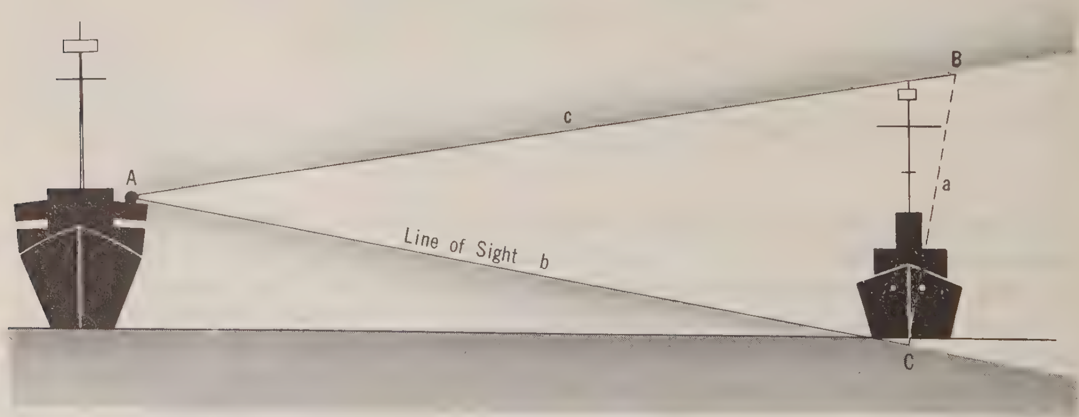

FIGURE 609b.—Geometry of a stadimeter measurement. The distance $b = a \cot A$.

resulting error is so small that it can be neglected under ordinary circumstances.

The aspect of a ship observed should be considered in stadimeter ranges. Thus, little error is introduced if the observer is broad on the beam of the other vessel, as in figure 609b, but less accuracy is obtained if the other vessel presents an end-on view, unless the water line directly below the masthead is correctly estimated.

A stadimeter can be used to indicate that a *change* in distance has occurred, even when the height of the object is not known. Similar indication of a change in distance can be obtained by a sextant (art. 905), or the actual distance can be determined by the measured angle and table 9 if the height is known.

610. Measurement of distance traveled may be made directly, or the distance can be determined indirectly by means of the speed and time, using the relationship given in article 608.

One of the simplest mechanical distance-measuring devices is the **taffrail log,** consisting of (1) a *rotator* which turns like a screw propeller when it is towed through the water; (2) a braided *log line,* up to 100 fathoms in length, which tows the rotator and transmits its rotation to an indicator on the vessel; and (3) a dial and pointer mechanism which registers the distance traveled through the water. In some installations, the readings of the register are transferred electrically to a dial on or near the bridge.

The taffrail log is usually streamed from the ship's quarter, although it may be carried at the end of a short boom extending outboard from the vessel. The log line should be sufficiently long, and attached in such position, that the rotator is clear of the disturbed water of the wake of the vessel; otherwise an error is introduced. Errors may also be introduced by a head or following sea; by mechanical wear or damage, such as a bent fin; or by fouling of the rotator, as by seaweed or refuse.

An accurately calibrated taffrail log in good working order provides information of sufficient reliability for most purposes of navigation. Its readings should be checked at various speeds by towing it over a known distance in an area free from currents. Usually, the average of several runs, preferably in opposite directions, is more accurate than a single one. If an error is found, it is expressed as a percentage and applied to later readings. The calibration should be checked from time to time.

Although a taffrail log is included in the equipment carried by many oceangoing vessels, the convenience and reliability of other methods of determining distance or speed have reduced the dependence formerly placed upon this instrument.

611. Measurement of speed.—Speed can be determined indirectly by means of distance and time, or it can be measured directly. All instruments now in common use for measuring speed determine rate of motion *through the water.* This is done (1) electromagnetically, (2) by measuring the water pressure due solely to the forward motion of the vessel, (3) by means of a small screw propeller having a speed of rotation proportional to speed of the vessel, and (4) by determining the relationship between ship speed and speed of rotation of its screw or screws. Instruments for measuring speed, like those for measuring distance, are called **logs.**

Before the development of modern logs, speed was determined in a number of ways. Perhaps the most common primitive device is the **chip log** (art. 112), although a **ground log** (a weight, with line attached, which was thrown overboard and rested on the bottom in shallow water) and a **Dutchman's log** (art. 112) have also been used. These devices are rarely used by modern navigators.

Speed over the bottom can be determined (1) by direct measurement; (2) by measuring on the chart or plotting sheet the distance made good between fixes, and dividing this by the time; or (3) by finding the vector sum of velocity through the water and velocity of the current. A suitable instrument for measuring speed over the bottom is not generally available, although some developmental work along this

line has been done. Measurement of the distance between two fixes requires a method of obtaining accurate fixes. The third method requires knowledge of velocity through the water, and current. An estimate of the current can be used to determine the approximate course and speed over the bottom. However, estimates are not always accurate, and an instrument to measure current would provide better results. Such an instrument, called the **geomagnetic electrokinetograph (GEK)**, has been developed. By means of two electrodes towed astern, beyond the magnetic influence of the vessel, the component of current perpendicular to the course is measured. By measurement of two such components, preferably on perpendicular courses, one can determine the total current. This device has given satisfactory results in experimental work, having been used primarily by oceanographers in their study of ocean currents, but has not been adapted for use in ordinary navigation.

612. The electromagnetic type underwater log consists essentially of a rodmeter, an oscillator-amplifier, and an indicator-transmitter. The rodmeter, which protrudes below the hull of the vessel, contains an electromagnetic sensing element which produces a voltage directly proportional to speed through the water. This voltage is amplified in the oscillator-amplifier, and is converted to pointer and synchro indications of speed in the indicator-transmitter. The speed signals are also converted to distance, by means of a roller-and-disk mechanism in the indicator-transmitter. This system has no orifice or moving parts external to the vessel, and has high precision and accuracy from zero speed to full scale.

613. Speed measurement by dynamic water pressure.—When an object is moving through a fluid such as water or air, its forward side is exposed to a *dynamic* pressure which is proportional to the speed at which the object is moving, in addition to the *static* pressure due to depth and density of the fluid above the object. When the fluid is water, and ship speeds are involved, dynamic pressure is equal to

$$P=\frac{S^2}{1.832g}$$

where P is dynamic pressure, S is speed through the water, and g is the acceleration due to gravity (32.2 feet per second per second, approximately). If this formula is solved for S, it becomes

$$S=1.353\sqrt{gP}.$$

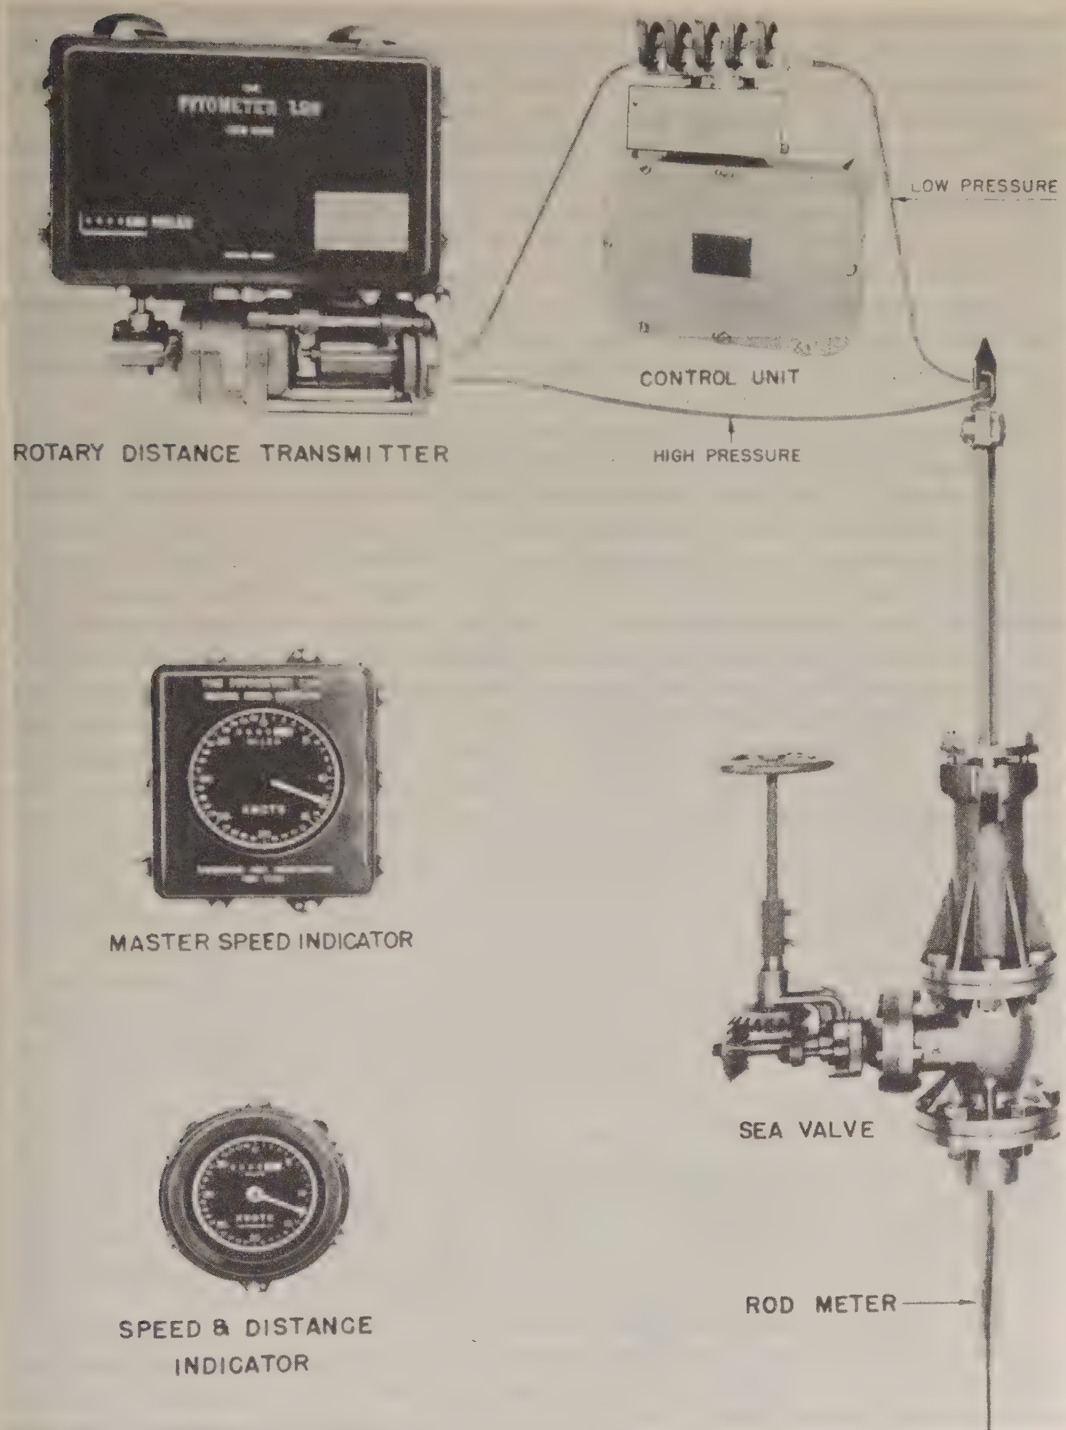
If 32.2 is substituted for g:

$$S=7.68\sqrt{P}.$$

Therefore, if dynamic pressure can be measured, this principle can be used for determining speed.

One of the most widely used means of measuring dynamic pressure is by a **Pitot tube.** This device consists of a tube having an opening on its forward side or end. If the tube is stationary in the water, this opening is subject to static pressure only. But when the tube is in motion, the pressure at the opening is the sum of static and dynamic pressures. This is called **Pitot pressure** or **total pressure.** The Pitot tube is surrounded by an outer tube which has openings along its athwartship sides. Whether the tube is stationary or in motion, these openings are subject to static pressure only.

In the **Pitot-static log** (fig. 613) the Pitot tube is in the form of a vertical "rodmeter" which extends through and is supported by a sea valve in the vessel's bottom. The tube extends 24 to 30 inches below the bottom of the vessel, into water relatively undisturbed by motion of the hull. The two pressures, Pitot and static, are led to separate bellows attached to opposite ends of a centrally pivoted lever. This lever is



Courtesy of Pitometer Log Corporation.

FIGURE 613.—A Pitot-static log.

electrically connected to a mechanism which controls the speed of a pump. When the vessel is dead in the water, the pressures are equal, and the pump is stopped. When the ship is moving, the pump speed is regulated so that the pressures in the two bellows are equalized. Thus, the pump speed is proportional to the ship speed.

Through suitable gearing, the pump provides a mechanical output at the rate of 60 revolutions per nautical mile. This rotation is transmitted electrically to the master indicator, where the distance traveled appears on the distance counter in units of 0.01 nautical mile. In addition, the master indicator has a timing device which transforms distance and time into speed, the latter appearing on the speed dial

Both speed and distance indications may be transmitted to various **repeaters** throughout the ship. Logs of this type have been replaced in ships of the U.S. Navy by those of the electromagnetic type to provide both greater accuracy at each calibration speed and over a given range of speeds.

In an early model of this type log, the two pressures from the Pitot tube are led to opposite sides of a manometer. The difference in pressure is indicated by a pressure gage graduated to read directly in knots. Distance is determined by a mechanical integrator and cam attached to the speed dial.

Various less accurate instruments have been devised for determining speed by measuring water pressure due to forward motion of the vessel. These are relatively simple, inexpensive instruments intended primarily for use by small craft. One instrument has a finger which the water pressure forces aft against a calibrated spring. A flexible hydraulic cable transmits the motion to a speed indicator. Another instrument uses a small scoop attached to the hull of the vessel. The pressure of the water scooped up is transmitted by tubing to the speed indicator, which is essentially a pressure gage graduated in knots. A third type measures the drag of a small towed object. The accuracy of such devices depends to a large extent upon the refinements of design, manufacture, installation, maintenance, and calibration.

614. Impeller-type log.—An impeller-type log has a small propeller-driven alternating-current generator located near the outer end of a rodmeter which extends through a sea valve on the hull plating, and projects approximately two feet into the water. The propeller rotates as it moves through the water. The number of its revolutions is proportional to the distance traveled through the water, and its speed of rotation is proportional to the ship's speed. The output of the generator is amplified, and passed to the master indicator-transmitter, where the number of cycles, reduced by gearing, is recorded on mileage counter dials in units of 0.01 nautical mile. The frequency of the alternating current, being proportional to ship speed, is transmitted to a tachometer mechanism geared to the pointer of the speed indicator. Calibration is accomplished by adjusting the position of driving rollers along the radius of a driven disk.

The speed and distance indications of the master indicator can be transmitted to remote indicators. Speed indications of this equipment are accurate to approximately 0.15 knot at speeds between 0.25 knot and 25 knots.

615. Speed by engine revolution counter.—The number of turns of a propeller shaft is proportional to the distance traveled. If the element of time is added, speed can be determined. If the screw were advancing through a solid substance, the distance it would advance in one revolution would be the **pitch** of the screw. Thus, if a propeller having a pitch of ten feet turns at 200 revolutions per minute, it advances 2,000 feet in one minute, equivalent to a speed of 19.75 knots. It does not do so in water because of **slip**, the difference between the distance it would advance in a solid substance and actual distance traveled, expressed as a percentage of the former. For example, if slip is 18 percent, both the ship's speed and distance covered are reduced by this percentage. Thus, instead of 19.75 knots, the speed is only $19.75 \times 0.82 = 16.2$ knots.

Slip depends upon the type and speed of rotation of the propeller, the type of ship, the condition of loading and ship's bottom, the state of the sea and the ship's course relative to it, and the apparent wind. Despite the many variables, slip can be determined with sufficient accuracy for practical navigation. This is usually accomplished by steaming a known distance and noting the time of passage. The speed corresponding to the number of revolutions being used can then be determined by means of the formula of article 608, in the form

$$\text{speed}=\frac{\text{distance}}{\text{time}}$$

or by reference to table 18 (if the distance is exactly one mile). Thus, speed can be determined directly, without computing slip, and a table or curve of ship speed for various engine revolution speeds can be made. In determining speed in this manner, the average speed of two runs (one in each direction) should be used. The vessel should be on course and speed long enough to stabilize slip before starting each run. Any suitable distance can be used, but a distance of one nautical mile has been measured at various convenient locations. Each such **measured mile** is suitably marked on the beach, and shown on the chart, with the course to steer.

This method of determining speed is widely used in the merchant marine. By means of an **engine revolution counter** the number of revolutions during any suitable time interval can be measured. If a **tachometer** is available, the *rate* of shaft revolution is determined, usually in revolutions per minute. For best results, allowance should be made for condition of the bottom, draft and trim of the vessel, and the state of the sea.

Depth Measurement

616. Importance.—Accurate knowledge of the depth of water under a vessel is of such navigational importance that there is a legal requirement that American merchant vessels of 500 gross tons or more engaged in ocean and coastwise service "shall be fitted with an efficient mechanical deep-sea sounding apparatus in addition to the deep-sea hand leads."

617. The lead (lĕd) is a device consisting of a suitably marked line having a weight attached to one of its ends. It is used for measuring depth of water. Although the lead is probably the oldest of all navigational aids, it is still a highly useful device, particularly in periods of reduced visibility. Although its greatest service is generally in the shoal water near the shore, it sometimes can provide valuable information when the vessel is out of sight of land.

Two types of lead are in common use, the **hand lead,** weighing from 7 to 14 pounds and having a line marked to about 25 fathoms; and the **deep-sea (dipsey) lead,** weighing from 30 to 100 pounds and having a line marked to 100 fathoms or more in length. The markings commonly used on lead lines are as follows:

Distance from lead in fathoms	*Marking*	*Distance from lead in fathoms*	*Marking*
2	two strips of leather	20	short line with two knots
3	three strips of leather	25	short line with one knot
5	white rag (usually cotton)	30	short line with three knots
7	red rag (usually wool)	35	short line with one knot
10	leather with hole	40	short line with four knots
13	same as three fathoms	45	short line with one knot
15	same as five fathoms	50	short line with five knots
17	same as seven fathoms		etc.

Fathoms marked on the lead line are called **marks.** The intermediate whole fathoms are called **deeps.** In reporting depths it is customary to use these terms, as "by the mark five," "deep six," etc. The only fractions of a fathom usually reported are halves and quarters, the customary expressions being "and a half, eight," "less a quarter, four," etc. A practice sometimes followed is to place distinctive markings on the hand lead line at each foot near the critical depths of the vessel with which it is to be used. The markings should be placed on the lead line when it is wet, and the accuracy of the marking should be checked from time to time to detect any changes in the length of the line. The distance from the hand of the leadsman to the surface of the water under various conditions of loading should be determined so that correct allowance can be made when the marking nearest the surface cannot be observed.

The lead itself has a recess in its bottom. If this recess is filled with tallow or other suitable substance, a sample of the bottom can sometimes be obtained. This information can prove helpful in establishing the position of the vessel. If tallow is not available, some other substance can be used. Soap is suitable if it is replaced from time to time. When the recess is filled for obtaining a sample, the lead is said to be **armed** with the substance used.

618. The sounding machine, developed by William Thomson (Lord Kelvin) as a substitute for the deep-sea lead, provides means for obtaining approximate soundings to a depth of about 100 fathoms without slowing or stopping the vessel. This is accomplished by attaching a depth-registering device to the lead so that a vertical cast is unnecessary.

Several types of depth-registering device have been developed, all depending upon the increase of pressure with depth (art. 3008). The most common form is a slender glass tube coated on the inside with a chemical which changes color when contacted by sea water, or having a ground surface on the inside so that it appears white when dry and clear when wet. The chemical tube requires recoating after each sounding, but the ground glass tube can be used over and over again, if it is cleaned thoroughly and allowed to dry after each using. The top of the tube is closed. As the lead sinks, water is forced into the tube, compressing the entrapped air. The height to which the water rises is an indication of depth. The upper end of a ground glass tube is sealed with a cap which can be removed to facilitate cleaning and drying.

Errors are introduced if the inside diameter of the glass tube is not uniform throughout its length, if the chemical has deteriorated, or if salt is not washed out of the ground glass tube after use. Errors from these sources may be as much as 20 percent. If the indicated depth is too great, a dangerous situation exists. A slight error may be introduced by atmospheric pressure, but since the scale is calibrated for a lower-than-normal pressure, the usual error is on the side of safety. For usual pressures, readings are about three percent too little. If the temperature of the air is different from that of the sea, the entrapped air will expand or contract as it is immersed in the water, causing an error of about one percent for each 3° change of temperature. If the air is cooled, the indicated depth is too great. Error will also be introduced if the cap permits leakage of air.

A mechanical depth recorder is sometimes used. This consists essentially of a pointer which is attached to a piston forced against the tension of a spring as the water pressure increases. The pointer remains at the greatest depth reached, requiring resetting before the next sounding is made.

In critical areas, it is wise to check the readings of a sounding machine, or to use another method of sounding. If an echo sounder (art. 619) is not available, a check can be made by stopping the vessel, running out a measured length of sounding wire

(at least 50 fathoms if depth permits), and comparing this measured length with the indication of the depth-registering device.

619. Echo sounder.—Most soundings are now made by means of an **echo sounder.** This instrument produces an underwater sound-wave signal, and measures the elapsed time until return of an echo from the bottom. It is a form of **sonar** (art. 1108), although this term is usually applied only to similar equipment which directs the sound-wave signal horizontally to measure range. An echo sounder operating within the range of audible sound (about 20 to 20,000 cycles per second) may be called a **sonic depth finder.** One using sound waves of a higher frequency may be called an **ultrasonic depth finder.** The trend has been toward higher frequency, to reduce interference from ship noise.

FIGURE 619.—The indicator of an echo sounder.

There are many forms of echo sounder. In a typical installation (fig. 619) a light tube is mounted vertically behind an opaque shield which rotates at a predetermined speed. A narrow slot in the shield permits the light to be seen at one place only. This slot is under or adjacent to a circular scale graduated in depth. The sound-wave signal is transmitted when the slot is at the top or zero of the scale. At this instant, the light flashes. When an echo is received, the light again flashes. The graduation adjacent to the second flash indicates the depth. Several different scales may be available for use in various depths. The scale is controlled by adjusting the speed of rotation of the opaque shield. If the depth is greater than the maximum graduation of the scale in use, an erroneous reading may be obtained unless the operator is alert. Thus, if the maximum reading is 400 fathoms, and the depth of the water is 600 fathoms, the shield will make a complete rotation and half of another before the echo returns. The scale would indicate a reading of 200 fathoms. If allowance is made for the number of complete rotations, accurate soundings can be obtained at a relatively large scale. However, there is less possibility of error if the correct scale is used. Doubt as to the correct scale can be removed by switching to a smaller scale (greater depth), if one is available. In some models the light itself rotates. Some of the newer echo sounders are equipped with a recording device that produces a written trace of the bottom, called a **bottom profile** (fig. 4206a). This is accomplished by means of an arm which moves across a graduated tape, making one transit for each sounding. When the echo is received, a short line is produced on a moving tape graduated in time and depth units.

Echo sounders of American manufacture are calibrated for a speed of sound of 4,800 feet per second. The actual speed varies primarily with the temperature, pressure, and salinity, as discussed in article 3503, but in the ocean is nearly always faster than the speed of calibration. The error thus introduced is on the side of safety unless the water is fresh or very cold. Soundings shown on charts of the U. S. Navy Hydrographic Office are those obtained by an echo sounder without correction, and can therefore be compared directly with the readings obtained aboard ship since the variation in speed from mean conditions is not great. Only in precise scientific work should it be necessary to correct the readings for actual sound speed under prevailing conditions. Accurate adjustment can be made only if information is available on conditions at various depths.

Errors are sometimes introduced by false bottoms. If soft mud covers the ocean floor, some of the sound-wave energy may penetrate to a harder layer beneath, resulting in indication of two bottoms. It is not unusual in deep water to receive a strong return at a depth of about 200 fathoms during the day, and somewhat nearer the surface at night. This is called the **phantom bottom** or **deep scattering layer.** It is believed to be due to large numbers of tiny marine animals. Schools of fish return an echo sufficiently strong to make the echo sounder a valuable aid to commercial fishermen.

In modern equipment the sound waves, whether sonic or ultrasonic, are produced electrically by means of a **transducer,** a device for converting electrical energy to sound waves, or vice versa. The transducer utilizes either the piezo-electric properties of quartz or the magnetostriction properties of nickel and its alloys.

Early models produced sound signals by striking the ship's hull with a mechanical hammer in the forward part of the vessel. The echo was received by a microphone in the after part of the vessel, depth being determined by the angle at which the signal returned.

Direction Measurement

620. Reference directions.—A horizontal direction is generally expressed as an angle between a line extending in some **reference direction** and a line extending in the given direction. The angle is numerically equal to the difference between the two directions, called the **angular distance** from the reference direction. Unless the reference direction is stated or otherwise understood, the intended direction is in doubt. Thus, to a navigator, direction 135° is southeast. To an astronomer or surveyor, it may be northwest.

A number of reference directions are used in navigation. If a direction is stated in three figures, without designation of reference direction, it is generally understood that the direction is related to true (geographical) north. When grid navigation (art. 2510) is being used, particularly in high latitudes, grid north is generally used as the reference direction. The reference direction for magnetic directions is magnetic north, and that for compass directions is compass north. For relative bearings it is the heading of the ship. For amplitudes, the reference direction is east or west, usually 090° or 270° true, but magnetic, compass, or even grid east or west may be used. In maneuvering situations, the heading of another vessel might be used as the reference direction.

The primary function of an instrument used for measuring direction is to determine the reference direction. This having been done, other directions can be indicated by a compass rose oriented in the reference direction. North is established by some form of compass. A compass rose is attached to the north-seeking element so that other directions can be determined directly. However, if one always keeps in mind that the primary function of the instrument is to indicate a reference direction, he should be able to avoid some of the mistakes commonly made in the application of compass errors.

621. Desirable characteristics of a navigational compass.—To adequately serve its purpose, a navigational compass needs to have certain characteristics to permit it to meet requirements of accuracy, reliability, and convenience.

The most important characteristic is accuracy. No other quality, however important or to whatever extent it may be possessed, compensates for the lack of accuracy. This does not mean that the compass need be without error, but that such errors as it may possess can be readily determined. Provision should be made for removing deviation or reducing it to a minimum (ch. VII). If accurate horizontal directions are to be determined, the compass needs to be provided with some type of compass rose maintained in a horizontal position (art. 2903). Adequate sighting equipment is needed if bearings are to be observed, and an index is needed to mark the forward direction parallel to the keel if heading is to be measured. Accurate readings cannot be expected from a compass that **hunts** (oscillates) excessively. A characteristic closely related to accuracy is precision (art. O3). The amount of precision required varies somewhat with the use and depends as much upon the steadiness of the compass and its design as upon its inherent qualities.

A compass is reliable when its operation is not often interrupted; when its indications are relatively free from unknown or unsuspected disturbances; when it is little affected by extremes of temperature, moisture, vibration, or the shock of gunfire; and when it is not so sensitive that large errors are introduced by ordinary changes in conditions or equipment near the compass.

The value of a compass is dependent somewhat upon the convenience with which it can be used. Accuracy, too, may be involved. Thus, a compass should not be installed in such a position that one must be in an unnatural or uncomfortable position to use it. A compass intended for use in obtaining bearings is of reduced value if it is installed at a location that does not permit an unobstructed view in most directions. The compass graduations and index should be clean, adequately lighted if the instrument is to be used at night, and clearly marked.

622. Kinds of compasses.—The compasses commonly used by the mariner are (1) *magnetic* and (2) *gyroscopic.* The magnetic compass tends to align itself with the magnetic lines of force of the earth, while the gyro compass seeks the true (geographic) meridian. The word "compass" is also applied to instruments which do not continuously indicate some form of north. Thus, an aircraft directional gyro (art. 2803) tends to remain approximately aligned with any great circle to which it is set. An astro compass, sun compass, or sky compass (art. 2515) is used to determine the heading or other reference directly at any given moment, by means of celestial bodies.

A compass may be designated to indicate its principal use, as a **standard, steering,** or **boat compass.** The compass designated as standard is usually a magnetic compass installed in an exposed position having an unobstructed view in most directions, permitting accurate determination of error. Preferably, it is located at a magnetically favorable position near the bridge. Before the development of a reliable gyro compass, the standard compass was used for navigation of the vessel and for determining the error of the steering compass.

Although the modern, reliable gyro compass has largely superseded the magnetic compass for most purposes, directional information is so important to a vessel that the availability of a second method is considered justified. It is wise to understand both types, keep a record of errors and the performance of all compasses, and to compare the indications of magnetic and gyro compasses at frequent intervals, as every half hour when underway.

623. Magnetic compasses.—If a small magnet is pivoted at its center of gravity in such manner that it is free to turn and dip, it will tend to align itself with the magnetic

field of the earth (art. 706). It thus provides a directional reference and becomes a simple compass. However, such a compass would not be adequate for use aboard ship. For this purpose a compass should have a stronger directive element than that provided by a single, pivoted magnet, should have provision for measuring various directions, should have some means of damping the oscillations of the directive element, should be approximately horizontal, and should have some means of neutralizing local magnetic influences.

In a mariner's compass, several magnets are mounted parallel to each other. To them is attached a **compass card** having a compass rose to indicate various directions (art. 624). Both magnets and compass card are enclosed in a bowl having a glass top through which the card can be seen. The bowl is weighted at the bottom and is suspended in gimbals in such manner that it remains nearly horizontal as the vessel rolls and pitches. In nearly all modern compasses the bowl is filled with a liquid that supplies a buoyant force almost equal to the force of gravity acting upon the directive element and card. This reduces the friction on the pivot (a metal point in a jeweled bearing), and provides a means of damping the oscillations of the compass card. The card is mounted in such manner as to remain in an essentially horizontal position. A mark called a **lubber's line** is placed on the inner surface of the bowl, adjacent to the compass card, to indicate the forward direction parallel to the keel when the bowl is correctly installed. The gimbals used for mounting the compass bowl are attached to a stand called a **binnacle,** which in most installations is permanently and rigidly attached to the deck of the vessel, usually on its longitudinal center line. Most binnacles provide means for neutralization of local magnetic influences due to magnetism within the vessel. A cover or "hood" is provided to protect the compass from the elements, dust, etc.

Directional information is of such importance that selection and installation of a suitable compass should be made carefully, seeking such guidance as may be needed. In the U. S. Navy this is covered by Bureau of Ships' directives. For merchant vessels and yachts, one would do well to consult a dependable compass adjustor before selecting and installing a compass or making any alteration in the vicinity of the compass. Common errors are the use of a compass designed for a different type craft (as an aircraft compass in a boat), permitting chrome plating of a binnacle by someone who does not know how to do this without creating a magnetic field, authorizing electric welding of steel near the compass, improper installation of magnetic equipment or electric appliances near the compass, allowing short circuits to occur in the vicinity of the compass, etc.

After the compass has been selected and installed, proper adjustment and compensation (ch. VII) are important, and future care of the instrument should not be neglected. It should be checked and overhauled at regular intervals, and any indication of malfunctioning or deterioration, however slight, should not be overlooked. Discoloration of the liquid or the presence of a bubble, for instance, indicates a condition that should be investigated and corrected at once. If it becomes necessary to add liquid, one should be certain that he has the correct substance, and should attempt to determine the source of the leak. Except as a temporary expedient, this is best done by a professional. Some compasses should be protected from prolonged exposure to sunlight, to prevent discoloration of the card and liquid.

If a vessel is to be inactive for a long period of time—at least several months—it is good practice to remove the magnetic compass from its binnacle and store it in a place relatively free from magnetic influences, and of approximately even temperature. Unless instructions indicate otherwise, the compass should be stored upside down, to remove the weight from the pivot, and prevent the card from swinging.

624. The compass card is composed of light, nonmagnetic material. In nearly all modern compasses the card is graduated in 360°, increasing clockwise from north through east, south, and west. An older system still used somewhat is to graduate the card through 90° in each quadrant, increasing from both north and south. Some compass cards are graduated in "points," usually in addition to the degree graduations. There are 32 **points of the compass,** 11¼° apart. The four **cardinal points** are north, east, south, and west. Midway between these are four **intercardinal points** at northeast, southeast, southwest, and northwest. These eight points are the only ones appearing on the cards of compasses used by the U. S. Navy. The eight points between cardinal and intercardinal points are named for the two directions between which they lie, the cardinal name being given first, as north northeast, east northeast, east southeast, etc. The remaining 16 points are named for the nearest cardinal or intercardinal point "by" the next cardinal point in the direction of measurement, as north by east, northeast by north, etc. Smaller graduations are provided by dividing each point into four "quarter points," thus producing 128 graduations altogether. There are several systems of naming the quarter points. That used in the U. S. Navy when quarter points were used is given in table 2.

The naming of the various graduations of the compass card in order is called **boxing the compass,** an important attainment by the student mariner of earlier generations. The point system of indicating relative bearings (art. 904) survived long after degrees became almost universally used for compass and true directions. Except for the cardinal and intercardinal points, and occasionally the two-point graduations, all of which are used to indicate directions generally (as "northwest winds," meaning winds from a general northwesterly direction), the point system has become largely historical.

625. The U. S. Navy 7½-inch compass has a liquid-filled bowl in which a 7½-inch aluminum card is pivoted. There is provision for either one or two pairs of magnets, symmetrically placed. The card and magnet assembly is provided with a central float or air chamber to reduce the weight on the pivot to between 60 and 90 grains (0.14 and 0.21 oz.) at 60° F when the correct compass fluid is used. Older compasses use a fluid consisting of 45 percent ethyl alcohol and 55 percent distilled water. Newer compasses use a highly refined petroleum distillate similar to varsol. Use of this oil increases the stability and efficiency of the compass. A hollow cone extends into the underside of the float. The bottom of this cone is open. The pointed top has a jewel bearing of synthetic sapphire. The card-float-magnet assembly rests on an osmium-iridium tipped pivot at the jewel center. This pivot extends upward from the bottom of the bowl. This compass is illustrated in figure 625.

The compass bowl is made of cast bronze, and has a tightly gasketed glass top cover to prevent leakage of the liquid. A bellows-type expansion chamber is provided to allow for changes in volume of the liquid as the temperature changes. The top rim or bezel of the bowl is accurately machined so that an azimuth or bearing circle can be placed over it. The compass is equipped with a gimbal ring for keeping the compass level when mounted in a binnacle. In addition to providing support for the compass, the binnacle has provision for housing the correctors used to neutralize local magnetic effects within the vessel.

626. The U. S. Navy six-inch compass is a newly developed instrument which differs in a number of respects from older magnetic compasses. It is lighter in weight, requires less space, and is expected to prove more reliable with less maintenance than the 7½-inch compass. The six-inch diameter card is of magnesium foil, strengthened by concentric and radial ribs. This card and the small, powerful Alnico V magnets are sufficiently light in weight that a float is unnecessary. An osmium-tipped pivot

attached to the underside of the card, at its center, rests on a concave synthetic sapphire jewel in the top of a spindle attached to the bottom of the compass bowl. Expansion of the liquid, an oil similar to varsol, is taken care of by a bubble-trap type expansion chamber. This chamber is in the form of a cylinder surrounding the card area and connected to it by a single, small opening at the bottom. The top half, approximately, of the expansion chamber is filled with air which is compressed as the liquid expands. As the liquid contracts, the trapped air pushes more of it into the card area. This arrangement eliminates the need for the troublesome bellows of older compasses. The light for illuminating the compass card and lubber's line is housed at the bottom of the compass. Its intensity can be adjusted by a rheostat at the base of the binnacle.

Both the binnacle and pedestal upon which it stands are of cast aluminum. The binnacle has provision for neutralizing the effects of the magnetism within the vessel,

Figure 625.—U. S. Navy 7½-inch compass.

and the pedestal houses electrical coils and resistor panels for reducing or eliminating the magnetic effects introduced by degaussing (ch. VII). The soft iron correctors (ch. VII), both quadrantal and Flinders bar, are thin-walled tubes supported in aluminum spacers with heavier aluminum housings bracketed to the outer wall of the binnacle. The quadrantal correctors can be slewed to reduce E error (ch. VII). Provision is made for mounting the Flinders bar on either the forward or after side of the compass.

627. Other magnetic compasses.—In addition to the 7½-inch and 6-inch compasses, the U. S. Navy has a five-inch alcohol-and-water filled compass, and two three-inch varsol-filled compasses. One of the three-inch compasses is top-reading like the larger compasses, and the other has the graduations on the side of the beveled outer edge of the card, so that the reading can be made through a window on the after side of the compass bowl, in a manner similar to the reading of an aircraft compass mounted on an instrument panel.

A wide variety of magnetic compasses are used in merchant ships and yachts. The basic principles of operation of all magnetic compasses are the same, the various

types differing only in details of construction. A feature which is widely used in commercial compasses is a hemispherical top (fig. 627) which provides magnification of the graduations.

An older type which is now rarely encountered is the **dry compass,** so called because it does not have a liquid-filled bowl. A typical dry compass has a card of strong paper, with the central part cut away and the outer edge stiffened by a thin aluminum ring. The weight of the paper card is sustained by 32 radial silk threads. Eight small, magnetized steel needles are suspended by silk threads from the aluminum ring.

FIGURE 627.—A compass with a hemispherical top.

628. Magnetic compass limitations.—Because of its essential simplicity, a magnetic compass does not easily become totally inoperative. Being independent of any power supply or other service, a magnetic compass may survive major damage to its ship without losing its utility. Small boat compasses often remain serviceable under the most rigorous conditions.

Despite its great reliability, however, a magnetic compass is subject to some limitations. Since it responds to *any* magnetic field, it is affected by any change in the local magnetic situation. Hence, the undetected presence or change of position of magnetic material near the compass may introduce an unknown error. Thus, an error might be introduced by a steel wrench or paint can left near the compass, or by a change in position of a steel boom or gun in the vicinity of the compass. Even such small amounts of magnetic material as might be included in a pocketknife or steel keys are sufficient to affect the compass if brought as close as they are when on the person of an individual standing by a compass. Nylon clothing may also introduce error in a magnetic compass. As distance from the compass increases, the strength of the magnetic field needed to introduce an error increases. A cargo of large amounts of iron or steel may be sufficient to affect the compass. The compass may also be affected by changes of the magnetic characteristics of the vessel itself. Such changes may occur during a protracted docking period, during a long sea voyage on substantially the same course, when repairs or changes of equipment are made, if the ship sustains heavy shock as by gunfire or riding out a heavy sea, if the vessel is struck by lightning, or if a short circuit occurs near the compass.

The directive force acting upon a magnetic compass is the horizontal component of the earth's magnetic field. This component is strongest at or near the magnetic equator, decreasing to zero at the magnetic poles (ch. VII). Near the magnetic poles, therefore, the magnetic compass is useless (art. 2513), and in a wider area its indications are of questionable reliability. The magnetic field of the earth has a number of local anomalies due to the presence of magnetic material within the earth. During magnetic

storms (art. 2526) it may be altered considerably. Changes in the magnetic field surrounding a vessel, due either to changes of the field itself or to change of position of the vessel within the field, affect the magnetism of the vessel and the correctors used to neutralize this effect, with a possible disturbance of the balance set up between them.

For these and other reasons, frequent determination of compass error is necessary for safe navigation. Methods of determining and correcting compass error are discussed in chapter VII.

629. Magnetic compass accessories.—Compass heading is indicated by the lubber's line. Compass bearings may be measured by sighting across the compass, bringing the object and the vertical axis of the compass in line. Accuracy in making this alignment is increased by the use of a device to direct the line of sight across the center of the compass. Perhaps the simplest device of this kind is a **bearing bar,** consisting of two vertical **sighting vanes** mounted at opposite ends of a horizontal bar having a small pivot which fits into a hole drilled part way through the glass cover of the compass, at its center. The "near" vane (nearer the eye of the observer) has a very thin, open, vertical slot through which the line of sight is directed; the "far" vane has a thin, vertical wire or thread mounted on a suitable frame. The bar is rotated until the object is in line with the two vanes. The bearing is the reading of the compass in line with the vanes, on the far side from the observer. If a reflecting surface is pivoted to the far vane to permit observation of the azimuth (art. 1428) of a celestial body, the device is called an **azimuth instrument.** Bearing bars and azimuth instruments are usually used only with smaller compasses, and never with an after-reading compass (art. 627).

Larger compasses or repeaters (art. 641) are usually provided with a **bearing circle** or **azimuth circle** (fig. 629). These devices take a variety of forms, but consist essentially of two parts: (1) a pair of sighting vanes attached to a ring which fits snugly over the compass, and (2) a mirror to reflect the compass graduation into the line of sight. The use of these devices is similar to that of the bearing bar and azimuth instrument. The azimuth circle has a pivoted reflecting surface attached to the far vane, to permit observation of celestial bodies. In most cases it also has a reflecting mirror and prism mounted on opposite sides of the ring, midway between the vanes. The prism is covered with opaque material except for a thin, vertical slot at its center. The surface of the mirror is curved so that reflection of sunlight falling upon it is in the form of a slender vertical line (at the distance of the prism) of about the same width as the slot. When the azimuth circle is adjusted so that this line of light falls upon the slot, a thin, bright line appears on the compass card graduations at the bearing of the sun. Most bearing and azimuth circles are provided with reverse compass rose graduations to permit reading of relative bearings or azimuths (by the vanes) at a mark on top of the compass bowl, in line with the lubber's line; bubbles for indicating the level position during observation; means for adjusting the snugness of the fit over the compass bowl; and handles for turning the device.

If a bearing or azimuth circle does not fit snugly over the compass bowl, an error might be introduced. Inaccuracy may also result from tilting of the reflecting surface of an azimuth circle with respect to the vertical plane through the line of sight. This can be checked by comparing an azimuth of the sun observed by means of the prism with one observed with the sighting vanes (with suitable protection being provided for the eyes). If the prism attachment is not available, a check can be made by comparing observed (compass) azimuths at different altitudes with computed (true) values at the time of observation. If both observed and computed azimuths are correct, the difference between them will be constant (if the compass error remains constant throughout the observation).

FIGURE 629.—An azimuth circle.

None of the bearing or azimuth instruments described above can be used with a compass not designed for it, as one having a hemispherical top, or an after-reading compass.

Some modern magnetic compasses are provided with electrical pick-offs of sufficient sensitivity that the instrument can be used to control such devices as remote indicators, automatic steering equipment, course recorders, and dead reckoning equipment without disturbing the reliability of the compass. However, these devices are more commonly controlled by a gyro compass and hence are considered later in the chapter, after a discussion of this type compass.

630. The gyroscope.—Leon Foucault, a French physicist, first demonstrated the rotation of the earth by means of a pendulum. However, the pendulum was not entirely acceptable as proof of rotation because it required the earth's gravity for operation. In 1852, he gave the name **gyroscope** to a toy top which had been known for a quarter of a century as a "rotascope." By means of the gyroscope, Foucault illustrated the earth's rotation without the use of gravity.

A conventional gyroscope consists of a comparatively massive, wheel-like rotor balanced in gimbals which permit rotation in any direction about three mutually perpendicular axes through the center of gravity. The three axes are called the **spin axis,** the **torque axis,** and the **precession axis,** as shown in figure 630.

Since the rapidly spinning rotor is balanced at its center of gravity, it is in a state

of neutral rotational equilibrium. If the gimbal bearings were completely frictionless, the spin axis would retain its direction in space despite any motion applied to the system as a whole, as by the rotation of the earth. This property is called **gyroscopic inertia.** Thus, if the spin axis were directed toward a star, the axis would continue to point toward the star during its apparent motion across the sky. To an observer on the earth, the spin axis would appear to change direction as the earth rotated eastward. If the spin axis were placed parallel to the earth's axis, the earth's rotation would have no effect and the device would become a kind of compass, since the spin axis would be in the plane of a meridian. However, such a device would require frictionless bearings and perfect balance. Even if these obstacles could be overcome, the device would not be suitable as a compass because it would not be *north-seeking.*

The method by which a gyroscope is made to *seek* north involves the surprising behavior exhibited by any rotating mass, when a force is applied which tends to change the *direction* in space of the spin axis. The motion resulting from such a force is not in line with the force, as might be expected, but *perpendicular* to it. This property is called **gyroscopic precession.**

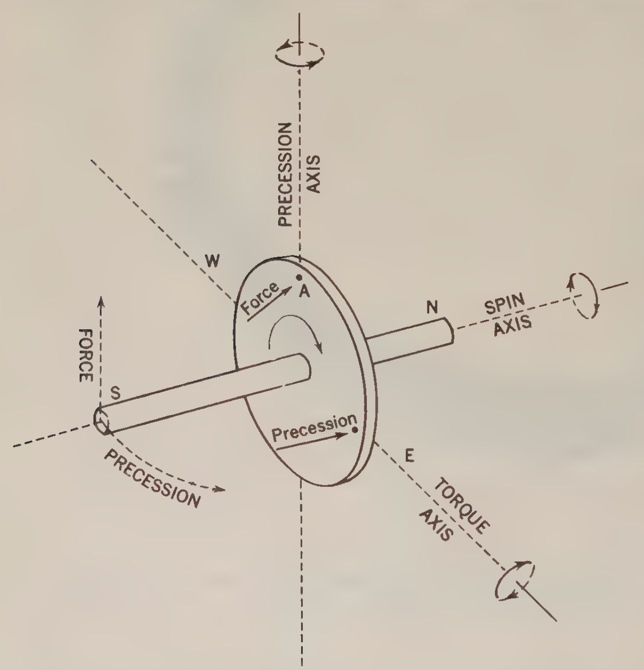

FIGURE 630.—Axes of a gyroscope, and the direction of precession.

Refer to figure 630 and suppose that the torque and spin axes are horizontal, that the spin axis is directed north and south, and that the rotation about the spin axis is clockwise, looking north. If a force is applied to the rotor at A tending to raise the south end of the spin axis, the south end, if free to move, will turn or "precess" to the east, as shown. The direction of precession is such that it appears as though a force applied to the rotor at A is, instead, applied at a point *90° away in the direction of spin* from point A. Precession tends to move the plane *and direction* of rotation of the gyroscope into alignment with the force applied to the rotor. If precession is prevented, as by restraining motion of the spin axis, this axis will rotate in the direction of the applied force, as if the rotor were not spinning. Thus, in figure 630, a force applied to the rotor at A causes the south end of the spin axis to rise. The reason for this is that if precession is blocked, the force thus introduced causes precession in the direction of the original force. This effect is used to stabilize some types of gyro compasses and avoid cumulative errors due to rolling while the vessel is on intercardinal headings.

A recently developed gyroscope called a **Gyrotron vibratory gyro** uses a vibrating mass instead of a rotating one. It is based upon the same principle used in the halteres of certain two-winged insects, such as the common housefly, to give them the sensing needed to achieve stability in flight. Instead of a single vibrating reed, the vibratory gyro uses a two-pronged device similar to a tuning fork. The vibratory gyro has no bearings, and so is free from the errors introduced by bearing friction. It is a rugged

device having long life and requiring little attention. Its most promising application is for measurement of rate of turn, which it performs more accurately than a rotating gyro, and over a wide range from a rate of as little as one or two degrees per hour to 100 revolutions or more per minute. The Gyrotron vibratory gyro has a number of possible applications to navigation.

631. The gyro compass.—A gyro compass is essentially one or more north-seeking gyroscopes with a suitable compass rose, housing, etc.

One method of utilizing precession to cause a gyroscope to seek north is illustrated in figure 631a. Two reservoirs connected by a tube are attached to the bottom of the case enclosing the gyro rotor, with one reservoir north of the rotor and the other south of it. The reservoirs are filled with mercury to such a level that the weight below the spin axis is equal to the weight above it, so that the gyroscope is nonpendulus. The system of reservoirs and connecting tubes is called a **mercury ballistic.** In practice, there are usually four symmetrically placed reservoirs.

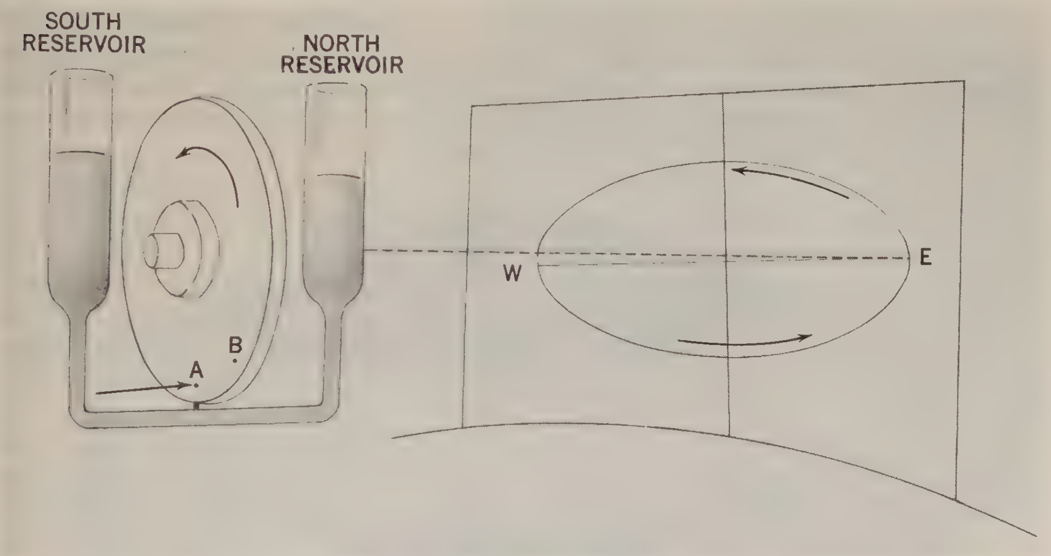

FIGURE 631a.—The mercury ballistic (left) and the elliptical path (right) of the axis of spin without damping.

Suppose that the spin axis is horizontal but is directed to the eastward of north. As the earth rotates eastward on its axis, the spin axis tends to maintain its direction in space; that is, it appears to follow a point, such as a star rising in the northeastern sky. With respect to the earth, the north reservoir rises and some of the mercury flows under the force of gravity into the south reservoir. The south side becomes heavier than the north side, and a force is applied to the bottom of the rotor case at point A. If the gyro rotor is spinning in the direction shown, the north end of the spin axis precesses slowly to the westward, following an elliptical path. When it reaches the meridian, upward tilt reaches a maximum. Precession continues, so that the axis is carried past the meridian and commences to sink as the earth continues to rotate. When the sinking has continued to the point where the axis is horizontal again, the excess mercury has returned to the north reservoir and precession stops. As sinking continues, due to continued rotation of the earth, an excess of mercury accumulates in the north reservoir, thus reversing the direction of precession and causing the spin axis to return slowly to its original position with respect to the earth, following the path shown at the right of figure 631a. One circuit of the ellipse requires about 84 minutes.

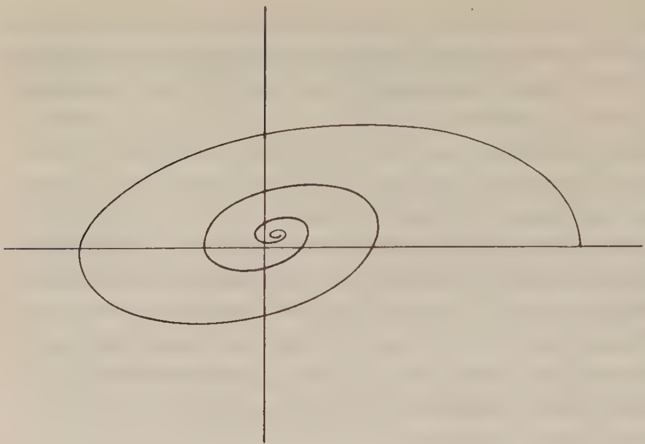

FIGURE 631b.—Spiral path of the axis of spin with damping.

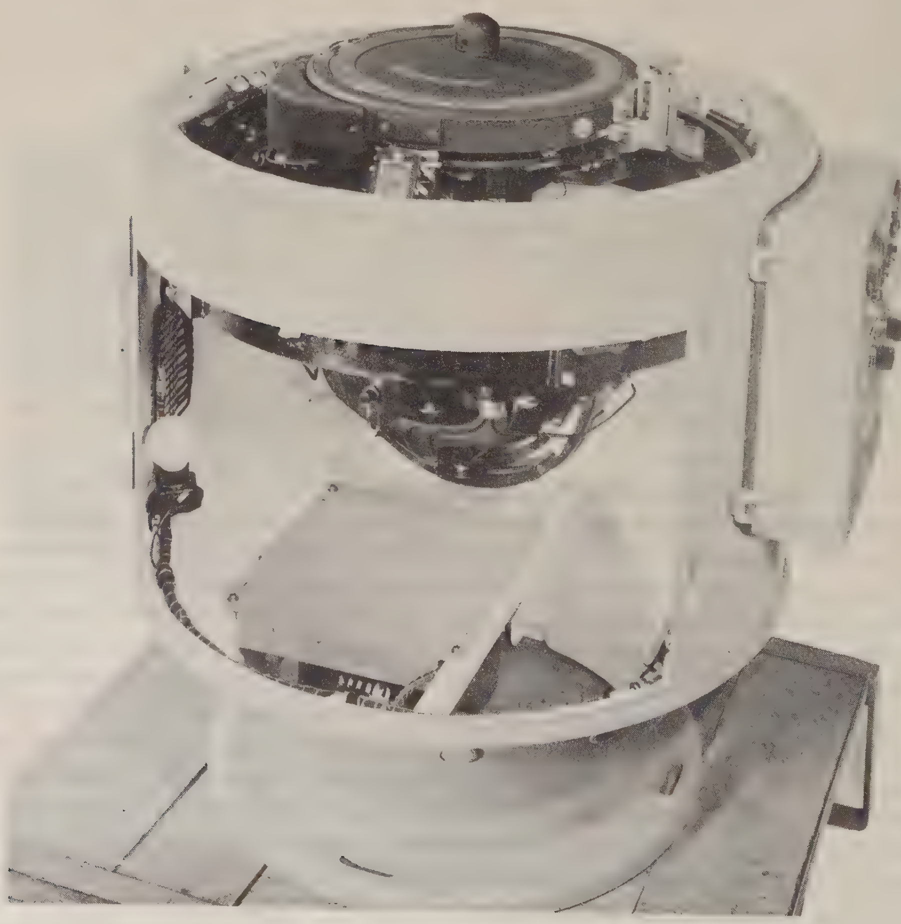
The elliptical path is symmetrical with respect to the meridian, and, neglecting friction, would be retraced indefinitely, unless some method of damping the oscillation were found. One method is by offsetting the point of application of the force from the mercury ballistic. Thus, if the force is applied not in the vertical plane, but at a point to the eastward of it, as at *B* in figure 631a, the resulting precession causes the spin axis to trace a spiral path as shown in figure 631b, and eventually to settle near the meridian. The gyroscope is now north-seeking and can be used as a compass. Some compasses are provided with means for automatically moving the point of application to the center line during a large change of course or speed, to avoid introduction of a temporary error.



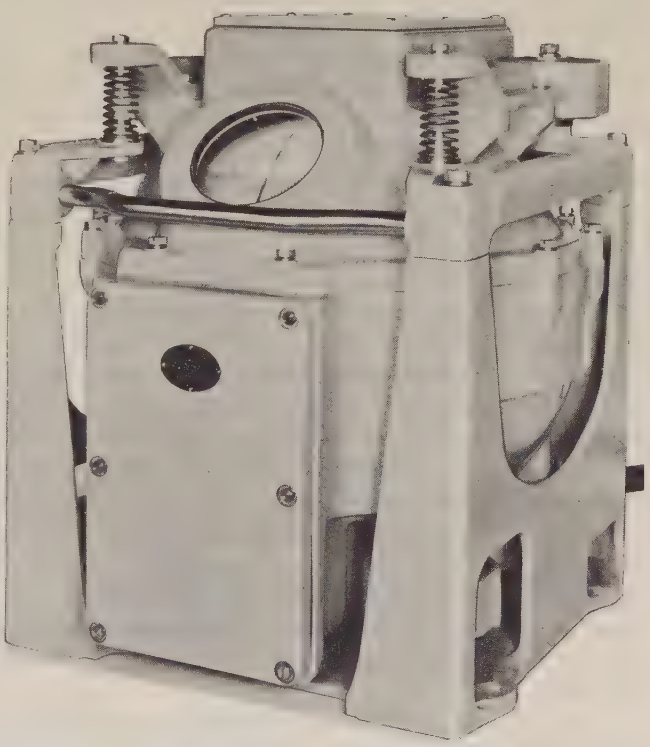
Courtesy of the Sperry Gyroscope Co.

FIGURE 631c.—The Mark 14 Mod 2 gyro compass.

Another method of damping the oscillations caused by the rotation of the earth is to reduce the precessing force of a pendulous gyro as the spin axis approaches the meridian. One way of accomplishing this is to cause oil to flow from one damping tank to another in such a manner as to counteract some of the tendency of an offset pendulous weight to cause precession. Oscillations are completely damped out in approximately one and one-half swings.

Details of construction differ considerably in the various compasses. Each instrument is provided with a manual giving such information and operating instructions. Figure 631c illustrates the Mark 14, Mod 2 gyro compass, a type that is widely used in the U. S. Navy and the merchant marine. The Mark 23 Mod 0 gyro compass, illustrated in figure 631d, is a much smaller compass recently developed in accordance with U. S. Navy specifications to provide an instrument that can be used in vessels of many types.

632. Desirable characteristics of the gyro compass.—Since a gyro compass is not affected by a magnetic field, it is not subject to magnetic compass errors (ch. VII), nor is it useless near the earth's magnetic poles. If an error is present, it is the same on all headings, and no table of corrections is needed. The directive force is sufficiently strong to permit directional pick-off for use in remote-indicating repeaters, automatic steering, dead reckoning and fire-control equipment, course recorders, etc.



Courtesy of the Sperry Gyroscope Co.

FIGURE 631d.—The Mark 23 Mod 0 gyro compass.

633. Undesirable characteristics of the gyro compass.—A gyro compass is dependent upon a source of suitable electric power.

If operation of the compass is interrupted long enough to permit uncertainty in its indications, a considerable period (as much as four hours for some gyro compasses) may be needed for it to settle on the meridian after it reaches operating speed. This period can be reduced by orienting the compass in the proper direction before it is started. If this is not practicable, the settling period can be hastened by leveling the compass when it reaches the meridian (one-fourth of a cycle or 21 minutes after starting at maximum deflection) or by leveling *and* precessing the gyro to the approximate meridian after its direction and rate of precession are observed for several minutes. Either process may need to be repeated several times and followed by a settling period.

The gyro compass is subject to certain errors requiring applications of corrections, either manually or automatically (art. 634).

The compass is an intricate mechanism of many parts. Thus, it requires some maintenance. In heavy seas a gyro compass may become unreliable unless certain

features are included in the design—features which are generally omitted from the smaller, simpler compasses.

The directive force of a gyro compass decreases with latitude, being maximum at the equator and zero at the geographical poles. The compass remains usable at all latitudes thus far attained by surface vessels, except those which have become beset and drifted with the ice across the Arctic Ocean. The use of the gyro compass in high latitudes is discussed in articles 640 and 2514.

A gyro compass has generally been considered unsuitable for use in aircraft because of its weight and the question of whether it will operate at the high speeds (approaching or exceeding that of rotation of the earth) and accelerations to which it would be subjected in aircraft. A gyro compasss weighing only nine pounds has been developed for use in small craft. A light compass designed for use in aircraft is being developed and evaluated.

634. Gyro compass errors.—Gyro compasses are subject to several systematic errors (art. 2903). Some of these can be eliminated or offset in the design of the compass, while others require manual adjustment for their correction.

The total combined error (the resultant error) at any time is called **gyro error (GE)**, which is expressed in degrees east or west to indicate the direction in which the axis of the compass is offset from true north. If the gyro error is east, the readings are too low; and if it is west, they are too high. Thus, if GE is 1° W, 1° is subtracted from all readings of the compass, either headings or bearings, to determine the equivalent true directions. One degree is added to all true directions to determine the equivalent gyro directions. The gyro error of modern compasses is generally so small that it can be ignored for practical navigation. However, significant errors can be introduced in several ways, and it is good practice to compare the gyro heading with the magnetic heading at frequent intervals (as every half hour and after each change of course) and to check the accuracy of the gyro compass by celestial observation or landmarks from time to time (as every morning and afternoon when means are available).

The errors generally associated with the gyro compass are speed error, damping error, ballistic deflection error, quadrantal error, and gimballing error. In addition, gyro compasses are subject to the errors common to directional instruments, such as those introduced by inaccurate graduation of the compass rose or incorrectly located lubber's line. Error may also be introduced, of course, by malfunctioning of the compass.

635. Speed error is introduced by motion of the vessel along its track. Refer to figure 635a. If a vessel is at anchor at any point *A*, it is being carried eastward by rotation of the earth at the rate of 902.46 minutes of longitude per hour (with respect to the stars). In terms of knots, this is equal to 902.46 times the cosine of the latitude, approximately. Because of the ellipticity of the earth, the actual value is a little more than this in low latitudes, and a little less in high latitudes. The actual value at any latitude can be found by multiplying the length of a degree of longitude at that latitude (from table 6) by $\frac{902.46}{60}=15.041$.

This eastward motion due to rotation of the earth is shown in figure 635a by the vector *AB*. The north-south axis of the gyro compass settles in a direction 90° from the direction of motion. Therefore, if the vessel is stationary with respect to the earth, 0° on the compass card coincides with a true meridian, and no error is introduced. This is also true if the vessel is moving due east or due west. In this case the speed of the ship over the surface of the earth is added to or subtracted from the motion due to rotation of the earth, but the direction of motion is unchanged (unless the speed of the vessel is

greater than the rotational speed of the earth, and in the opposite direction). The only effect, therefore, is to strengthen or weaken the directive force, usually by a small amount.

If the vessel is on course north or south, as shown by the vector AC in figure 635a, the motion in space is tilted toward the north or south of due east. In this case, it is the vector sum (art. O18) of the motion due to rotation of the earth and the velocity of the vessel over the surface of the earth, or AD in figure 635a. Since AD is not due east, the perpendicular to it does not lie in the true meridian, but at some angle δ to it, along AM_v. Since the axis of the gyro lies along AM_v, the "virtual meridian," the angle is the error introduced by the motion of the vessel along its track. Since AD is perpendicular to AM_v, and AB is perpendicular to AC, angle BAD is equal to angle δ. Therefore, the angle δ can be found by the formula

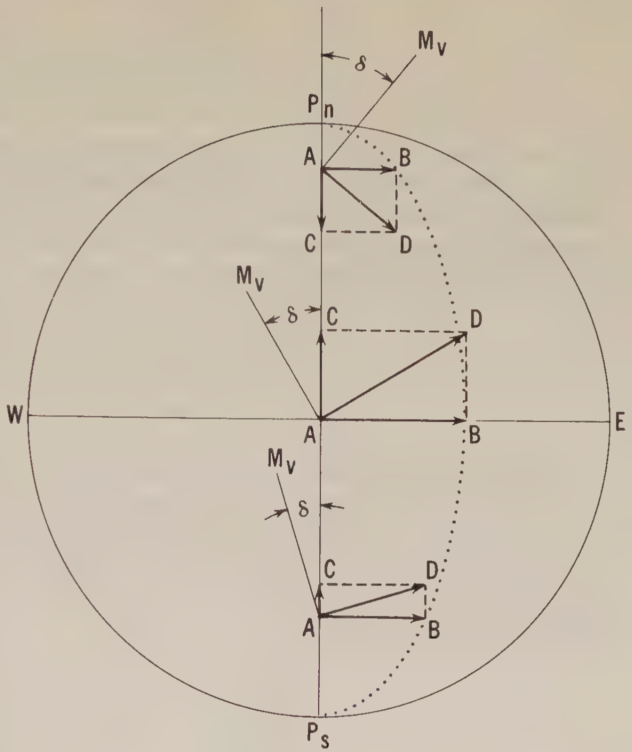


FIGURE 635a.—Speed error.

$$\tan \delta = \frac{AC}{AB}.$$

Since AC is the speed of the vessel and AB is 902.46 cos L, approximately, the formula can be written

$$\tan \delta = \frac{S}{902.46 \cos L}$$

where S is the speed and L the latitude of the vessel.

If the course of the vessel is not a cardinal direction, the resultant is still the vector sum of the two speed vectors, and can be found graphically or by computation. One method is to resolve the vessel's speed vector into two components, as shown in figure 635b, obtaining the N–S component along the true meridian, and the E–W component in the direction of rotation of the earth. The N–S component is equal to S cos C, and the E–W component to S sin C, where C is the true course angle. The total N–S motion is then S cos C. The total easterly motion is that due to rotation of the earth plus or minus the E–W component of the ship's speed across the surface of the earth, or 902.46 cos L±S sin C, approximately. The term S sin C is positive (+) for easterly courses and negative (−) for westerly courses. The formula for finding δ now becomes

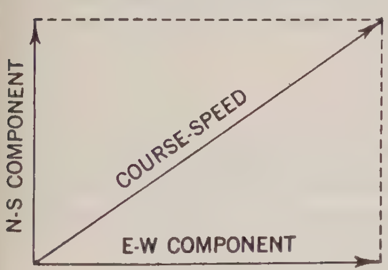

FIGURE 635b.—Components of vessel's motion.

$$\tan \delta=\frac{S \cos C}{902.46 \cos L \pm S \sin C} \text{ (approximately).}$$

At ship speeds in latitudes less than 70°, the term S sin C is much smaller than 902.46 cos L and has so little effect upon the answer that it can be ignored. The angle δ is small enough that its tangent can be considered the angle itself (expressed in radians). That is, a tangent to a circle can be considered of the same length as an arc of the circle over a short distance from the point of tangency. Therefore, the formula for δ can be written

$$\delta=\frac{57.3 \text{ S} \cos C}{902.46 \cos L}$$

or

$$\delta=0.0635 \text{ S} \cos C \sec L.$$

As shown in this formula, the speed error δ is affected by the three variables, speed, course, and latitude. If the course has a northerly component, the error is westerly; and if it has a southerly component, the error is easterly.

Example.—A ship at latitude 30° N is steaming on true course 045°, at a speed of 20 knots.

Required.—Speed error.

Solution.—

0.0635	log	8. 80277
S 20 kn.	log	1. 30103
C N45° E	*l* cos	9. 84949
L 30° N	*l* sec	10. 06247
δ 1°.04 W	log	10. 01576

Answer.— δ 1°.04 W.

In most gyro compasses this error is corrected mechanically. Speed and latitude are set in by hand, and the cosine of the course is introduced automatically by means of a "cosine cam" running in an eccentric groove on the underside of the azimuth gear. In some compasses these corrections combine to offset the lubber's line by the correct amount. Small changes in speed or latitude have relatively little effect upon the result. Therefore, in normal operations, infrequent changes are sufficient for satisfactory results. If no provision is made for mechanically applying this correction, a table or curves can be used to indicate the correction to be applied mathematically to readings of the compass. These are made up from the formula given above, and are entered with the speed, course, and latitude (art. 640).

636. Damping error applies only to those gyro compasses in which damping is accomplished by offsetting the point of application of the force from a mercury ballistic (art. 631). For this reason it is sometimes called **ballistic damping error.** It can be found from the equation

$$\alpha=r \tan L$$

in which α is the damping error, r is the angle between the vertical through the spin axis of the gyro rotor and a line through this axis and the point of application of the force from the mercury ballistic (1°.7 for Sperry compasses), and L is the latitude. The error is easterly in north latitude and westerly in south latitude.

Example.—A gyro compass having a value of r of 1°.7 is at latitude 50° N.

Required.—The damping error.

Solution.—

$$\alpha = r \tan L$$
$$= 1^\circ 7 \times 1.1918$$
$$= 2^\circ 03 \text{ E}$$

Answer.—$\alpha = 2^\circ 03$ E.

As in the case of speed error, provision is made in most compasses (to which it applies) for correcting this error. An auxiliary latitude-correction scale is provided for this purpose. In some compasses this offsets the lubber's line. In others, it alters the position of a small weight attached to the casing near one end of the axle. The first method is preferable because it is unaffected by changes of gyro speed of rotation.

If this error is not corrected mechanically, it can be combined algebraically with speed error and a single set of tables or graphs made up. This is a method sometimes used in polar regions, beyond the scale of the latitude corrections (arts. 640, 2514).

637. Ballistic deflection error.—When the north-south component of the speed changes, an accelerating force acts upon the compass, causing a surge of mercury from one part of the system to another, or a deflection (along the meridian) of the mass of a pendulous compass. In either case, this is called **ballistic deflection.** It results in a precessing force which introduces a temporary **ballistic deflection error** in the readings of the compass unless it is corrected.

A change of course or speed also results in a change in the speed error, and unless the correcting mechanism responds promptly to this change, a temporary error from this source is also introduced. The sign of this error is opposite that of the ballistic deflection, and so the two tend to cancel each other. If they are of equal magnitude and equal duration, the cancellation is complete and the compass responds immediately and automatically to changes of speed error. This can be accomplished by designing the compass so that

$$\frac{B}{H} = 0.0211 \sec L$$

in which B is the pendulous moment of a pendulous compass and the couple per unit angle applied by a mercury ballistic, H is the angular momentum of the gyro rotor, and L is the latitude.

It is customary to design a gyro compass so that the ratio $\frac{B}{H}$ is correct for some particular latitude (as 41° or 45°) and accept the small residual error that is temporarily present at other latitudes. This is satisfactory for vessels which remain within relatively narrow limits of latitude, or which are seldom subjected to large accelerating forces. However, where these conditions are not met, provision is made for varying the ratio with latitude. In a compass having a mercury ballistic, this is customarily accomplished by moving the mercury reservoirs radially toward or away from the center of the compass, thus altering the value of B. In a pendulous gyro, the value of H is changed by altering the rotational speed of the gyro.

When the ratio $\frac{B}{H}$ is as given in the equation above, the period of oscillation about the vertical axis is given by the equation

$$T = \frac{\pi}{30}\sqrt{\frac{R}{g}}$$

in which T is the period in minutes, R is the radius of the earth in feet (approximately 20,900,000) and g is the acceleration due to gravity (approximately 32.2 feet per second per second). Substituting in the formula,

$$T=0.1047\sqrt{\frac{20,900,000}{32.2}}$$

$$=84 \text{ minutes (approximately).}$$

This is sometimes stated as the period of a pendulum having a radius equal to the radius of the earth, since the equation for a short pendulum is the same as that given above with l (length) being substituted for R. More accurately, it is the period of a pendulum of infinite length with its bottom at the surface of the earth, or the largest period that a simple pendulum can have when acting under the gravitational force of the earth. When a device is adjusted so as to have this period it is said to be "Schuler tuned," after Ivan Schuler, a German scientist who discovered the relationship. It is because of this tuning of the gyro compass that one oscillation occurs in about 84 minutes, and that the maximum effect of certain disturbing forces occurs about 21 minutes (one-fourth cycle) after application of the force.

638. Quadrantal error.—If a body mounted in gimbals is not suitably balanced, a disturbing force causes it to swing from side to side. A swinging body tends to rotate so that its long axis of weight is in the plane of the swing. The rolling of a vessel introduces the force needed to start a gyro compass swinging. The effect reaches a maximum on intercardinal headings, midway between the two horizontal axes of the compass, and changes direction of error in consecutive quadrants. This is called **quadrantal error,** or sometimes **intercardinal rolling error.** It is corrected by the addition of weights to balance the compass so that the weight is the same in all directions from the center. Without a long axis of weight, there is no tendency to rotate during a swing.

A second cause of quadrantal error is more difficult to eliminate. As a vessel rolls, the apparent vertical is displaced first to one side and then to the other, due to the accelerations involved. The vertical axis of the gyro compass tends to align itself with the apparent vertical. If the vessel is on a northerly or southerly course, the pivot of the compass is displaced from the vertical, resulting in a precession first to one side, then to the other. The effect is negligible and would be exactly balanced if successive rolls on opposite sides were equal. On an easterly or westerly heading, the pivot remains under the gyro axle, but the dynamic effect of the roll, acting upon the damping mechanism, introduces a precessing force which causes an error. However, the period is short and the error is in opposite directions on opposite rolls, so the effect is negligible. On noncardinal headings, both effects are present, and the relationship is such that the error is in the same direction regardless of the direction of roll. Thus, a persistent error is introduced, which changes direction in successive quadrants. This error is generally eliminated by the use of a second gyroscope. In some compasses, this is in the form of a small gyroscope called a **floating ballistic** which stabilizes the point of application of the mercury ballistic with respect to the true vertical as the vessel rolls. In others, two gyroscopes are used for the directive element and these are so installed that they tend to precess in opposite directions. Thus, they neutralize each other. Another way of eliminating this error is to design the mercury ballistic system so that the surge of liquid due to north-south component of the roll is diminished in amount and delayed so that it is about a quarter of a cycle out of phase with the roll.

639. Gimballing error is that due to tilt of the compass rose. Directions are measured in the horizontal plane. If the compass card is tilted, the projection of its

outer rim onto the horizontal is an ellipse, and the graduations are not equally spaced with respect to a circle. This error, which applies to all instruments making use of a compass rose that can be tilted, is discussed in article 2903. For normal angles of tilt, this error is small and can be neglected. For accurate results, readings should be made when the card is horizontal. This error applies to the reading of the compass *or its repeaters* (art. 641), rather than to the compass itself. If the compass and its repeaters are installed so that the outer gimbals are in the longitudinal axis of the vessel, this error is minimized.

640. Use of the gyro compass in polar regions is discussed in article 2514. If means are not available for determining an equivalent setting or correction, a correction graph can be constructed. Ballistic deflection error, quadrantal error, and gimballing error are temporary or corrected in the design of the compass, and so can be ignored. Speed error and damping error (if it applies to the particular compass involved) can be combined into a single table or curve of corrections, using the formulas of articles 635 and 636. In high latitudes the east-west component of the vessel's speed is significant, and the error may be too large to consider its tangent equal to the angle itself expressed in radians. Therefore, the applicable formulas are:

$$\tan \delta = \frac{S \cos C}{902.46 \cos L \pm S \sin C} \tag{1}$$

$$\alpha = r \tan L. \tag{2}$$

The only approximation remaining is the use of 902.46, which varies slightly with latitude. The error thus introduced is not significant. The U. S. Navy Bureau of Ships' curves for latitude 80° are shown in figure 640. From the intersection of the appropriate speed curve and the radial line representing the *true* course (interpolating if necessary) a horizontal line is drawn to the vertical line through the origin, where the correction is indicated. To construct the curve for speed 35 knots, proceed as follows:

(1) Compute the speed error, δ, for true courses at intervals of perhaps 30°. As an example, the error for course 210° (C S30°W) is:

$$\tan \delta = \frac{35 \times 0.86603}{902.46 \times 0.17365 - 35 \times 0.50000}$$

$$= 0.21773.$$

$$\delta = 12^\circ\!.3 \text{ E}.$$

The error is easterly because the course has a southerly component (art. 635).

(2) Compute the damping error. The curves of figure 640 are for a value of r of 1°.7:

$$\alpha = 1^\circ\!.7 \times 5.6713 = 9^\circ\!.6 \text{ E}.$$

In northern latitudes damping error is easterly.

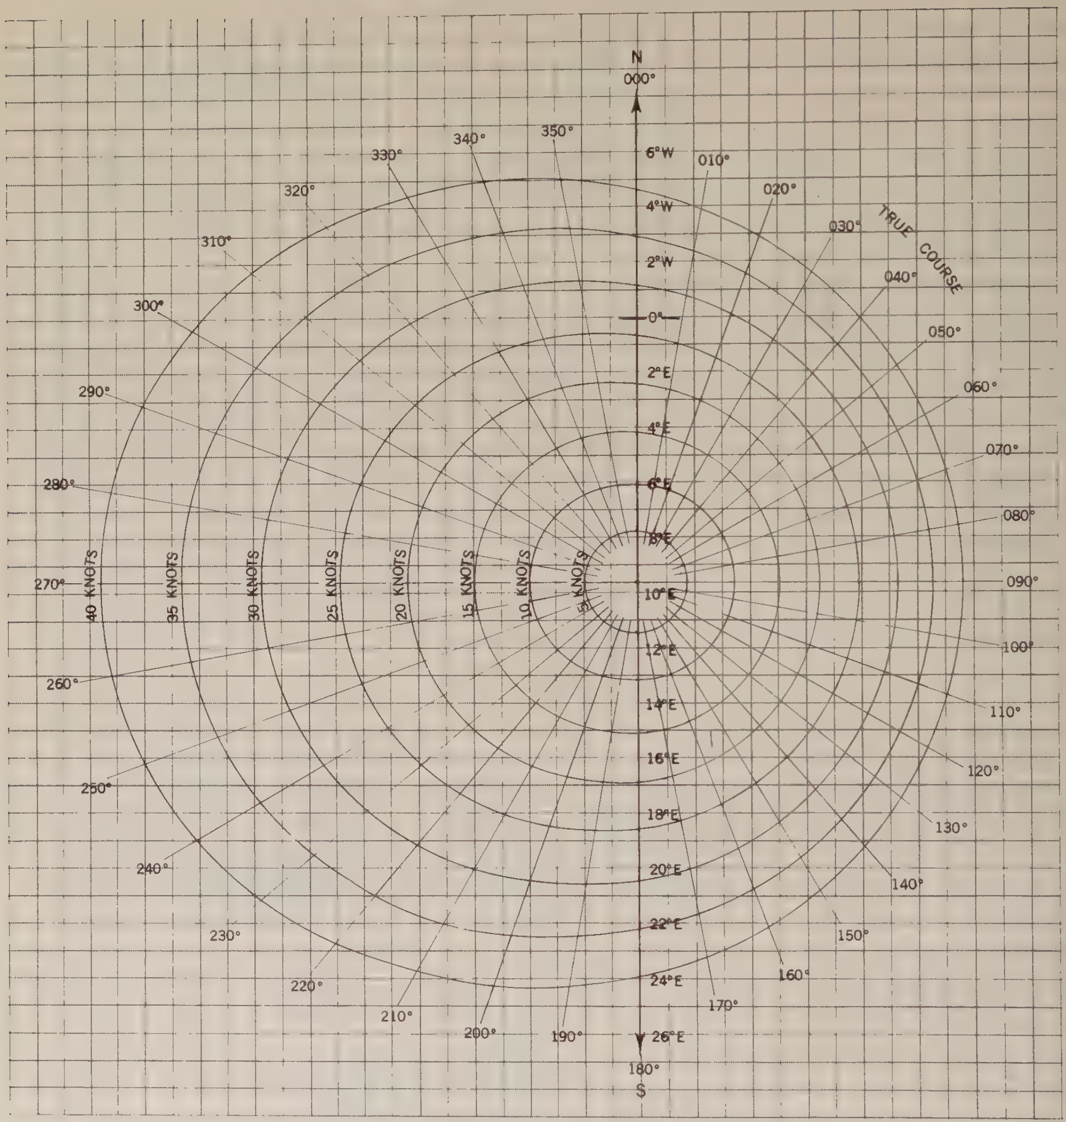

FIGURE 640.—Gyro compass error curves for latitude 80°.

(3) Combine δ and α algebraically to obtain gyro error (GE):

TC °	δ °	α °	*GE* °
000	12. 6 W	9. 6 E	3. 0 W
030	9. 9 W	9. 6 E	0. 3 W
060	5. 3 W	9. 6 E	4. 3 E
090	0. 0	9. 6 E	9. 6 E
120	5. 3 E	9. 6 E	14. 9 E
150	9. 9 E	9. 6 E	19. 5 E
180	12. 6 E	9. 6 E	22. 2 E
210	12. 3 E	9. 6 E	21. 9 E
240	7. 9 E	9. 6 E	17. 5 E
270	0. 0	9. 6 E	9. 6 E
300	7. 9 W	9. 6 E	1. 7 E
330	12. 3 W	9. 6 E	2. 7 W

(4) To draw the curve, select a convenient origin and label this with the value of α. Draw a vertical line through the origin and mark off a convenient scale such that all values of δ can be shown both above and below the origin. The zero on this scale is at point α units above the origin (below in the southern hemisphere). Label the scale according to GE. Through the origin draw various radial lines at any convenient interval to represent true courses. For each computed course draw a horizontal construction line from the GE on the central scale to the appropriate radial line. The intersection of each pair of lines is one point on the curve. Connect all such points with a smooth curve, and erase the construction lines. If a straightedge or graph paper is used, the construction lines need not be drawn.

It is good practice to draw the curve for the highest speed first, to be sure that succeeding curves will fit on the paper. From such curves the gyro courses corresponding to various true courses can be determined and the radial lines labeled with these values for converting gyro directions to true directions.

The curves described in this article are for use *when all correctors are set on zero*, or if no provision is made for mechanically correcting for speed and damping errors. If the compass does not have a mercury ballistic, the damping error is omitted from the calculations and curves.

641. Gyro compass repeaters.—A gyro compass is customarily located at a favorable position below decks, and its indications transmitted electrically to various positions throughout the vessel. Each repeater consists of a compass rose on a suitable card so mounted that the direction of the ship's head is indicated at a lubber's line. Although the repeater may be mounted in any position, including vertically on a bulkhead, it is generally placed in gimbals in a bowl, similar to the mounting of a compass, which it resembles (fig. 641). This is true particularly of repeaters used for obtaining bearings. A gyro repeater used primarily to indicate the gyro heading is sometimes called a **ship's course indicator.**

FIGURE 641.—A gyro repeater used as a ship's course indicator (Mark 2 Mod 5).

Gyro compass indications are also used in automatic steering devices, direction-stabilized radar scopes, wind indicators, fire control equipment, etc.

A compass used to control other equipment, particularly repeaters, is sometimes called a **master compass.** In the case of a gyro compass, it is usually called a **master gyro compass.** It is good practice to check all repeaters periodically with the master compass to insure continued synchronization.

642. Alidade.—A gyro repeater with a telescopic sight mounted over it is called an **alidade.** If the telescopic sight is mounted so that it remains pointed in the same gyro direction regardless of motions of the vessel, the instrument is called a **self-synchronous alidade.** This instrument will retain its setting until oriented to a new gyro direction.

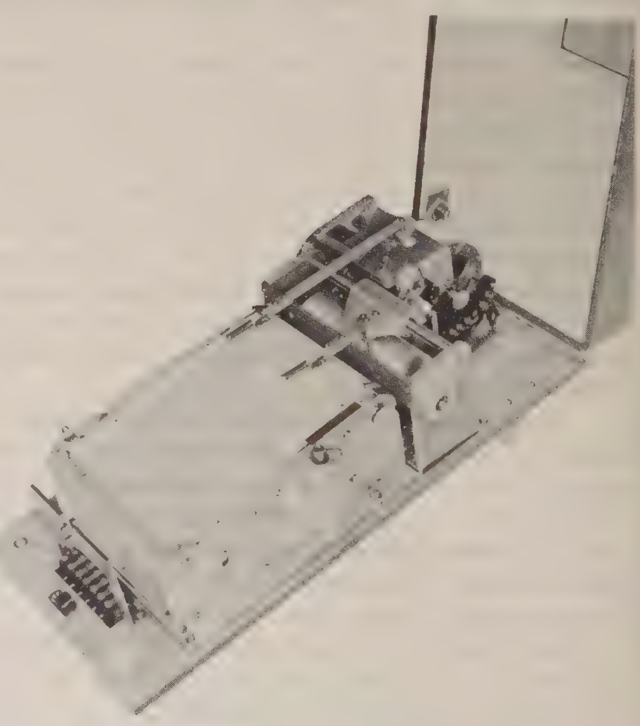
FIGURE 643.—A pelorus.

643. Pelorus.—Although it is desirable to have a compass, a compass repeater, or an alidade for obtaining bearings, satisfactory results can be obtained by means of an inexpensive device known as a **pelorus** (fig. 643). In appearance and use this device resembles a compass or compass repeater, with sighting vanes or a sighting telescope attached, but it has no directive properties. That is, it remains at any *relative* direction to which it is set. It is generally used by setting 000° at the lubber's line. Relative bearings are then observed. They can be converted to bearings true, magnetic, grid, etc., by *adding* the appropriate heading. The direct use of relative bearings is sometimes of value. A pelorus is useful, for instance, in determining the moment at which an aid to navigation is broad on the beam. It is also useful in measuring pairs of relative bearings for use with table 7 or for determining distance off and distance abeam without a table (art. 910).

If the true heading is set at the lubber's line, true bearings are observed directly. Similarly, compass bearings can be observed if the compass heading is set at the lubber's line, etc. However, the vessel must be on the heading to which the pelorus is set if accurate results are to be obtained, or else a correction must be applied to the observed results. Perhaps the easiest way of avoiding error is to have the steersman indicate when the vessel is on course. This is usually done by calling out "mark, mark, mark" as long as the vessel is within a specified fraction of a degree of the desired heading. The observer, who is watching a distant object across the pelorus, selects an instant when the vessel is steady and is on course. An alternative method is to have the observer call out "mark" when the relative bearing is steady, and the steersman note the heading. If the compass is swinging at the moment of observation, the observation should be rejected. The number of degrees between the desired and actual headings is *added* if the vessel is to the *right* of the course, and *subtracted* if



Courtesy of Sperry Gyroscope Co.

FIGURE 644.—A course recorder.

to the *left*. Thus, if the course is 060° and the heading is 062° at the moment of observation, a correction of 2° is added to the bearing.

Each observer should determine for himself the technique that produces the most reliable results.

644. Course recorder.—A continuous graphical record of the headings of a vessel can be obtained by means of a **course recorder** (fig. 644). In its usual form, paper with both heading and time graduations is slowly wound from one drum to another, its speed being controlled by a spring-powered clockwork mechanism. A pen is in contact with the paper, tracing a line to indicate the heading at each moment. The pen is attached to an arm controlled by indications from a compass, usually the master gyro compass.

645. Dead reckoning equipment.—The primary navigational functions of **dead reckoning equipment** (DRE) are to (1) provide continuous indications of the vessel's present latitude and longitude, and (2) provide a graphical record of the vessel's dead reckoning track. In addition, most types of dead reckoning equipment provide means for tracking one or more other craft, to obtain a graphical record of the other craft's course and speed. This equipment is generally installed only on warships.

Dead reckoning equipment consists in general of four components: (1) an analyzer; (2) latitude and longitude indicator dials; (3) a desk-size unit called a **dead reckoning tracer** (**DRT**), usually installed in the chart house; and (4) a glass plotting surface over the dead reckoning tracer.

The analyzer receives directional signals from the vessel's gyro compass, and distance signals from the underwater log. The course and distance data are transformed automatically to electrical signals proportional to the north-south and east-west components of the vessel's movement. These distance signals are transmitted to the latitude and longitude indicators, changing their readings by the correct amount to indicate the new latitude and the new longitude in degrees and minutes. Since the number of miles in the north-south component of distance traveled is nearly equal to the change in latitude expressed in minutes, the latitude indicator is fed directly. Departure (art. 204) is automatically transformed to difference of longitude before being registered on the longitude indicator dials. If the indicator dials are correctly set to latitude and longitude, they continuously show subsequent dead reckoning positions of the vessel.

The north-south and east-west component signals from the analyzer are also transmitted to the DRT (fig. 645), where they control the motion of a pencil which moves across a chart or plotting sheet attached to the DRT base. The pencil draws a line which conforms to the maneuvers of the vessel. The mechanism can be set to plot the track at any scale from ¼ mile per inch (1/10 mile on some) to 16 miles per inch. A clock-controlled contact lifts the pencil from the paper for 15 seconds of each minute and for a longer period each 10 minutes, thus providing automatic time measurement. The pencil carriage can be moved manually to any part of the chart for initial setting and the direction of travel can be adjusted so that the chart can be placed with any cardinal direction "up."

The cover of the DRT is a sheet of glass to which a plotting sheet or blank paper can be fastened. An electric lamp on the top of the pencil carriage throws a spot of light through the paper directly over the carriage, thus providing a moving reference scaled to the course and speed of the vessel. If the position of the spot of light is marked periodically on the paper, a second record of the vessel's track is obtained. However, the principal use of this sheet is for plotting successive positions of another craft, using the spot of light as the origin. A polar grid centered on the light may be projected onto the paper to facilitate measurement. The course of the other vessel

Courtesy of Ahrendt Instrument Co.

FIGURE 645.—A dead reckoning tracer.

can be measured directly from the plot, and its speed can be determined by means of the time needed to travel any distance measured on the plot. This process is called **tracking.** If the ranges and bearings are plotted from a fixed point, *relative* movement is determined, a practice commonly followed in connection with radar (art. 1212).

While dead reckoning equipment is a great convenience, particularly when changes of course or speed are numerous, its indications should be checked by graphical plot on the chart or plotting sheet. Reliable dead reckoning is too important to be left entirely to mechanical equipment without an independent check.

Problems

634. Gyro error is 1° E.

Required.—(1) True heading when the gyro heading is 155°.

(2) The course to steer by gyro compass if the desired true course is 211°.

(3) The true bearing of a lighthouse if the bearing by gyro compass is 043°.

Answers.—(1) TH 156°, (2) C_{pgc} 210°, (3) TB 044°.

635. A ship at latitude 53° N is steaming on true course 205°, at a speed of 18 knots.

Required.—Speed error.

Answer.— δ 1°72 E.

636. A gyro compass having a value of r of 1°.0 is at latitude 20° S.

Required.—The damping error.

Answer.— α 0°.36 W.

643a. A pelorus is set with 000° at the lubber's line, and a bearing of 216° is observed when the heading is 155° true.

Required.—The true bearing.

Answer.—TB 011°.

643b. A pelorus is set with 070° at the lubber's line. A bearing of 030° is observed when the compass heading is 068°.

Required.—The compass bearing.

Answer.—CB 028°.

CHAPTER VII

COMPASS ERROR

Magnetism

701. Theory of magnetism.—The fact that iron can be magnetized (given the ability to attract other iron) has been known for thousands of years, but the explanation of this phenomenon has awaited the recently acquired knowledge of atomic structure. According to present theory, the magnetic field around a current-carrying wire and the magnetism of a permanent **magnet** are the same phenomenon—fields created by moving electrical charges. This occurs whether the charge is moving along a wire, flowing with the magma of the earth's core, encircling the earth at high altitude as a stream of charged particles, or rotating around the nucleus of an atom.

It has recently been shown that microscopically small regions, called **domains,** exist in iron and other ferromagnetic substances. In each domain the fields created by electrons spinning around their atomic nuclei are parallel to each other, causing the domain to be magnetized to saturation. In a piece of unmagnetized iron, the directions of the various domains are arranged in a random manner with respect to each other. If the substance is placed in a weak magnetic field, the domains rotate somewhat toward the direction of that field. Those domains which are more nearly parallel to the field increase in size at the expense of the more non parallel ones. If the field is made sufficiently strong, entire domains rotate suddenly by angles of as much as 90° or 180° so as to become parallel to that "crystal axis" which is most nearly parallel to the direction of the field. If the strength of the field is increased to a certain value depending upon individual conditions, all of the domains rotate into parallelism with the field, and the iron itself is said to be magnetically **saturated.** If the field is removed, the domains have a tendency to rotate more or less rapidly to a more natural direction parallel to some crystal axis, and more slowly to random directions under the influence of thermal agitation.

Magnetism which is present only when the material is under the influence of an external field is called **induced magnetism.** That which remains after the magnetizing force is removed is called **residual magnetism.** That which is retained for long periods without appreciable reduction, unless the material is subjected to a demagnetizing force, is called **permanent magnetism.**

Certain substances respond readily to a magnetic field. These **magnetic materials** are principally those composed largely of iron, although nickel and cobalt also exhibit magnetic properties. The best magnets are made of an alloy composed mostly of iron, nickel, and cobalt. Aluminum and some copper may be added. Platinum and silver, properly alloyed with other material, make excellent magnets, but for ordinary purposes the increased expense is not justified by the improvement in performance. Permanent magnets occur in nature in the form of **lodestone,** a form of magnetite (an oxide of iron) possessing magnetic properties. A piece of this material constitutes a **natural magnet.**

702. Hard and soft iron.—In some alloys of iron, the crystals can be so arranged and internally stressed that the domains remain parallel to each other indefinitely, and the metal thus becomes a **permanent magnet.** Such alloys are used for the magnets of a compass. In other kinds of iron, the domains reorient themselves rapidly to conform to the direction of a changing external field, and soon take random directions if the field is removed. A ferromagnetic substance which retains much of its magnetism in the

absence of an external field, is said to have high **remanence** or **retentivity.** The strength of a reverse field (one of opposite polarity) required to reduce the magnetism of a magnet to zero is called the **coercivity** or **coercive force** of the magnet. Hence, a compass magnet should have high remanence in order to be strong, and high coercivity so that stray fields will not materially affect it. For convenience, iron is called "hard" if it has high remanence, and "soft" if it has low remanence. **Permeability** (μ) is the ratio of the strength of the magnetic field inside the metal (B) to the strength of the external field (H), or $\mu=\frac{B}{H}$.

703. Lines of force.—The direction of a magnetic field is usually represented by lines, called **lines of force.** Relative intensity in different parts of a magnetic field is indicated by the spacing of the lines of force, a strong field having the lines close together. If a piece of unmagnetized iron is placed in a magnetic field, the lines of force tend to crowd into the iron, following its long axis, and the field is stronger in the vicinity of the iron, somewhat as shown in figure 703a. If the iron becomes permanently magnetized

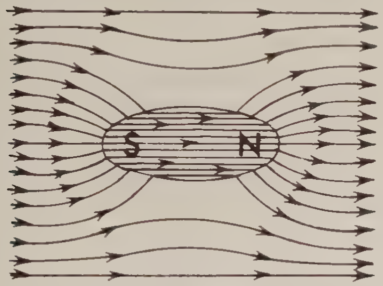


FIGURE 703a.—Lines of force crowd into ferromagnetic material placed in a magnetic field.

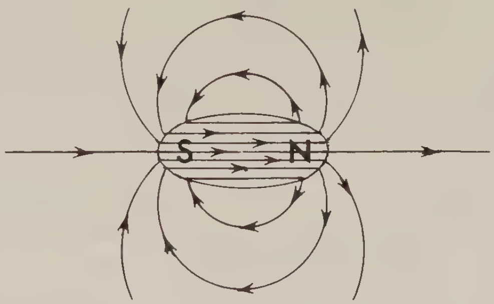

FIGURE 703b.—Field of a permanent magnet.

and is removed from this field, the lines of force around the iron follow paths about as shown in figure 703b.

704. Magnetic poles.—The region in which the lines of force enter the iron is called the **south pole,** and the region in which they leave the iron is called the **north pole.** Thus, the lines of force are directed from south to north within the magnet, and and from north to south in the external field. Every magnet has a north pole and a south pole. If a magnet is cut into two pieces, each becomes a magnet with a north pole and south pole. A single pole cannot exist independently. If two magnets are brought close together, *unlike poles attract each other and like poles repel.* Thus, a north pole attracts a south pole but repels another north pole.

The earth itself has a magnetic field (art. 706), with its magnetic poles being some distance from the geographical poles. If a permanent bar magnet is supported so that it can turn freely, both horizontally and vertically, it aligns itself with the magnetic field of the earth, which at most places is in a general north-south direction and inclined to the horizontal. Since the north pole of the magnet points in a northerly direction, the earth's magnetic pole in the northern hemisphere has *south* magnetism. Nevertheless, it is called the **north magnetic pole** because of its geographical location. For a similar reason, the pole in the southern hemisphere, although it has north magnetism, is called the **south magnetic pole.** To avoid confusion, north magnetism is usually called "red," and south magnetism, "blue." The red (north) pole of a magnet is usually painted red, and in some cases the south (blue) pole is painted blue. The north magnetic pole of the earth is a blue pole, and the south magnetic pole is a red pole.

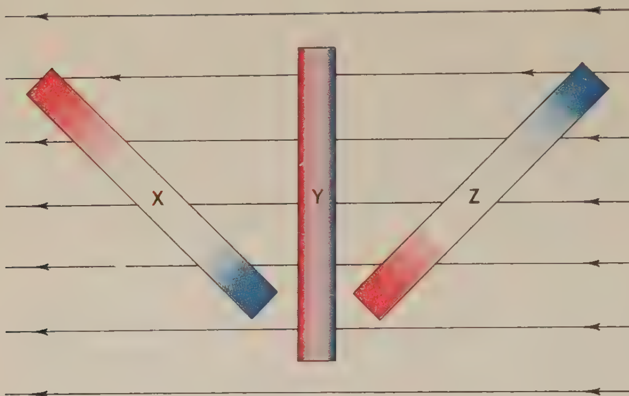

FIGURE 705.—The polarity of a soft iron bar in a magnetic field.

705. The magnetism of soft iron, in which remanence is low, depends upon the position of the iron with respect to an external field. It is strongest if the long axis is parallel to the lines of force, and decreases to a minimum if the material is rotated so that the long axis is perpendicular to the lines of force. Figure 705 shows three positions of a bar magnet with respect to a magnetic field. At position *X* the pole at the upper end of the bar is red and relatively strong. As the bar is rotated toward position *Y*, the upper end remains red, but its strength decreases. At position *Y*, no pole is apparent at either end, but a red pole extends along the entire left side of the bar, and a blue pole along the right side. Poles are strongest when concentrated into a small area. Hence, when spread over an entire side, as at position *Y*, they are relatively weak. At position *Z*, the upper end is blue.

The change in polarity as a bar of soft iron is rotated in a magnetic field can easily be demonstrated. If a bar of soft iron is placed vertical in northern magnetic latitudes (as in any part of the United States), the north (red) end of a compass magnet brought near it will be attracted by the upper end of the bar, and repelled by the lower end. If the bar is inverted, so that its ends are interchanged, the upper end (which as the lower end previously repelled the compass needle) will attract the north end of the needle, and the lower end will repel it. Thus, the polarity of the rod is reversed, *either* end having blue magnetism if it is at the top. This changing polarity of soft iron in the earth's field is a major factor affecting the magnetic compasses of a steel vessel.

706. Terrestrial magnetism.—The earth itself can be considered to be a gigantic magnet. Although man has known for many centuries that the earth has a magnetic field, the origin of the magnetism is not completely understood. Nevertheless, the horizontal component of this field is a valuable reference in navigation, for it provides the directive force for the magnetic compass, which indicates the ship's heading *in relation to the horizontal component of this field.*

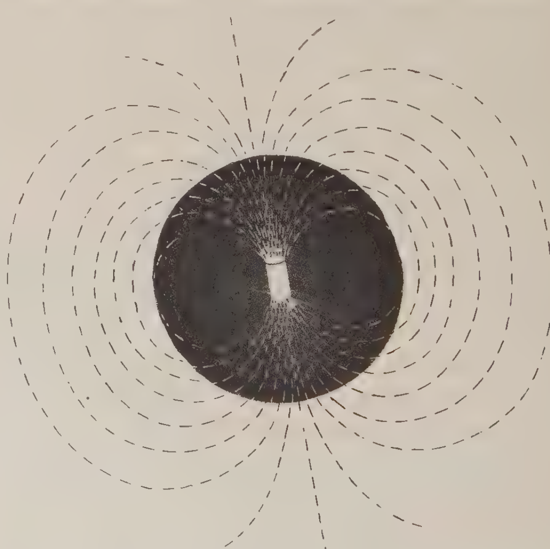

FIGURE 706.—The magnetic field of the earth.

The world-wide pattern of the earth's magnetism is roughly like that which would result from a short, powerful, bar magnet near the earth's center, as shown in figure 706. The geographical poles are at the top and bottom, and the magnetic poles are offset somewhat from them. This representation, however, is greatly simplified. The actual field is more

complex, and requires measurement of its strength and direction at many places (art. 707) before it can be defined accurately enough to be of practical use to the navigator. Not only are the magnetic poles offset from the geographical poles, but the magnetic poles themselves are not 180° apart and, in general, a magnetic compass aligned with the lines of force does not point toward either magnetic pole. In 1960, the north magnetic pole was located at latitude 74°9 N, longitude 101°0 W, approximately, to the northward of Prince of Wales Island; and the south magnetic pole was at latitude 67°1 S, longitude 142°7 E, approximately, in the northeastern part of Wilkes Land. However, the magnetic poles are not stationary. The entire magnetic field of the earth, including the magnetic poles, undergoes a small daily or **diurnal change,** and a very slow, progressive **secular change.** In addition, temporary sporadic changes occur from time to time during magnetic storms (art. 2526). During a severe storm, variation may change as much as 5°, or more. However, such disturbances are never so rapid as to cause noticeable deflection of the compass card, and in most navigable waters the change is so little that it is not significant in practical navigation. Even when there is no temporary disturbance, the earth's field is considerably more intricate than indicated by an isomagnetic chart (art. 708). Natural magnetic irregularities occurring over relatively small areas are called **magnetic anomalies** by the magneticians, but the navigator generally refers to these phenomena as **local disturbances.** Notes warning of such disturbances are shown on charts. In addition, artificial disturbances may be quite severe when a vessel is in close proximity to other vessels, piers, machinery, electric currents, etc.

The elements of the earth's field are as follows:

Total intensity (F) is the strength of the field at any point, measured in a direction parallel to the field. Intensity is usually measured in **oersteds,** one oersted being equal to a force of one dyne acting on a unit pole. The range of intensity of the earth's field is about 0.25 to 0.70 oersted. For convenience in geomagnetic surveying, a smaller unit is used, called the **gamma.** One oersted equals 100,000 gammas, so that the range of intensity of the earth's field is about 25,000 to 70,000 gammas.

Horizontal intensity (H) is the horizontal component of the total intensity. At the **magnetic equator,** which corresponds roughly with the geographic equator, the field is parallel to the surface of the earth, and the horizontal intensity is the same as total intensity. At the magnetic poles of the earth, the field is vertical and there is no horizontal component. The direction of the horizontal component at any place defines the **magnetic meridian** at that place. This component provides the desired directive force of a magnetic compass.

North component (X) is the horizontal intensity's component along a geographic (true) meridian.

East component (Y) is the horizontal intensity's component perpendicular to the north component.

Vertical intensity (Z) is the vertical component of the total intensity. It is zero at the magnetic equator. At the magnetic poles it is the same as the total intensity. While the vertical intensity has no direct effect upon the direction indicated by a magnetic compass, it does induce magnetic fields in vertical soft iron, and these may affect the compass.

Variation (V, Var.), called **declination** (D) by magneticians, is the angle between the geographic and magnetic meridians at any place. The expression **magnetic variation** is used when it is necessary to distinguish this from other forms of variation. This element is measured in angular units and named east or west to indicate the side of true north on which the (magnetic) northerly part of the magnetic meridian lies. For computational purposes, easterly variation is sometimes designated positive (+),

and westerly variation negative (−). **Grid variation** (GV) or **grivation** is the angle between the grid and magnetic meridians at any place, measured and named in a manner similar to variation.

Magnetic dip (I), called **inclination** (I) by magneticians, is the vertical angle, expressed in angular units, between the horizontal at any point and a line of force through that point. The **magnetic latitude** of a place is the angle having a tangent equal to half that of the magnetic dip of the place.

At a distance of several hundred miles above the earth's surface, the magnetic field surrounding the earth is believed to be uniform, as it appears in figure 706, and centered around two **geomagnetic poles.** These do not coincide with either the magnetic poles (art. 704) or the geographical poles. However, they are 180° apart, the north geomagnetic pole being at latitude 78°.5 N, longitude 69° W (near Etah, Greenland) and the south geomagnetic pole being at latitude 78°.5 S, longitude 111° E. The great circles through these poles are called **geomagnetic meridians.** That geomagnetic meridian passing through the south geographical pole is the origin for measurement of **geomagnetic longitude,** which is measured eastward through 360°. The complement of the arc of a geomagnetic meridian from the nearer geomagnetic pole to a place is called the **geomagnetic latitude.** When the sun is over the upper branch of the geomagnetic meridian of a place, it is **geomagnetic noon** there, and when it is over the lower branch of the geomagnetic meridian, it is **geomagnetic midnight.** The angle between the lower branch of the geomagnetic meridian of a place and the geomagnetic meridian over which the sun is located is called **geomagnetic time.** The diurnal change is related to geomagnetic time. The auroral zones (art. 2526) are centered on the geomagnetic poles.

707. Measurement of the earth's magnetic field is made continuously at about 70 permanent **magnetic observatories** throughout the world. In addition, large numbers of temporary stations are occupied for short periods to add to man's knowledge of the earth's field. In the past, measurements at sea have been made by means of nonmagnetic ships constructed especially for this purpose. However, this is a slow and expensive method, and quite inadequate to survey properly the 71 percent of the earth's surface covered with water. Since World War II, a satisfactory **airborne magnetometer** has been developed by the U. S. Navy. By means of this instrument, continuous readings can be recorded automatically during long overwater flights.

708. Isomagnetic charts showing lines of equality of some magnetic element are published by the U. S. Navy Hydrographic Office in collaboration with the U. S. Coast and Geodetic Survey. Formerly, three charts of each element were published, in addition to a north polar grid variation chart, making a total of 22 in the series. Beginning with the series for epoch 1955, charts for the north and east components (X and Y) are not published, as this information is of limited use and can be determined easily from the horizontal component and variation. The three charts of each element consist of one on the Mercator projection (art. 305) covering most of the world, and one on a polar projection (azimuthal equidistant (art. 320) or stereographic) for each of the two polar areas. All charts now included in the series are published at intervals of 10 years, showing the values for the beginning of each year ending in five. Charts showing variation are also published for the years ending in zero (1950, 1960, etc.).

The isomagnetic chart of most concern to a navigator is H.O. Chart No. 1706, *The Variation of the Compass*, a simplified version of which is shown in figure 708a. The lines connecting points of equal magnetic variation are called **isogonic lines.** *These are not magnetic meridians (lines of force).* The line connecting points of zero variation is called the **agonic line.** Variation is also shown on nautical charts. Those of relatively small scale generally show isogonic lines. Those of scale larger than 1:100,000 generally give the information in the form of statements inside compass roses placed at various

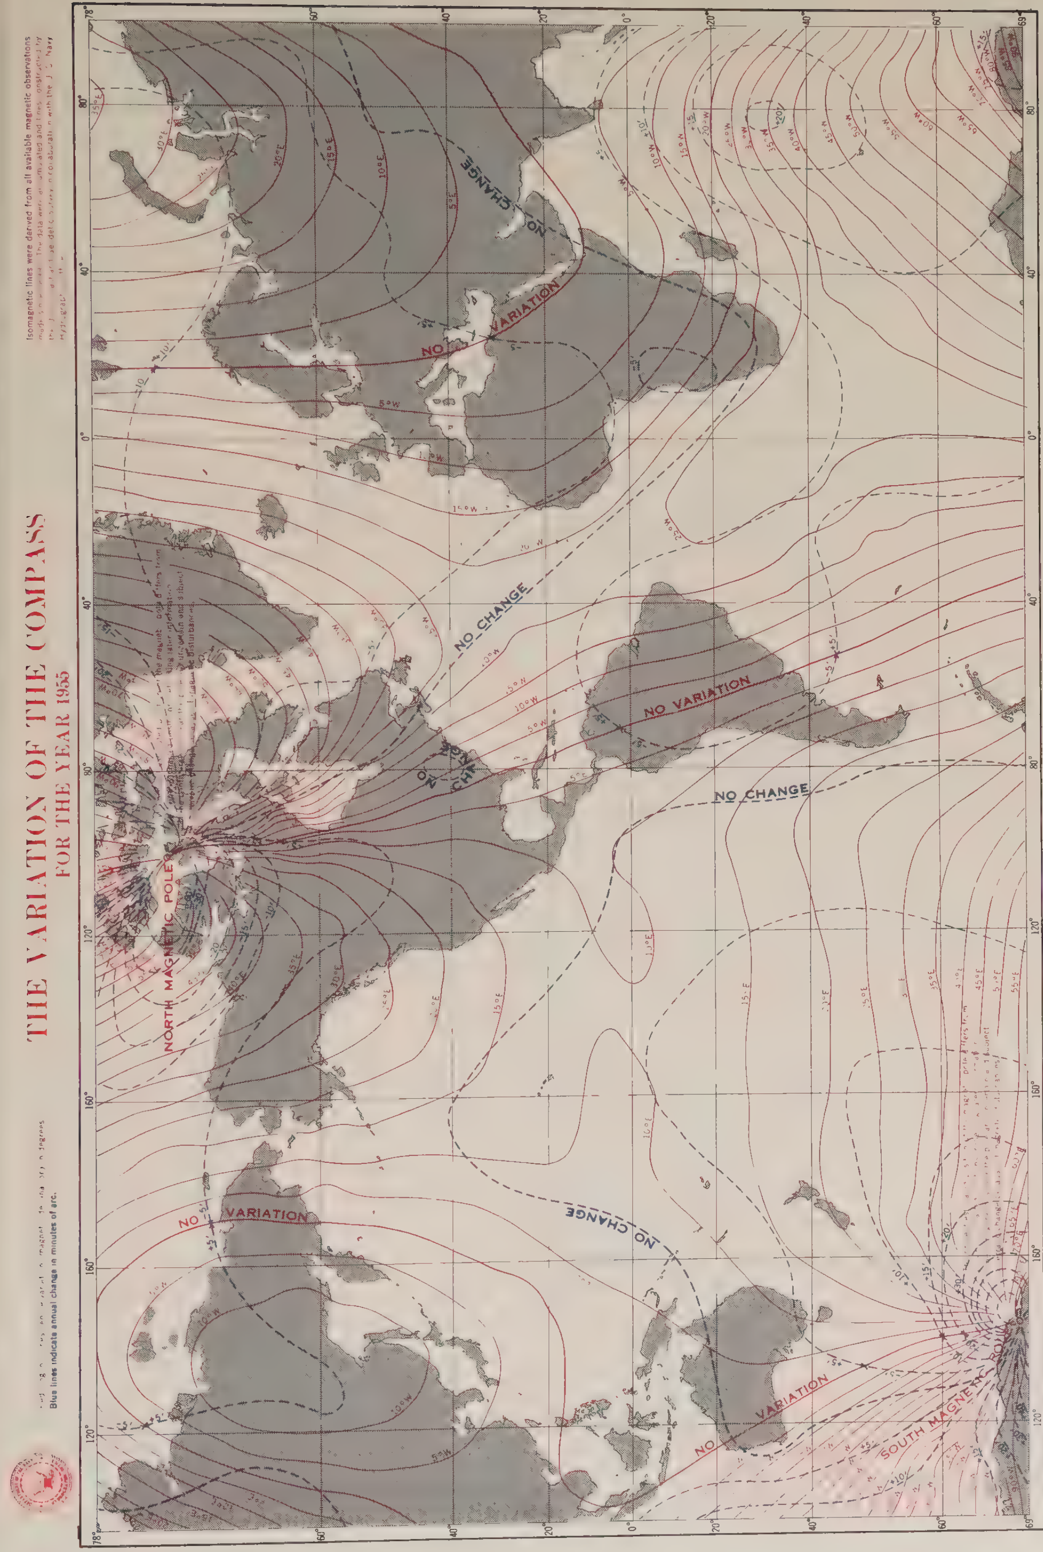

FIGURE 708a.—Variation. A simplification of H.O. Chart No. 1706.

places on the chart, and sometimes, also, by a **magnetic compass rose** within the true compass rose and offset from it by the amount of the variation. By means of this arrangement, true directions can be plotted without arithmetically applying variation to magnetic directions, or magnetic directions can be read directly from the chart. The magnetic compass rose is generally graduated in both degrees and points. Variation is given to the nearest 15′, and the annual change to the nearest 1′. However, since the rate of change is not constant, a very old chart should not be used, even though it has been corrected for all changes shown in *Notices to Mariners*.

Another isomagnetic chart of value to the mariners is H.O. Chart No. 1700, *Magnetic Dip*, figure 708b. Lines connecting points of equal magnetic dip are called **isoclinal lines.** The line connecting points of zero dip is called the **magnetic equator.**

Other isomagnetic charts are H.O. Chart No. 1701, showing horizontal intensity; H.O. Chart No. 1702, showing vertical intensity; and H.O. Chart No. 1703, showing total intensity. Lines connecting points of equal intensity on any of these charts are called **isodynamic lines.**

In all series of isomagnetic charts, the same number is used for polar charts, but with N or S following the number (and N–G or S–G for the grid variation charts) to indicate the north or south polar region, respectively. All of the isomagnetic charts also show **isopors,** in a distinctive color, connecting points of equal **annual change** of the element at the epoch of the chart.

The charts are as accurate as can be made with available information, except that the lines are smoothed somewhat, rather than depicting every small irregularity. The larger irregularities are reflected in the information shown on nautical charts, but local disturbance is indicated by warning notes at appropriate places. In areas where measurements of the magnetic field have not been made for a long period, the previous information is altered in accordance with the best information available on secular change, with some adjustment to provide continuous smooth curves. When information is thus carried forward for many years, errors may be introduced, particularly in areas where the rate of change is large and variable. Magneticians have not detected a recognizable world-wide pattern in secular change, such as would occur if it were due only to shifting of the positions of the magnetic poles. Rather, these shifts are part of the general complex, little-understood secular change.

The Compass Error

709. Magnetic compass error.—Directions relative to the northerly direction along a geographic meridian are **true.** In this case, true north is the **reference direction.** If a compass card is horizontal and oriented so that a straight line from its center to 000° points to true north, any direction measured by the card is a true direction and has no error (assuming there is no calibration or observational error). If the card remains horizontal but is rotated so that it points in any other direction, the amount of the rotation is the **compass error.** Stated differently, compass error is the angular difference between true north and **compass north** (the direction north as indicated by a magnetic compass). It is named east or west to indicate the side of true north on which compass north lies.

If a magnetic compass is influenced by no other magnetic field than that of the earth, and there is no instrumental error, its magnets are aligned with the magnetic meridian at the compass, and 000° of the compass card coincides with **magnetic north.** All directions indicated by the card are **magnetic.** As stated in article 706, the angle between geographic and magnetic meridians is called **variation (V** or **Var.).** Therefore, if a compass is aligned with the magnetic meridian, compass error and variation are the same.

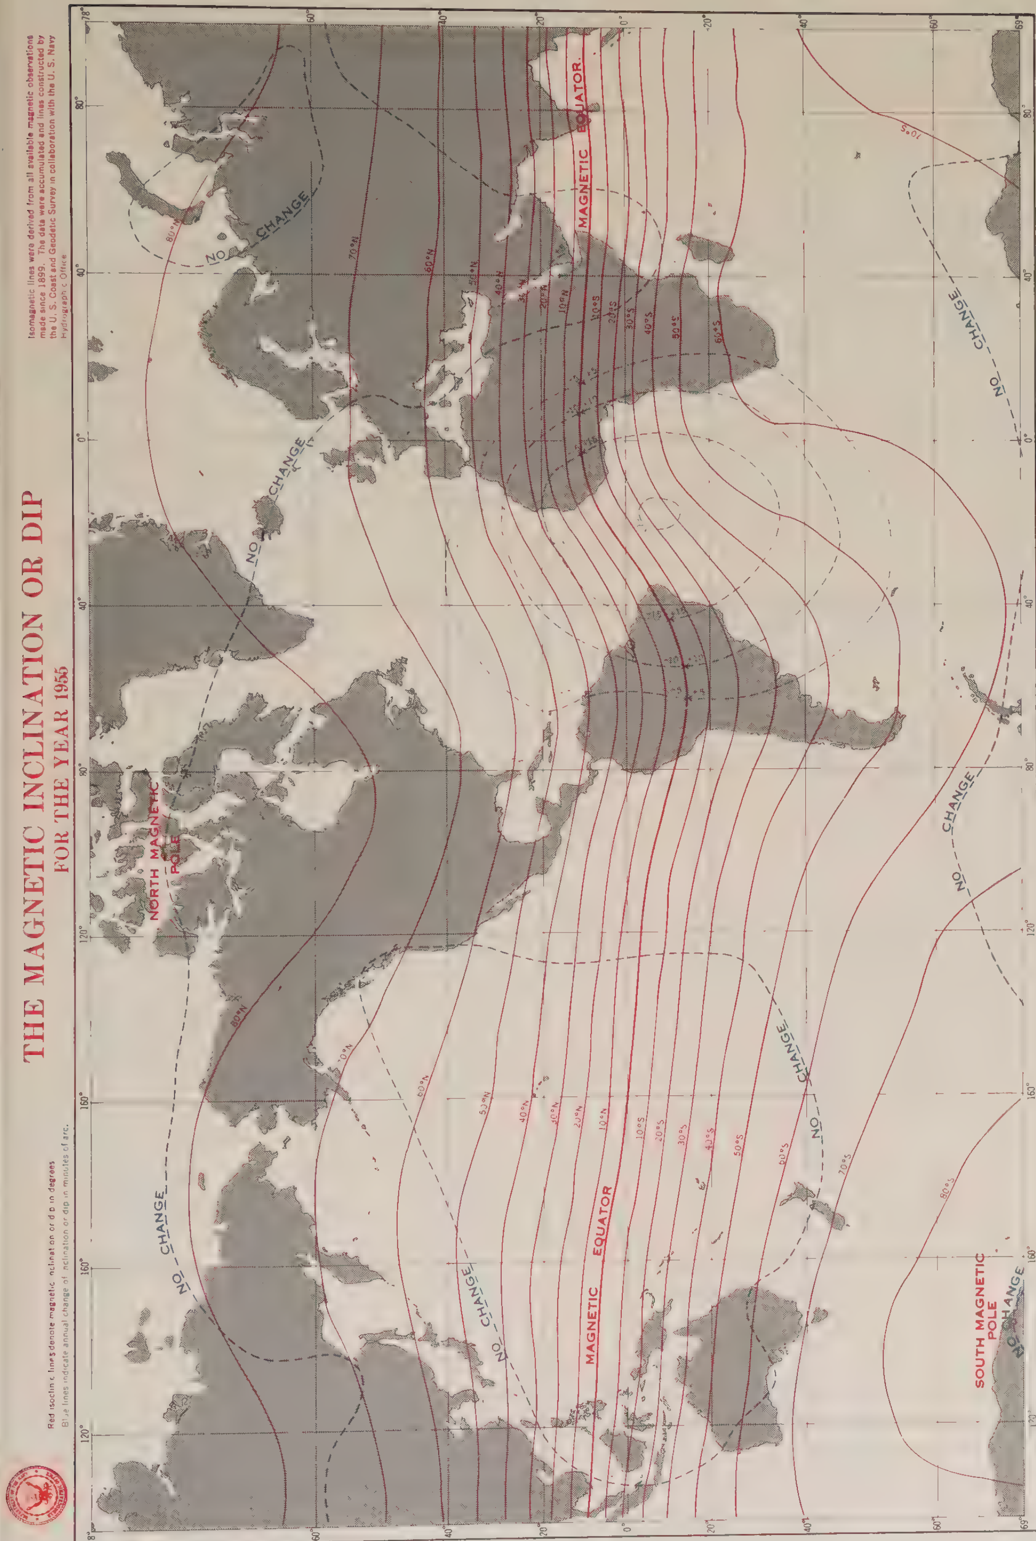

FIGURE 708b.—Magnetic dip. A simplification of H. O. Chart No. 1700.

When a compass is mounted in a vessel, it is generally subjected to various magnetic influences other than that of the earth. These arise largely from induced magnetism in metal decks, bulkheads, masts, stacks, boat davits, guns, etc., and from electromagnetic fields associated with direct current in electrical circuits. Some metal in the vicinity of the compass may have acquired permanent magnetism. The actual magnetic field at the compass is the vector sum, or resultant (art. O18), of all individual fields at that point. Since the direction of this resultant field is generally not the same as that of the earth's field alone, the compass magnets do not lie in the magnetic meridian, but in a direction that makes an angle with it. This angle is called **deviation (D** or **Dev.)**. Thus, deviation is the angular difference between magnetic north and compass north. It is expressed in angular units and named east or west to indicate the side of magnetic north on which compass north lies. Thus, deviation is the error of the compass in pointing to magnetic north, and all directions measured with compass north as the reference direction are **compass directions.** Since variation and deviation may each be either east or west, the effect of deviation may be to either increase or decrease the error due to variation alone. The algebraic sum (art. O6) of variation and deviation is the total compass error.

For computational purposes (art. 727), deviation and compass error, like variation, may be designated positive (+) if east and negative (−) if west.

Variation changes with location, as indicated in figure 708a. Deviation depends upon the magnetic latitude and also upon the individual vessel, its trim and loading, whether it is pitching or rolling, the heading (orientation of the vessel with respect to the earth's magnetic field), and the location of the compass within the vessel. Therefore, deviation is not published on charts.

710. Deviation table.—In practice aboard ship, the deviation is reduced to a minimum, as explained later in this chapter. The remaining value, called **residual deviation,** is determined on various headings and recorded in some form of **deviation table.** Figure 710 shows both sides of the form used by the United States Navy. This table is entered with the magnetic heading, and the deviation on that heading is determined from the tabulation, separate columns being given for degaussing (DG) off and on (art. 740). If the deviation is not more than about 2° on any heading, satisfactory results may be obtained by entering the values at intervals of 45° only.

If the deviation is small, no appreciable error is introduced by entering the table with either magnetic or compass heading. If the deviation on some headings is large, the desirable action is to reduce it, but if this is not practicable, a separate deviation table for compass heading entry may be useful. This may be made by applying the tabulated deviation to each entry value of magnetic heading, to find the corresponding compass heading, and then interpolating between these to find the value of deviation at each 15° compass heading. Another method is to plot the values on cross-section paper and select the desired values graphically.

A nomogram especially designed for interconversion of magnetic and compass headings is called a **Napier diagram,** having been devised by James Robert Napier (1821–79). It consists of a dotted, vertical center line graduated from 000° to 360° (usually in two parallel parts of 180° each), with two series of cross lines making angles of 60° with the dotted vertical line and with each other. If magnetic headings are used, deviation is measured along a solid cross line; and if compass headings are used, deviation is measured along a dotted cross line. A deviation curve is drawn through the various points. To convert a magnetic heading to a compass heading, one finds the magnetic heading on the vertical center line, moves parallel to a solid cross line until the curve is reached, and returns to the center line by moving parallel to a dotted line.

The compass heading is the value at the point of return. The reverse process is used for converting a compass heading to a magnetic heading. This nomogram is of particular value where the deviation is large and changing rapidly. It is now possible, however, to reduce deviation to such small values that the Napier diagram has lost much of its appeal and is seldom used.

REMARKS

INSTRUCTIONS

1. This form shall be filled out by the Navigator for each magnetic compass as set forth in Chapter 24, Part 2, and Chapter 81, Section III, of Bureau of Ships Manual.
2. When a swing for deviations is made, the deviations should be recorded both with degaussing coils off and with degaussing coils energized at the proper currents for heading and magnetic zone.
3. Each time this form is filled out after a swing for deviations, a copy shall be submitted to the Bureau of Ships. A letter of transmittal is not required.
4. When choice of box is given, check applicable box.
5. Before adjusting, fill out section on "Vertical Induction Data" above.

NAVSHIPS-1104 (REV. 10-57) BACK D-20867

FIGURE 710.—Deviation table.

Another solution is to make a deviation table with one column for magnetic heading, a second column for deviation, and a third for compass heading. Still another solution, most popular among yachtsmen, is to center a compass rose inside a larger one so that an open space is between them and a radial line would connect points of the same graduation on both roses. Each magnetic heading for which deviation has been determined is located on the outer rose, and a straight line is drawn from this point to the corresponding compass heading on the inner rose.

A variation of this method is to draw two parallel lines a short distance apart, and graduate each from 0 to 360 so that a perpendicular between the two lines connects points of the same graduation. Straight lines are drawn from magnetic directions on one line to the corresponding compass directions on the other. If the lines are horizontal and the upper one represents magnetic directions, the slope of the line indicates the direction of the deviation. That is, for westerly deviation the upper part of the connecting line is left (west) of the bottom part, and for easterly deviation it is right.

An important point to remember regarding deviation is that it varies with the *heading*. Therefore, a deviation table is *never* entered with a bearing (art. 904). If the deviation table converts directly from one type heading to another, deviation is found by taking the difference between the two values. On the compass rose or straight-line type, the deviation can be written alongside the connecting line, and the intermediate values determined by estimate. If one has trouble determining whether to add or subtract deviation when bearings are involved, he has only to note which heading, magnetic or compass, is larger. The same relationship holds between the two values of bearing.

The deviation table should be protected from damage due to handling or weather, and placed in a position where it will always be available when needed. A method commonly used is to mount it on a board, cover it with shellac or varnish, and attach it to the binnacle. Another method is to post it under glass near the compass. It is good practice for the navigator to keep a second copy available at a convenient place for his use.

711. Applying variation and deviation.—As indicated in article 709, a single direction may have any of several numerical values depending upon the reference direction used. One should keep clearly in mind the relationship between the various expressions of a direction. Thus, true and magnetic directions differ by the variation, magnetic and compass directions differ by the deviation, and true and compass directions differ by the compass error. Other relationships are also useful. Thus, grid (art. 2510) and magnetic directions differ by the grid variation or grivation, and true and relative directions differ by the true heading. The use of variation and deviation is considered here. Other relationships are discussed elsewhere in this volume.

If variation or deviation is easterly, the compass card is rotated in a clockwise direction. This brings smaller numbers opposite the lubber's line. Conversely, if either error is westerly, the rotation is counterclockwise and larger numbers are brought opposite the lubber's line. Thus, if the heading is 090° true (fig. 711, A) and variation is 6° E, the magnetic heading is $090°-6°=084°$ (fig. 711, B). If the deviation on this heading is 2° W, the compass heading is $084°+2°=086°$ (fig. 711, C). Also, compass error is $6°\text{ E}-2°\text{ W}=4°\text{ E}$, and compass heading is $090°-4°=086°$. If compass error is easterly, the compass reads too low (in comparison with true directions), and if it is westerly, the reading is too high. Many rules-of-thumb have been devised as an aid to the memory, and any which assist in applying compass errors in the right direction are of value. However, one may forget the rule or its method of application, or may wish to have an independent check. If he understands the explanation given above, he can determine the correct sign without further information. The same rules apply to the use of gyro error. Since variation and deviation are compass errors, the process of removing either from an indication of a direction (converting compass to magnetic or magnetic to true) is often called **correcting.** Conversion in the opposite direction (inserting errors) is then called **uncorrecting.**

Example.—A vessel is on course 215° true in an area where the variation is 7° W. The deviation is as shown in figure 710. Degaussing is off. The gyro error (GE) is 1° E. A lighthouse bears 306°5 by magnetic compass.

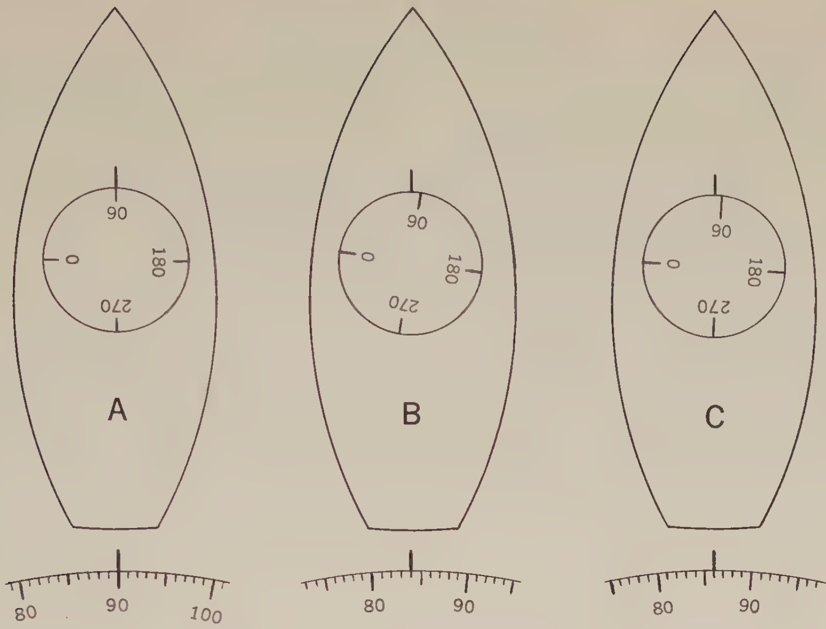

FIGURE 711.—Effect of variation and deviation on the compass card.

Required.—(1) Magnetic heading (MH).
(2) Deviation.
(3) Compass heading (CH).

(8) RB=TB−TH=298°−215°=083°.

Answers.—(1) MH 222°, (2) D 1°5 W, (3) CH 223°5, (4) CE 8°5 W, (5) Hpgc 214°, (6) MB 305°, (7) TB 298°, (8) RB 083°.

Deviation and Its Reduction

712. Magnetism of a steel vessel.—The materials of which a vessel is constructed are not, in general, selected for their magnetic properties. As a result, many degrees of permeability, remanence, and coercivity (art. 702) exist within its structure. Detailed analysis of the complex field existing at a magnetic compass is a specialized study not ordinarily required of the navigator. However, a general knowledge of the basic principles involved is of value to the navigator in helping him understand better the behavior of his magnetic compasses.

For most purposes, a vessel can be considered to be composed of two types of material: "hard iron" and "soft iron."

"Hard iron" is all material having some degree of permanent magnetism. This magnetism is acquired largely during construction of the vessel, when the rearrangement of the domains (art. 701) is facilitated by the bending, riveting, welding, and other violent mechanical processes. Since a vessel remains on a constant magnetic heading

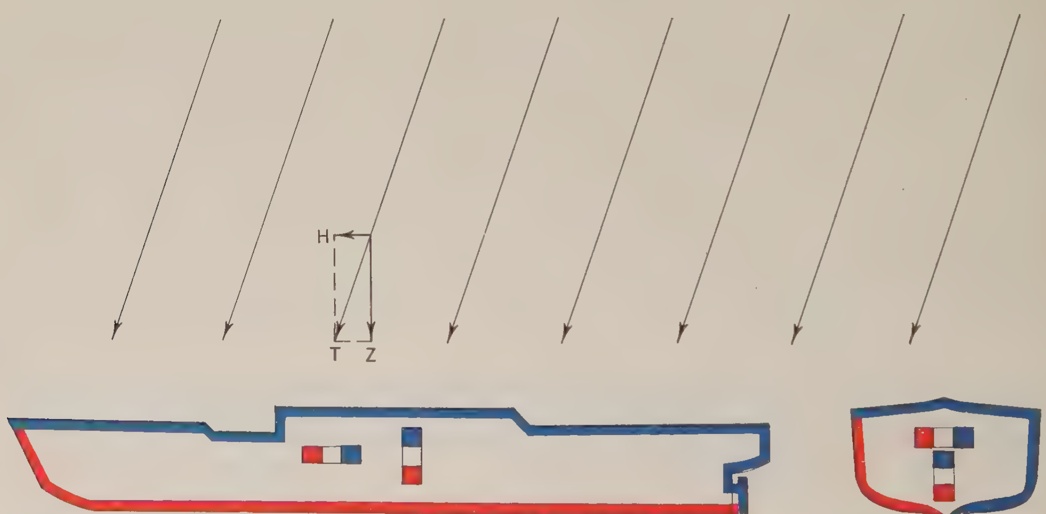

FIGURE 712.—Permanent magnetism of a vessel built on heading magnetic north (left) and magnetic east (right) at a place where the magnetic dip is 70°N.

while it is on the building ways, a field of permanent magnetism becomes established, the positions of the poles being dependent largely upon the orientation of the hull with respect to the magnetic field of the earth. If a vessel is constructed on a heading of magnetic north, at a place where the magnetic dip is 70° N (the approximate value at the midpoint of the east coast of the United States), its field of permanent magnetism is about as shown at the left of figure 712. The upper and stern portions are magnetically blue, while the lower and forward portions are magnetically red. If the vessel is built on a heading of magnetic east, the starboard and upper portions are blue, and the port and lower portions are red, as shown by the stern view at the right of figure 712. If the heading is magnetic northeast, the upper, starboard, and stern portions are blue, and the lower, port, and forward portions red. The red and blue portions for any given vessel can be visualized by drawing a sketch similar to that of figure 712, with the correct orientation

The "permanent" magnetism thus acquired during construction is less permanent than that of a permanent magnet such as one of those used in a compass, and is modified somewhat after launching, particularly if the vessel remains on another heading for a

considerable time during fitting out. The change is especially rapid during the first few days after launching, when the domains of the softer iron become reoriented. At this stage, deviation due to permanent magnetism may change several degrees. Further changes in the permanent magnetism may occur during long periods of being tied up or moored on a constant heading, or during a run of several days on nearly the same heading. This change is gradual and affects the strength, but usually not the polarity, of the magnetic field. The permanent field may be changed quickly, in polarity as well as in strength, if the vessel grounds, collides with another vessel, is struck by lightning, undergoes magnetic treatment (art. 744), fires its guns, or is struck by shells or bombs, etc.

The effect that the permanent magnetism of hard iron has upon a compass depends upon the position and strength of the poles relative to the compass. When the poles are in line with the north-south axis of the compass card, the only effect is to strengthen or weaken the directive force of the compass. When the compass heading is approximately 90° away, so that the poles are east and west of the compass, the deviating effect is maximum. The direction of the deviation is the same as that of the blue pole with respect to the compass.

"Soft iron" is all that material in which induced magnetism (art. 701) is present. With respect to its effect upon the magnetic compass, it is classed as either vertical or horizontal. Unlike hard iron, its magnetic field changes quickly as its orientation with respect to the earth's field changes. It also changes as the strength of the earth's field changes. For some purposes induced magnetism can be treated as if it were concentrated in two bars of soft iron, one vertical and the other horizontal. The polarity depends upon the position of the vessel relative to the earth's magnetic field, and the strength depends upon the strength of the vertical and horizontal components of the earth's field. This is illustrated in figure 712. In north magnetic latitude the bottom of the vertical rod has red magnetism and the top has blue magnetism. In south magnetic latitude these are reversed. In both north and south magnetic latitudes the magnetic north end of the horizontal bar has red magnetism, and the magnetic south end has blue magnetism. Thus, whatever the position of the rod, that part in the direction of magnetic north has red magnetism, and that part in the direction of magnetic south has blue magnetism. That is, each end has magnetism opposite to that of the magnetic pole indicated by the direction in which it is pointed.

The effect upon a magnetic compass of the induced magnetism in soft iron depends upon the strength and direction of the field relative to the compass. The cumulative effect of the induced magnetism in vertical soft iron is generally on the center line of the vessel (if of conventional construction), and for a compass located forward, as on the bridge, is aft of the compass. In magnetic north latitude the effect is generally that of a blue pole at the level of the compass card. In magnetic south latitude the pole is red. On a heading of compass north or south the pole is in line with the magnets of a center line compass and serves only to strengthen or weaken the directive force. On a heading of compass east or west the pole is perpendicular to the north-south axis of the compass card, and the deviating force is greatest.

For a compass located on the center line of a vessel of conventional construction, the horizontal soft iron close enough to have appreciable effect upon the compass is arranged in a more-or-less symmetrical manner with respect to the compass. Thus, on any cardinal compass heading, the fore-and-aft and athwartship horizontal soft iron is either in line with the compass magnets or equally and similarly arranged on both sides. No error is introduced by such symmetrical horizontal soft iron because the iron north and south of the compass magnets serves only to strengthen or weaken the directive force, and that east and west of the compass sets up an equal and opposite

field on each side. On intercardinal headings, the poles of the induced magnetism are offset and a maximum deviating force occurs. That part of horizontal soft iron which is not symmetrically arranged with respect to the compass—the asymmetrical soft iron—produces deviation which is maximum on the cardinal headings and zero on the intercardinal headings (by compass). This type of deviation is particularly great in a compass not mounted on the center line of the vessel. It may also produce deviation which is constant on all headings.

In wooden-hulled vessels such as certain yachts and small fishing vessels, one or more of these types of magnetism may be weak or entirely missing, but this does not justify the omission of any part of the correction procedure.

As far as its effect upon the compass is concerned, the magnetic field at a center line compass located forward on a vessel of conventional construction, and on an even keel, is essentially the same as that which would result from four sources: (1) the earth's magnetism; (2) a single blue pole the location and strength of which depends upon the magnetic history of the vessel; (3) a single pole which is blue in north magnetic latitude and red in south magnetic latitude, is on the center line aft of the compass, and increases in strength with higher magnetic latitude; and (4) a single blue pole on the starboard side for easterly headings and on the port side for westerly headings, being of zero strength on a heading of north or south and decreasing in strength with increased magnetic latitudes. The single pole concept assumes that the effect of one pole predominates. The locations of the poles depend partly upon the position of the compass to which they apply. The actual field surrounding any magnetic compass may be considerably more complex than indicated.

713. Compass adjustment.—There are at least two possible solutions to the problem of compass error. The error can be permitted to remain, and the various directions interconverted by means of variation and deviation, or compass error, as explained in article 711; or the error can be removed. In practice, a combination of both of these methods is used.

Variation depends upon location of the vessel, and the navigator has no control over it. Provision could be made for offsetting the lubber's line, but this would not be effective in correcting magnetic compass bearings, and this practice is not generally followed. Variation does not affect the operation of the compass itself, and so is not objectionable from this standpoint.

Deviation is undesirable because it is more troublesome to apply, and the magnetic field which causes it partly neutralizes the directive force acting upon the compass, causing it to be unsteady and sluggish. As the vessel rolls and pitches, or as it changes magnetic latitude, the magnetic field changes, producing a corresponding change in the deviation of an unadjusted compass.

Deviation is eliminated, as nearly as practicable, by introducing at the compass a magnetic field that is equal in magnitude and opposite in polarity to that of the vessel. This process is called **compass adjustment,** or sometimes **compass compensation,** although the latter designation is now more generally applied to the process of neutralizing the effect due to degaussing of the vessel (art. 745).

In general, the introduced field is of the same kind of magnetism as well as of the same intensity as those of the field causing deviation. That is, permanent magnets are used to neutralize permanent magnetism, and soft iron to neutralize induced magnetism, so that the adjustment remains effective with changes of heading and magnetic latitude. A relatively small mass of iron near the compass introduces a field equal to that of a much larger mass at a distance.

When a compass is properly adjusted, its remaining or **residual deviation** is small and practically constant at various magnetic latitudes, the directive force is as strong

as is obtainable on all headings, and the compass returns quickly from deflections and is comparatively steady as the vessel rolls and pitches.

714. Effect of latitude.—As indicated in article 706, the magnetic field of the earth is horizontal at the magnetic equator, and vertical at the magnetic poles, the change occurring gradually as a vessel proceeds away from the magnetic equator. At any place the relative strength of the horizontal and vertical components depends upon the magnetic dip. The directive force of a magnetic compass, provided by the horizontal component of the earth's magnetic field, is maximum on or near the magnetic equator and gradually decreases to zero at the magnetic poles. Within a certain area surrounding each magnetic pole the directive force is so weak that the compass is unreliable (art. 2513).

Deviation changes with a change of the relative strength of either the deviating force or the directive force. Thus, with *either* an increase in deviating force or a decrease in directive force, the deviation increases. However, if both the deviating and directive forces change by the same proportion, and with the same sign, there is no change in deviation. Also, if a deviating force is neutralized by an equal and opposite force *of the same kind*, there is no change of deviation with a change of magnetic latitude.

Permanent magnetism is the same at any latitude. If the permanent magnetism of the vessel is neutralized by properly placed permanent magnets of the correct strength, a change of magnetic latitude can be made without introduction of deviation. But if residual deviation due to permanent magnetism is present, it increases with a change to higher latitude. The deviating force remains unchanged while the directive force decreases, resulting in an increase in the relative strength of the deviating force.

As magnetic latitude increases, the vertical component of the earth's magnetic field becomes stronger, increasing the amount of induced magnetism in vertical soft iron. At the same time the directive force of the compass decreases. Both effects result in increased deviation unless the deviating force is neutralized by induced magnetism in vertical soft iron.

As magnetic latitude increases, the induced magnetism in the horizontal soft iron decreases in the same proportion as the decrease in the directive force of the compass, since both are produced by the horizontal component of the earth's magnetic field. Therefore, any deviation due to this cause is the same at any latitude.

715. Parameters.—Compass adjustment might be accomplished by locating the pole of each magnetic field, and establishing another pole of opposite polarity and equal intensity at the same place, or of less intensity and nearer to the compass; or a pole of opposite polarity and suitable intensity might be established at the correct distance on the opposite side of the compass. Thus, a blue pole east of a compass attracts the red northern ends of the compass magnets and repels the blue southern ends. Both effects cause rotation of the compass magnets and the attached compass card in a clockwise direction, producing easterly deviation. Either a red pole east of a compass, or a blue pole west of it, causes westerly deviation. If there are two fields of opposite polarity, one will tend to neutralize the other. If the intensities of the two fields are equal at the compass, one will cancel the other, and no deviation occurs.

Because of the complexities of the magnetic field of a vessel, and the fact that each individual field making up the total is present continuously, the process of isolating individual poles would be a difficult and time-consuming one. Fortunately, this is unnecessary. The vessel's field is resolved into certain specified components. Each of these components, regardless of its origin or the number of individual fields contributing to it, can be neutralized separately. Each component is called a **parameter,** and the various parameters are designated by letter, as follows:

Permanent magnetism. **Parameter *P*** is the fore-and-aft component. It is positive (+) if it is the equivalent of a blue pole forward of the compass, and negative (−) if red.

Parameter *Q* is the athwartship component. It is positive if it is the equivalent of a blue pole to starboard.

Parameter *R* is the vertical component. It is positive if it is the equivalent of a blue pole below the compass.

Induced magnetism has nine parameters, each the equivalent of that produced by a slender rod of soft iron. Each *end* of a rod is positive if it is forward, to starboard, or below the compass. Each rod is positive if both ends are positive or if both ends are negative, and negative if the two ends are of opposite sign. The rods are as follows:

a, b, c—one end level with the compass and in its fore-and-aft axis, either forward or aft. It is an *a* rod if it extends fore-and-aft, a *b* rod if athwartships, and a *c* rod if vertical.

d, e, f—one end level with the compass and in its athwartships axis, either to starboard or to port. It is a *d* rod if it extends fore-and-aft, an *e* rod if athwartships, and an *f* rod if vertical.

g, h, k—one end in the vertical axis of the compass, either above it or below it. It is a *g* rod if it extends fore-and-aft, an *h* rod if athwartships, and a *k* rod if vertical.

716. Coefficients.—Deviation which is easterly throughout approximately 180° of heading and westerly throughout the remainder is called **semicircular deviation,** indicating that its sign remains unchanged throughout a semicircle. Deviation caused by permanent magnetism and that caused by induced magnetism in vertical soft iron are semicircular. Deviation which changes sign in each quadrant, being easterly in two opposite quadrants and westerly in the other two, is called **quadrantal deviation.** It is caused by induced magnetism in horizontal soft iron. The types of deviation resulting from the various parameters are called coefficients. There are six, as follows:

Coefficient *A* is constant on all headings. If its cause is magnetic, as from an asymmetrical combination of parameters, it is a "true" constant. If its cause is mechanical, as from an incorrectly placed lubber's line, or mathematical, as from an error in computation of magnetic azimuth, it is an "apparent" constant.

Coefficient *B* is semicircular deviation which is proportional to the sine of the compass heading. It is maximum on compass headings east or west, and zero on compass headings north or south. Coefficient *B* is caused by permanent magnetism, and also by induced magnetism in asymmetrical vertical soft iron.

Coefficient *C* is semicircular deviation which is proportional to the cosine of the compass heading. It is maximum on compass headings north or south, and zero on compass headings east or west. Coefficient *C* is caused by permanent magnetism or by induced magnetism in asymmetrical vertical soft iron athwartship of the compass.

Coefficient *D* is quadrantal deviation which is proportional to the sine of twice the compass heading. It is maximum on intercardinal compass headings, and zero on cardinal compass headings. Coefficient *D* is caused by induced magnetism in horizontal soft iron which is symmetrical with respect to the compass.

Coefficient *E* is quadrantal deviation which is proportional to the cosine of twice the compass heading. It is maximum on cardinal compass headings, and zero on intercardinal compass headings. Coefficient *E* is caused by induced magnetism in horizontal soft iron which is asymmetrical with respect to the compass.

Coefficient *J* is the change of deviation for a heel of 1° while the vessel is on compass heading 000°.

The determination and use of the approximate coefficients in the analysis of compass deviation are discussed in article 727. The force components producing these coefficients are called **exact coefficients.** They are designated by the corresponding upper case German letters. The exact coefficients are now little used in practical

navigation. They are fully discussed in various books on compass adjustment.

717. Effect of compass location.—The location of a magnetic compass greatly influences the amount and type of deviation, as well as the adjustment. Thus, if a compass is on the center line, forward, the effective pole of vertical soft iron is aft of it; but if the compass is in the after part of the vessel, the effective pole is forward. If the compass is not on the center line, as the steering compass of an aircraft carrier, the magnetic field of the vessel is not symmetrical with respect to the compass. If a compass is located in a steel pilot house, the surrounding metal acts as a shield and reduces the strength of the magnetic field of the earth. This is of particular significance in high magnetic latitudes, where the directive force is weak.

Many factors influence the selection of a position for the compass. The most important consideration is the use to be made of it. A steering compass is of little use unless it is located so that it can be seen by the steersman. A compass to be used for emergency steering should be at the emergency steering station. A compass to be used for observing bearings or azimuths, or a standard compass to be used for checking other compasses, should be located so as to have a clear view in most directions.

However, some choice is possible. A compass should not be placed off the center line if it can be placed on the center line and still serve its purpose. It should not be placed near iron or steel equipment that will frequently be moved, if this can be avoided. Thus, a location near a gun, boat davit, or boat crane is not desirable. The immediate vicinity should be kept free from sources of deviation—particularly those of a changing nature—if this can be done. That is, no source of magnetism, other than the structure of the vessel, should be permitted within a radius of several feet of the magnetic compass. Some sources which might be overlooked are electric wires carrying direct current; magnetic instruments, searchlights, windshield wipers, electronic equipment, or motors; steel control rods, gears, or supports associated with the steering apparatus; fire extinguishers, gas detectors, etc.; and metal coat hangers, flashlights, keys, pocketknives, metal cap devices, or nylon clothing. The effect of some items such as an ammeter or electric windshield wiper varies considerably at different times. If direct current is used to light the compass, the wires should be twisted.

A magnetic compass cannot be expected to give reliable service unless it is properly installed and protected from disturbing magnetic influences.

718. The binnacle.—The compass is housed in a **binnacle.** This may vary from a simple wooden box to an elaborate device of bronze or other nonmagnetic material. Most binnacles provide means for housing or supporting the various objects used for compass adjustment, as well as the equipment for compensating for deviation caused by degaussing. The standard binnacle for the U. S. Navy 7½-inch compass is shown in figure 718. The trays for holding the fore-and-aft and

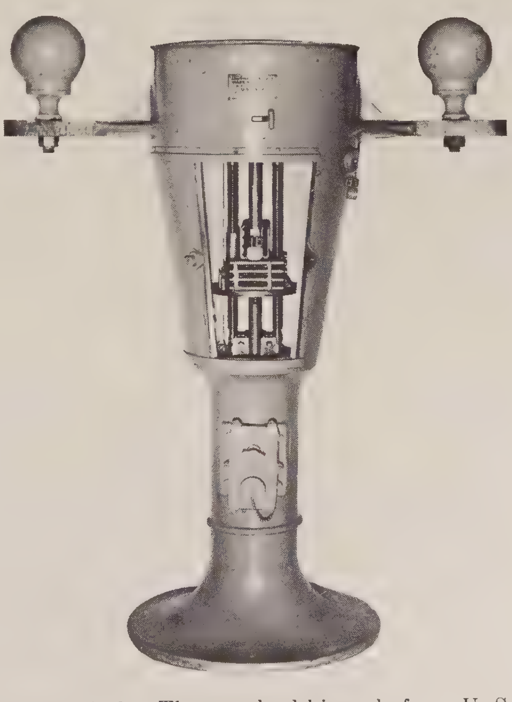

FIGURE 718.—The standard binnacle for a U. S. Navy 7½-inch compass.

athwartship magnets (art. 719), and the tube for the heeling magnet (art. 724), can be seen through the open door.

719. Adjustment for deviation due to permanent magnetism.—Permanent magnetism can be considered concentrated in a single pole, the position of which depends upon the magnetic heading upon which the vessel was constructed, and the subsequent magnetic history of the vessel. Figure 719a indicates the condi-

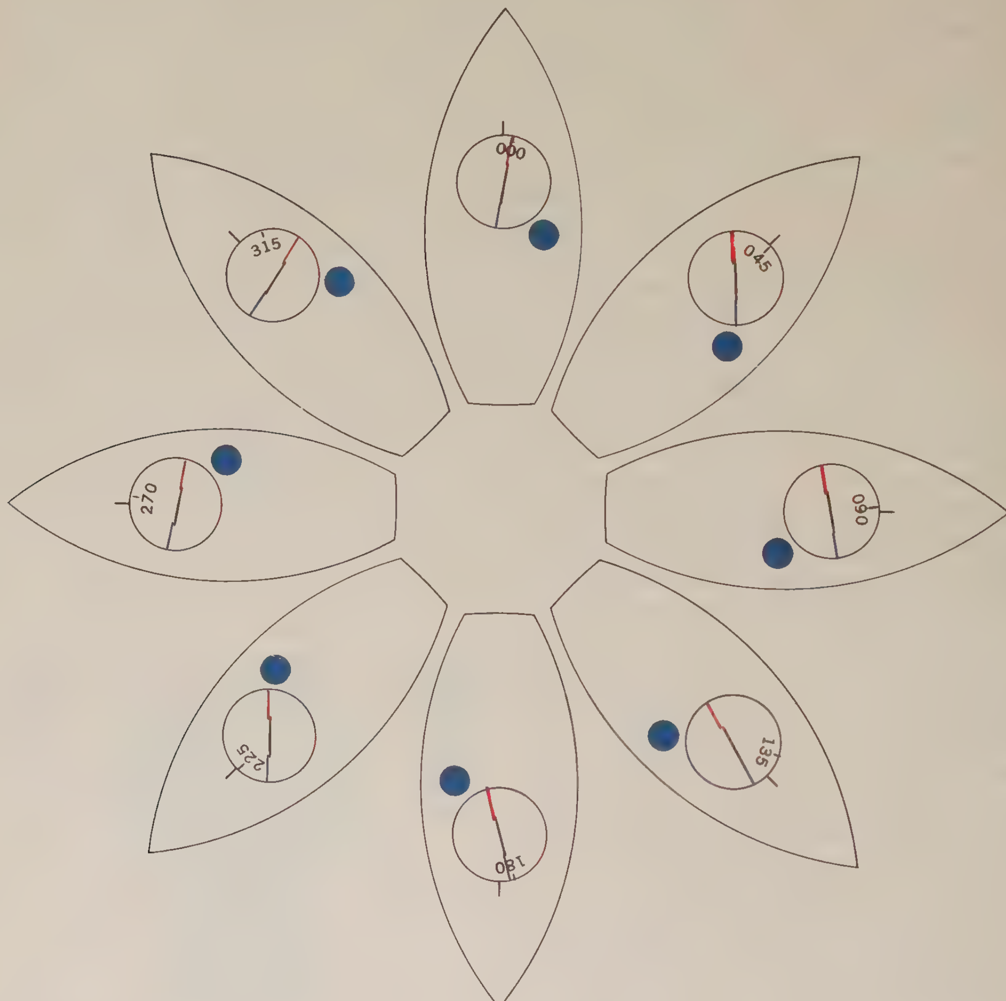

FIGURE 719a.—Deviation due to permanent magnetism if the resultant field is that of a blue pole on the starboard quarter of the vessel.

tion if the permanent magnetism can be considered concentrated in a single blue pole which is directly south of the compass when the vessel is headed magnetic northeast. The only effect on this heading is to weaken the directive force. No deviation is produced because the pole is in line with the compass magnets. On heading magnetic southwest, the pole is also in line with the compass magnets and there is no deviation, but the directive force is strengthened. On any other heading, the pole is not in line with the compass magnets, and deviation occurs, being in the same direction as that of the blue pole from the compass, since the blue pole attracts the red

northerly ends of the compass magnets and repels the blue southerly ends. The maximum effect occurs when the *compass* heading is approximately 90° from that of zero deviation. In figure 719a the headings shown on the compass card are the magnetic headings of the vessel. Their offset from the lubber's line shows the direction and relative magnitude of deviation.

If there were no other magnetism in the vessel, the poles might easily be located and neutralized by placing a magnet in such a position that a field of permanent magnetism but opposite polarity would occur at the compass. Although this method of adjustment has been used, it has not proven entirely satisfactory.

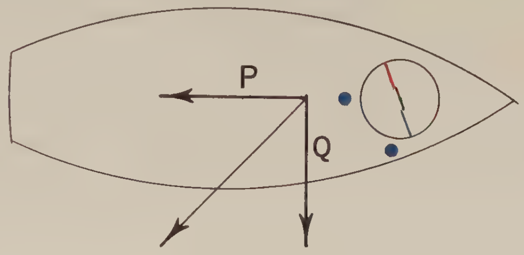

Figure 719b.—The horizontal component of the permanent field of figure 719a resolved into its components, parameters *P* and *Q*.

The usual method is to adjust for the fore-and-aft (parameter *P*) and athwartship (parameter *Q*) components separately. These are shown in figure 719b. The vertical parameter *R* does not produce deviation while the vessel is on an even keel. Its effect when the vessel heels is discussed in article 724. Thus, the effect of a single blue pole at the position shown in figure 719a is the same as that which would be produced by two weaker poles as shown in figure 719b. On heading east or west by the compass, parameter *Q* does not produce deviation directly. However, on easterly headings it does weaken the directive force due to the earth's magnetic field and therefore the deviating force of parameter *P* (causing deviation coefficient *B*) is relatively stronger and has a greater deviating effect. On a westerly heading the directive force would be strengthened, with a corresponding decrease in the *B* coefficient of deviation. By weakening the directive force on easterly headings, parameter *Q* also makes the compass sluggish on these headings. In high latitudes, where the horizontal component of the earth's magnetic field is weak, the compass may lose its directivity at a greater distance from the magnetic pole. Nearer the pole, it might point in the opposite direction.

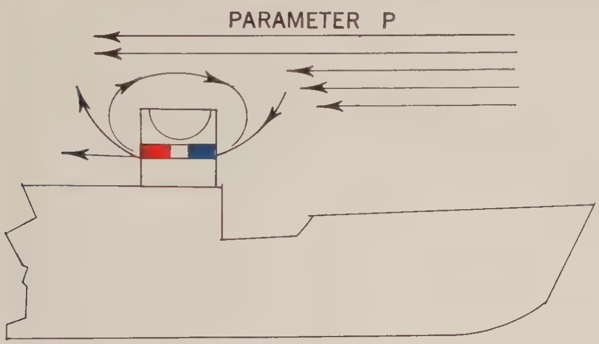

Figure 719c.—The field of a permanent magnet below the compass and opposing parameter *P* of figure 719b.

Many binnacles provide a group of several small tubes or "trays" extending in a fore-and-aft direction below the compass. One or more permanent magnets can be inserted in these trays, and the whole assembly moved up or down to vary the effect upon the compass. Figure 719c shows the situation if a single magnet is placed with its red end aft. The field at the compass is in the opposite direction of that of parameter *P*, and if it is of equal strength, the effect of this parameter is eliminated.

If now the vessel is headed north or south by the compass, the only pole remaining is that due to parameter *Q* (causing deviation coefficient *C*), as shown in figure 719d. A set of trays in an athwartship direction below the compass permits insertion of one or more permanent magnets to neutralize the remaining permanent magnetism. The

effect of inserting a single magnet with red end to starboard is shown in figure 719e. With both components removed, the field at the compass is completely neutralized.

Both the fore-and-aft (B) and athwartship (C) trays are in pairs with an equal number of trays on each side of the vertical axis of the compass. In each set of trays it is generally desirable to use an *even* number of magnets equally distributed on each side, to produce a symmetrical field at the compass. However, under some conditions, maximum reduction of deviation occurs with an *odd* number of magnets, particularly when two magnets at maximum distance from the compass overcorrect. If there is a choice, a greater number of magnets at a distance is preferable to a lesser number close to the compass.

With each parameter, the trays to use are those which are approximately perpendicular to the compass magnets. The magnets are placed so that the red ends will be on that side of the compass corresponding to the deviation. Thus, if deviation is easterly, the magnets should be placed so that the red ends will be east of the compass

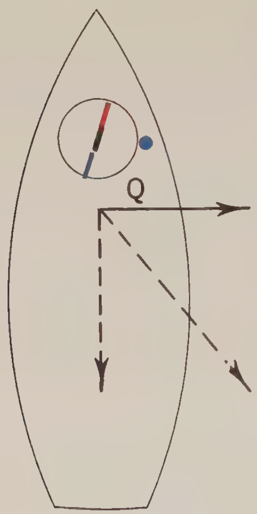

FIGURE 719d.—The permanent field of figure 719a after neutralization of parameter P.

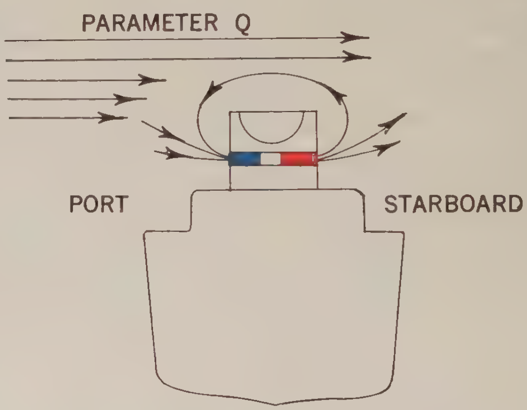

FIGURE 719e.—The field of a permanent magnet below the compass and opposing parameter Q of figure 719b.

(forward if the heading is east, and to starboard if the heading is north). However, if the wrong end is inserted in the trays, the fact will be immediately apparent because the compass card will rotate in the wrong direction. If the binnacle is not constructed to receive appropriate corrector magnets, these might be secured to some supporting surface near the compass.

During adjustment, the unused magnets should be kept far enough from the compass so that they will not affect it.

720. Adjustment for deviation due to induced magnetism in vertical soft iron.—Figure 720 shows the effect upon the compass of a single blue pole on the center line of the vessel, aft of the compass. This is a typical situation for induced magnetism in vertical soft iron, for a centerline compass located in the forward part of a vessel in magnetic north latitude. On heading north by compass there is no deviating force, but the directive force is weakened. In high northern latitudes, where this pole becomes strong and the directive force becomes weak, magnetism of this type, if not neutralized, can cause the compass to be unreliable in a much larger area than if the force is neutralized. On a heading of south by compass there is no deviation, but the

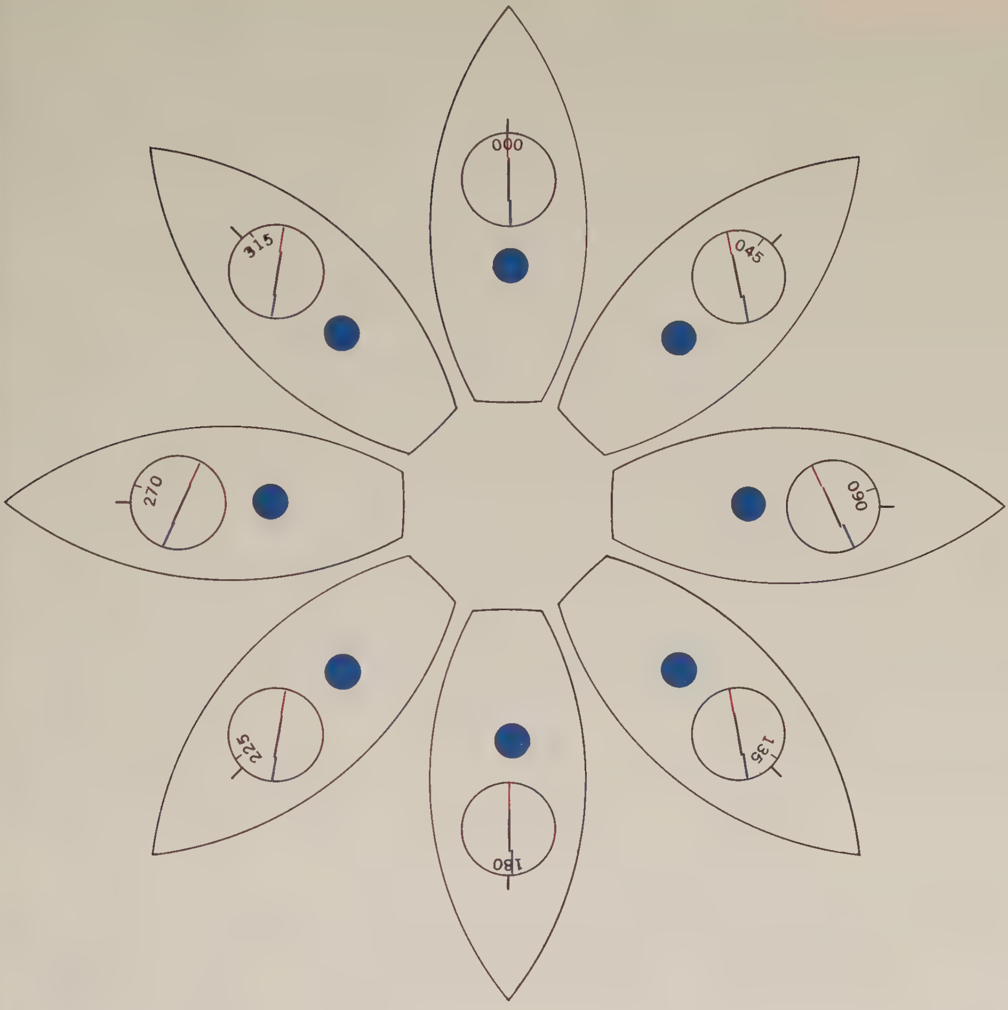

FIGURE 720.—Deviation due to induced magnetism in vertical soft iron if the resultant field is that of a blue pole on the center line aft of the compass.

directive force is strengthened. On headings with an easterly component the deviation is westerly, and on headings with a westerly component the deviation is easterly. In each case the maximum occurs when the vessel is on compass heading approximately east or west. Thus, the deviation due to induced magnetism in vertical soft iron is semicircular, coefficient *B*. In figure 720 the headings shown on the compass card are the magnetic headings of the vessel. Their offset from the lubber's line shows the direction and relative magnitude of deviation.

The deviating force due to induced magnetism in vertical soft iron is neutralized by placing a bar of soft iron in a vertical position on the opposite side of the compass from the effective pole due to the field of the vessel. This piece of metal is called a **Flinders bar,** after Captain Matthew Flinders, RN (1774–1814), an English navigator and explorer who is generally given credit for discovering both the effect and method of adjustment (art. 111). Today, most binnacles for large ships provide a tube for insertion of a Flinders bar. The bar consists of various lengths of soft iron placed end to end; with the remainder of the tube being filled with spacers of nonmagnetic mate-

rial, usually wood, brass, or aluminum. The standard Flinders bar is two inches in diameter and is divided into six sections, one each of 12, 6, 3, and 1½ inches, and two of ¾ inch. This permits use of any multiple of ¾ inch to 24 inches. All the iron pieces should be above the spacers in the tube, without a gap between pieces, the largest piece being on top. The upper end is then about two inches above the level of the compass card. For short lengths, one or more spacers should be omitted so that about $\frac{1}{12}$ of the length of the bar is above the level of the compass card.

The various pieces should be inserted in the tube carefully. If they are dropped, they may acquire some permanent magnetism. This reduces their effectiveness for the purpose intended. Each piece should be tested from time to time to determine whether or not it has acquired permanent magnetism. This can be done by holding it vertical with one end east or west of the compass and very near the compass magnets, noting the reading of the compass, and then inverting the piece so that the ends are interchanged. If the reading differs, permanent magnetism has been acquired by the iron rod. The temporary change of reading while the rod is being inverted should be ignored. In making the test, one should be careful to place the rod in the same position relative to the compass before and after inversion. On an easterly or westerly heading the Flinders bar holder can be used. A small amount of permanent magnetism can be removed by holding the rod approximately parallel to the lines of force of the earth's field, with the blue pole of the rod toward the north, and tapping one end of the rod gently with a hammer. Several alternate tests and treatments may be needed to make the rod magnetically neutral. If this process is not effective in removing the permanent magnetism, the rod should be heated to a dull red and allowed to cool slowly.

An older type Flinders bar, rarely encountered with modern compasses, consists of a number of slender rods of equal length, the *number* of rods being varied rather than the length of a single rod. Another old system consists of using a single rod of fixed length, and varying its distance from the compass.

721. Determination of Flinders bar length.—As indicated in articles 719 and 720, coefficient B magnetism may be introduced both by permanent magnetism of the vessel and by induced magnetism in asymmetrical vertical soft iron. A problem thus arises as to what part of the deviation on headings magnetic east and west is due to each cause. If the vessel remains on an even keel at about the same magnetic latitude, adjustment can be made without this knowledge. However, satisfactory performance under all conditions requires separate adjustment for each cause.

There are several possible solutions to this problem. The two sources can be separated by use of the fact that a change of magnetic latitude affects them differently. On the magnetic equator there is no vertical component of the earth's magnetic field, and consequently no induced magnetism in vertical soft iron. Therefore, if the compass is adjusted on the magnetic equator, all coefficient B deviation is due to permanent magnetism, and is removed by the fore-and-aft magnets. After a considerable change of magnetic latitude, the deviation on a heading of magnetic east or west is again measured. By means of the curves of figure 721, A, the required amount of standard two-inch Flinders bar is determined. Accurate results will be obtained only if the vessel is magnetically the same at both latitudes. That is, a structural change, an alteration in the number or position of magnets or other devices used in the adjustment, magnetic treatment, etc., invalidates the measurement. After the required amount of Flinders bar has been inserted, some deviation may be present due to mutual induction among the various devices used for adjustment. This should be removed by means of the permanent magnets. Once the correct amount of Flinders bar has been

installed, no change should be needed unless there is a substantial change in the amount or location of vertical soft iron, or unless the compass is relocated.

This method is not always practical. If the correct length and location of Flinders bar for another vessel of similar construction and compass location have been determined previously, the same length can be used for the compass being adjusted. If a large change in magnetic latitude can be made without appreciable change of deviation on headings east and west, the amount of Flinders bar is correct. If the deviation changes,

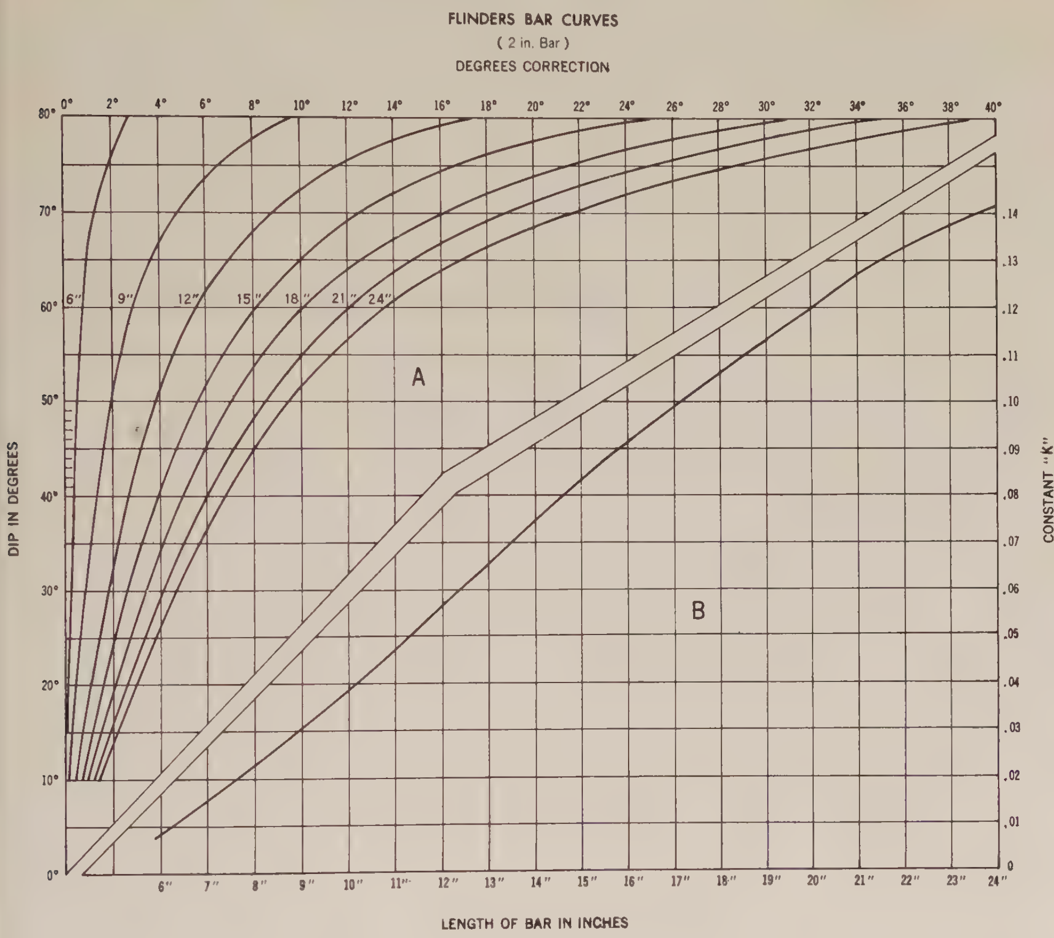

FIGURE 721.—Flinders bar curves: A, if deviation due to induced magnetism in vertical soft iron is known; B, if coefficient K is known.

readjustment is needed. By studying the structure of the vessel, an experienced compass adjuster may be able to make a reasonably accurate estimate of the length to use.

In the absence of enough reliable information to permit a reasonably accurate determination of the correct length, the Flinders bar may be omitted entirely, and the deviation on east and west headings removed by means of the fore-and-aft permanent magnets. This is common practice for yachts, fishing vessels, and even for some coastal vessels which do not change magnetic latitude more than a few degrees.

The correct length of Flinders bar can be determined by figure 721, B, if reliable data are available on the deviation occurring on magnetic east or west headings at two

widely separated magnetic latitudes. The constant K is determined by computation, using the formula

$$K=\lambda \frac{H_2 \tan d_2-H_1 \tan d_1}{Z_2-Z_1}$$

in which

K=a constant proportional to the required length of Flinders bar.

λ=shielding factor, or the proportion of the earth's field effective at the compass. Generally, it varies from about 0.7 to 1.0, averaging about 0.9 for compasses in exposed positions, and 0.8 for those surrounded by metal deck houses.

H_1=horizontal intensity of earth's magnetic field at place of first deviation reading.

H_2=horizontal intensity of earth's magnetic field at place of second deviation reading.

d_1=total deviation on heading magnetic east or west at place of first deviation reading.

d_2=total deviation on heading magnetic east or west at place of second deviation reading.

Z_1=vertical intensity of earth's magnetic field at place of first deviation reading.

Z_2=vertical intensity of earth's magnetic field at place of second deviation reading.

The values of horizontal and vertical intensity (H and Z) can be obtained from H.O. charts No. 1701 and 1702, respectively.

The constant K represents a mass of vertical soft iron (the *c* rod) causing deviation. From the intersection of the curve of figure 721, B, and a horizontal line through the value of constant K, draw a vertical line to the bottom scale, which shows the required length of Flinders bar.

If some length of Flinders bar was in place when the two deviation readings were made, enter the graph of figure 721, B, with this length and determine the corresponding value of K. Call this K_2 and that obtained by computation K_1. Algebraically add K_1 and K_2 to determine the value of K to use for finding the total length of Flinders bar required. If the Flinders bar is forward of the compass, K_2 is negative (−), and if aft of the compass, K_2 is positive (+). In the computation of K_2, both Z_1 and Z_2 are positive in north magnetic latitude and negative in south magnetic latitude. Also, d_1 and d_2 are positive if deviation is east on magnetic heading east in north latitude or magnetic heading west in south latitude. If *either* the heading or direction of the deviation is reversed, the sign of d_1 or d_2 is negative. If both are reversed, the sign is positive. If the value of K is negative, the Flinders bar should be installed forward of the compass, and if positive, it should be installed aft.

Example.—The deviation of a magnetic compass of a ship on heading magnetic east is 1°E at New York (H 0.170, Z 0.539) and 9°E at Panama (H 0.311, Z 0.260). The shielding factor is 0.8.

Required.—The correct length of Flinders bar if (1) no Flinders bar is in place during observations, (2) six inches of Flinders bar is in place forward of the compass during observations.

Solution.—

$$(1)\ K_1=0.8\left(\frac{0.311\times0.15838-0.170\times0.01746}{0.260-0.539}\right)$$

$$=(-)\ 0.133$$

$$K_2=0$$

$$K=K_1+K_2=(-)\ 0.133$$

From figure 721, B, the correct amount of Flinders bar is 22 inches. Since the amount used must be a multiple of ¾ inch, the amount to use is 21¾ inches. Since K is negative, the bar should be installed forward of the compass.

(2) From figure 721, B, the value of K_2 corresponding to six inches of Flinders bar is 0.009. The value is negative because the bar is forward of the compass. Therefore, $K_1+K_2=(-)\,0.133+(-)\,0.009=(-)\,0.142$. From figure 721, B, the *total* amount of Flinders bar required is 24 inches, which should be installed forward of the compass.

Answers.—(1) 21¾ inches of Flinders bar installed forward of the compass, (2) 24 inches of Flinders bar installed forward of the compass.

When the length of Flinders bar is determined in this way, accurate results can be expected only if the vessel is magnetically unchanged between deviation readings.

Lord Kelvin suggested the following rule for improving the adjustment for coefficient B if no better method is available:

Remove the deviation observed on magnetic east or west headings by means of fore-and-aft B *magnets when the vessel has arrived at places of weaker vertical magnetic field, and by means of Flinders bar when it has arrived at places of stronger vertical magnetic field, whether in the northern or southern hemisphere.*

After a number of applications of this rule following alternate passage from weaker to stronger fields and then stronger to weaker fields, the amount of Flinders bar should be very nearly correct.

722. Adjustment for deviation due to induced magnetism in symmetrical horizontal soft iron.—That part of horizontal soft iron which is symmetrically arranged with respect to the compass can be considered equivalent to two rods extending through the compass, one in a fore-and-aft direction ($-a$ rod) and the other in an athwartship direction ($-e$ rod). The deviation caused by both of these rods is quadrantal, but of opposite sign. If both rods were equally effective in causing deviation, they would cancel each other and no deviation would result on any heading. In most vessels, however, the athwartships iron dominates, and deviation due to all horizontal soft iron can generally be considered to be that which would result from a single $(-)\,e$ rod. In figure 722a the deviation resulting from such a rod is shown for various magnetic headings in any latitude. There is no deviation on any cardinal heading, but the directive force is weakened on heading magnetic east or west. The maximum deviation occurs on intercardinal headings by compass, being easterly in the northeast and southwest quadrants, and westerly in the other two quadrants. This is coefficient D deviation. In figure 722a the headings shown on the compass card are the magnetic headings of the vessel. Their offset from the lubber's line shows the direction and relative magnitude of deviation.

The field causing this deviation is neutralized by installing two masses of soft iron abeam of the compass, on opposite sides and equidistant from its center. Such iron is usually in the form of hollow spheres or cylinders, called **quadrantal correctors.** These can be moved in or out in an athwartship direction along brackets on the sides of the binnacle.

Quadrantal correctors act as $(+)\,e$ parameters which neutralize the $(-)\,e$ parameter of the athwartships iron. As shown in figure 722b, the portion of the corrector adjacent to the compass is always of opposite polarity to the deflecting force. The amount of the correction can be adjusted by moving the correctors toward or away from the compass card. If the inboard limit of travel is reached without fully removing the deviation, larger correctors are needed. If overcorrection occurs at the outboard limit, smaller correctors are needed. A single corrector can be used, but this produces an unbalanced field which is less desirable than a balanced one. In general, large correctors at a greater distance are preferable to small correctors close up because there is less mutual induction

between the correctors if they are widely separated. In the rare case when quadrantal deviation is *westerly* on heading northeast (coefficient D is negative, the fore-and-aft horizontal soft iron predominating), the quadrantal correctors should be mounted fore-and-aft on the binnacle.

Figure 722c shows the approximate amount of deviation correction to be expected from correctors of various sizes, shapes, and distance from the center of a standard

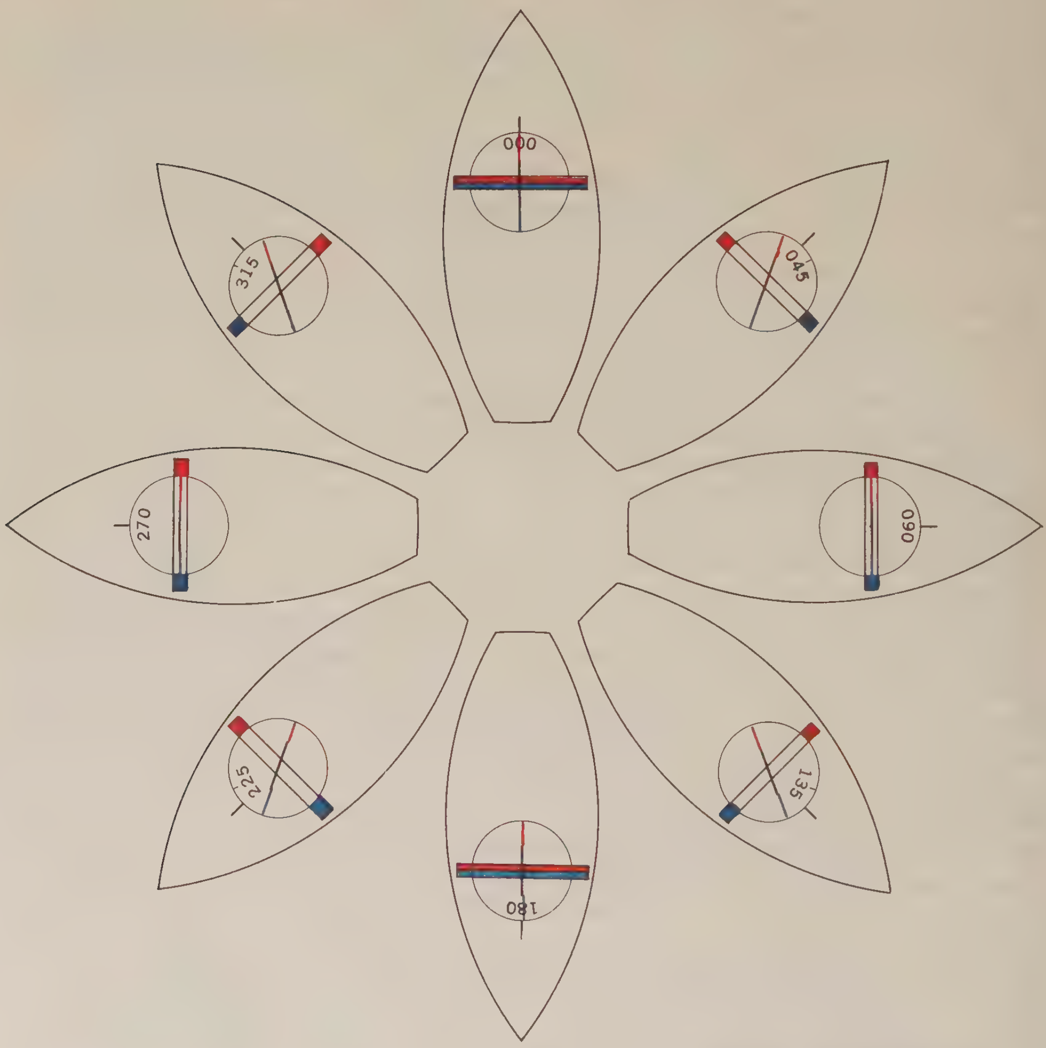

FIGURE 722a.—Deviation caused by induced magnetism in symmetrical horizontal soft iron.

Navy 7½-inch compass. The data apply to either the athwartships or fore-and-aft position.

Like the Flinders bar (art. 720), the quadrantal correctors should be handled carefully, and checked from time to time to see if they have acquired permanent magnetism. The test can be made by rotating each corrector through 180° without altering its distance from the center. If the compass heading changes, the correctors have acquired permanent magnetism which can be removed by tapping with a hammer when

the blue pole is toward the north, or by removing the spheres, heating them to a dull red, and permitting them to cool slowly.

723. Adjustment for deviation due to induced magnetism in asymmetrical horizontal soft iron.—If the horizontal soft iron is not arranged symmetrically with respect to the compass, resulting in an effective pole which is on neither the fore-and-aft nor athwartships axis through the compass, quadrantal deviation with its maximum values

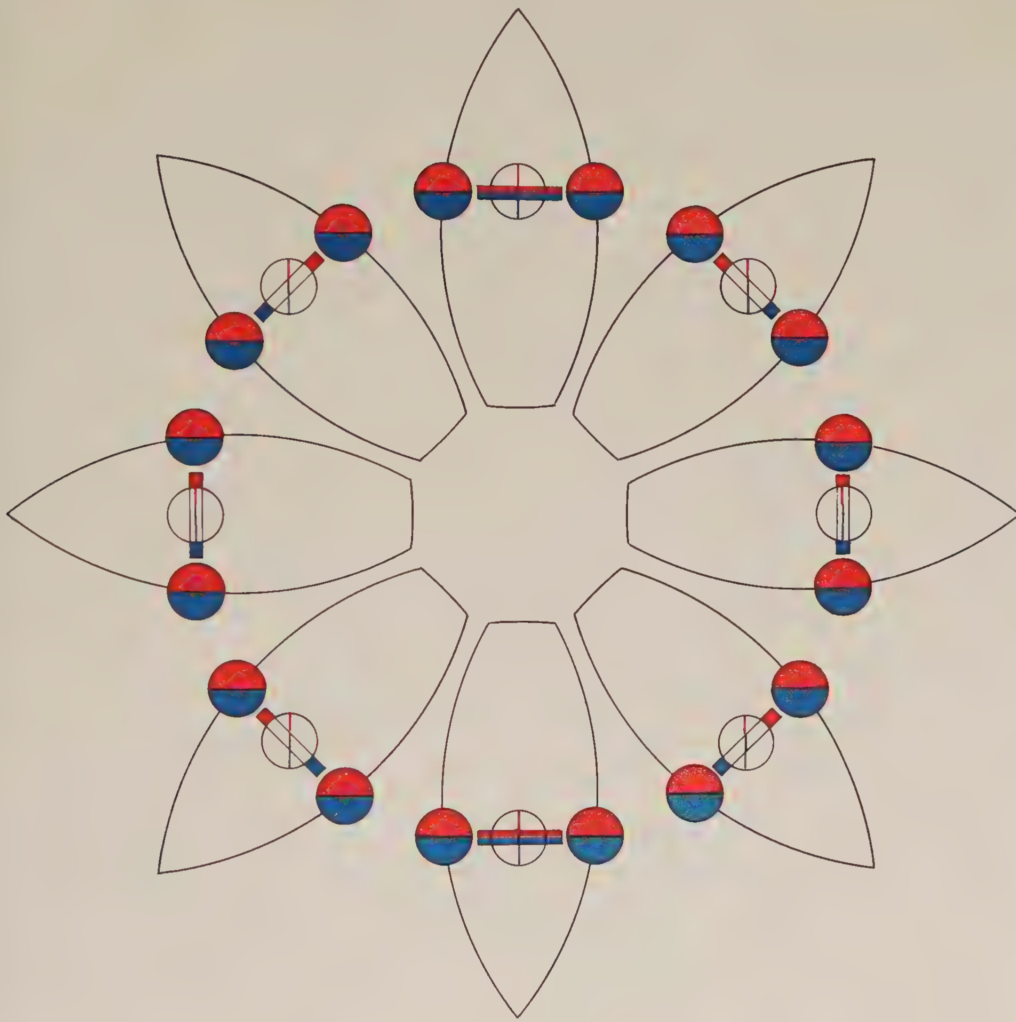

FIGURE 722b.—Adjustment for symmetrical horizontal soft iron.

on cardinal headings (coefficient E) results. Constant deviation (coefficient A) may also be caused by this arrangement. Either coefficient E or A is due to a combination of parameters.

For a centerline compass on a ship of conventional construction, any deviation due to induced magnetism in asymmetrical horizontal soft iron is small, and many installations make no provision for neutralizing the effect. However, some binnacles are provided with a pair of ***E*-links,** which are bars that can be attached to the side brackets to permit the quadrantal correctors to be slewed somewhat with respect to the com-

pass. When this has been done, the horizontal axis through the correctors and the compass makes an angle with the athwartship axis of the compass.

After a compass has been adjusted, any remaining constant deviation due to magnetic coefficient *A* is likely to be very small. If such deviation exists, its cause is likely to be chiefly mechanical. If a compass is used primarily for determining the heading (as a steering compass), all constant deviation can be removed by realignment of the binnacle so as to rotate the lubber's line by the required amount. However, if a compass is to be used for observing bearings or azimuths, only the mechanical *A*-error should be removed in this manner. This is because such readings are taken on the face of the card itself, and are therefore not affected by misalignment of the lubber's line. The two components of constant deviation can be separated in the following manner: Measure the deviation on various headings by means of bearings or azimuths (art. 1428). This includes only magnetic coefficient *A*. Then measure the deviation on various headings by means of the lubber's line, comparing the heading by compass with the magnetic heading determined by pelorus or gyro compass. This includes the combined effect of magnetic and mechanical coefficient *A* deviation. The difference between the two values is the mechanical coefficient *A*. For a properly adjusted compass the magnetic coefficient *A* deviation is so small that provision is not made for its removal.

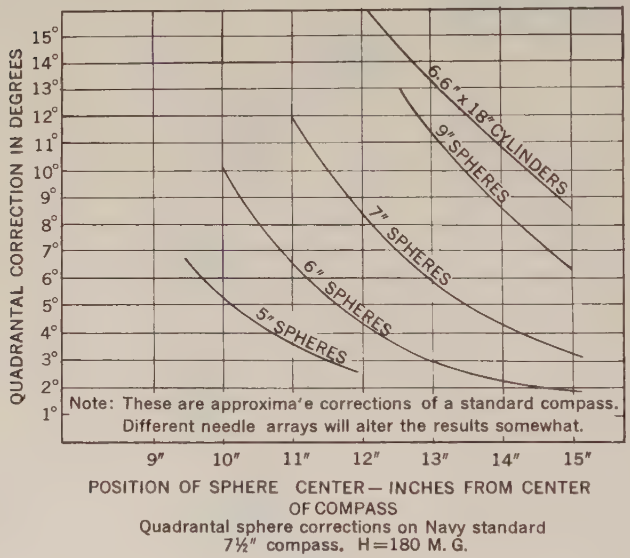

FIGURE 722c.—Effect of various quadrantal correctors.

724. Heeling error.—All of the effects discussed previously refer to a vessel on an even keel. When the vessel heels, conditions are altered. Deviation which now appears, or the *change* of deviation from that when the vessel was on an even keel, is called **heeling error.** For a constant angle of heel and a steady heading, this error remains essentially unchanged. However, it tends to increase as the heel becomes greater, and to reverse sign as the heel changes from one side to another. Therefore, if a vessel is rolling or pitching, the compass tends to oscillate. This increases the difficulty of reading the compass.

The cause of heeling error is the displacement of the permanent and induced magnetic fields with respect to the compass. Figure 724 shows a vessel heeled to starboard on heading magnetic north or south, in north magnetic latitude. The vessel was constructed in north magnetic latitude. On an even keel the vertical parameter *R* of permanent magnetism for a centrally located compass is directly below the compass, with the blue pole nearer the compass. When the vessel is heeled as shown at *A*, the blue pole is to port of the compass, causing deviation toward that side. A vertical rod of soft iron below the compass (parameter *k*) exerts a similar influence, as shown at *B*. An athwartship horizontal rod through the compass has no deviating effect while the vessel is on an even keel, but when it heels as shown in figure 724, the vertical component of the earth's field causes the port end to acquire a blue pole and the starboard end a red pole (parameter *e*), as shown at *C*. Each of the three causes shown in figure 724 results in a blue pole being established on the port or high side of the vessel. This causes

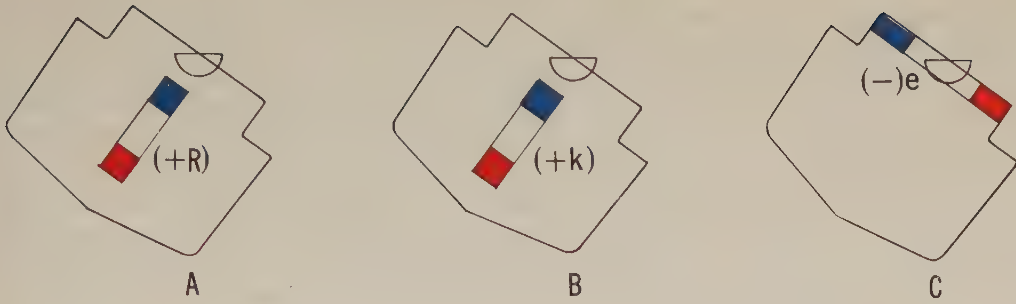

FIGURE 724.—Effect of heel.

the red north ends of the compass magnets to be attracted to this side. If the heading is magnetic north, the deviation is westerly, and if magnetic south, it is easterly. This effect is offset somewhat by the changed magnetic field surrounding the quadrantal correctors. On heading magnetic east or west, these components have no deviating effect, but the directive force of the compass is strengthened or weakened. When the vessel pitches, the effects described for north-south and east-west headings are reversed. On a heading other than a cardinal direction (magnetic) the effect is some combination of the two. The magnetic situation varies not only with the heading, but also with the magnetic latitude and the magnetic history of the vessel.

Although heeling error is due in part to permanent magnetism and in part to induced magnetism, the induced magnetism generally exerts the greater influence. The most effective method of neutralizing this effect would be to attack each parameter separately. This would require the placement of soft iron *above* the compass. Since this would not be a convenient arrangement, the condition is improved by placing a vertical permanent magnet, called a **heeling magnet,** centrally *below* the compass, and adjusting its height until the error is minimized. In north magnetic latitude, the red end is placed uppermost in most installations. As the vessel proceeds to lower magnetic latitudes, parameter R becomes less effective in producing deviation because of the stronger directive force due to the horizontal component of the earth's magnetic field. Parameters k and e become weaker because of decreased intensity of the vertical component of the earth's field, and the strengthening of the horizontal component also reduces their effect. Therefore, the heeling magnet requires readjustment as the magnetic latitude changes. As the vessel approaches the magnetic equator, the heeling magnet should be lowered. After the vessel crosses the magnetic equator, it may be necessary to invert the heeling magnets, so that the opposite end is uppermost. A change in the setting of the heeling magnet may introduce deviation on headings of compass east or west because of altered induction between the heeling magnet and the Flinders bar. This should be removed by means of the fore-and-aft (B) magnets in the trays below the compass.

If adjustment for heeling error is made when the vessel is tied up or at anchor, it is best done by listing the vessel on a northerly or southerly heading, and adjusting the heeling magnet until the reading of the compass is restored to what it was before the vessel heeled. If the adjustment is made at sea, the vessel should be placed on a heading of compass north or south. If there is little rolling, the vessel can be listed and the compass reading restored, as at dockside. If the vessel rolls moderately on this heading, the heeling magnet should be placed at that height at which oscillation of the compass card is minimum. If the setting for minimum oscillation is different on north and south headings, the mean position should be used. Any yawing of the vessel should be considered when reading the compass under rolling conditions.

The approximate position of the heeling magnet can be determined by means of

an instrument known as a **heeling adjuster** or a **vertical force instrument,** a form of **dip needle.** This consists of a small magnet balanced about a horizontal axis by means of a small adjustable weight. A scale indicates the distance of the weight from the axis. The instrument is taken ashore and balanced at a place where the earth's field is undisturbed, the magnet being in a magnetic north-south direction, approximately. The instrument is then taken aboard ship, the compass removed from its binnacle, and the heeling adjuster installed in its place. The weight is set to a distance equal to the distance determined ashore, multiplied by λ, the shielding factor (art. 721). The heeling magnet is then moved up or down until the magnet of the instrument is level. This should be approximately the correct setting. This method is used principally when the listing of a vessel is difficult or impractical.

725. Soft iron correctors and nearby magnets.—The soft iron correctors used in compass adjustment are near enough to the compass magnets and the magnets used in compass adjustment to be influenced by them.

The Flinders bar acquires a certain amount of induced magnetism from the fields of the heeling magnet and the fore-and-aft (*B*) corrector magnets. The approximate amount of deviation caused by induced magnetism from the heeling magnet of a 7½-inch compass when H=0.165 is shown in figure 725. Because of such induced magnetism, the "drop-in" method of determining the amount of Flinders bar is not accurate. By this method, Flinders bar lengths are added until the compass reading changes by the required amount. Better adjustment is achieved by using the required amount of Flinders bar and removing any remaining deviation on east-west headings by means of the fore-and-aft magnets. The principal reason that it is preferable to use a larger number of magnets at a distance from the compass than a smaller number near it, is that the former arrangement produces less induced magnetism in the Flinders bar and quadrantal correctors. If the Flinders bar length is changed, the deviation on headings of magnetic east and west should be checked, and any needed adjustment made by means of fore-and-aft magnets. When all correctors have been put in place, their positions relative to each other are constant. Therefore, the Flinders bar acts as a permanent magnet, and the resulting deviation is semicircular (coefficient *B*). The Flinders bar may also introduce a small amount of quadrantal deviation (coefficient *D*), its action being somewhat like that of a quadrantal corrector placed in the fore-and-aft axis of the compass.

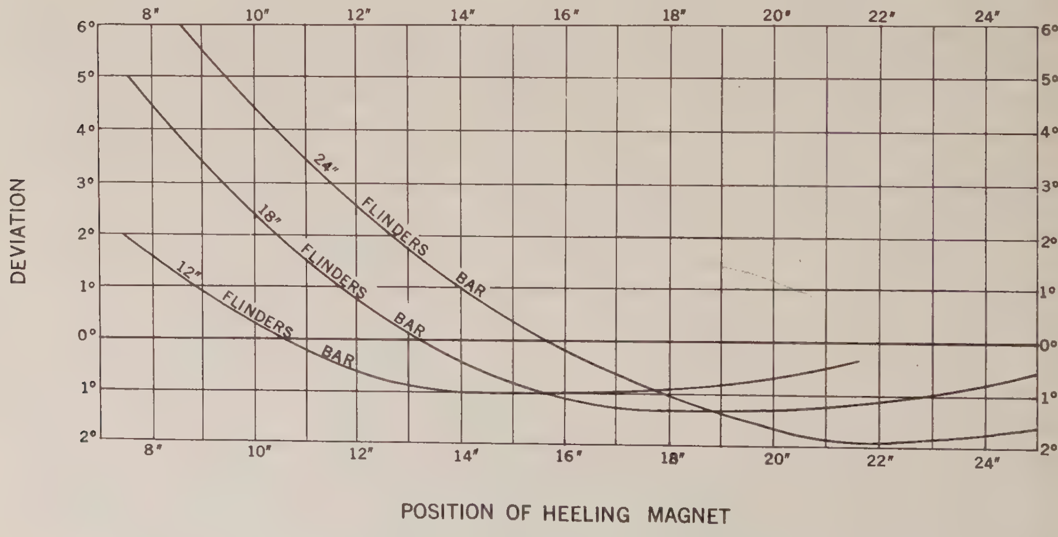

FIGURE 725.—Deviation due to inductive effect of heeling magnet on Flinders bar.

The quadrantal correctors acquire induced magnetism from the fields of the fore-and-aft (B) magnets, the athwartship (C) magnets, and the compass magnets. The magnetism acquired from the B and C magnets is semicircular (coefficient B from the B magnets, and coefficient C from the C magnets), and that acquired from the field of the compass magnets is quadrantal (coefficient D). The semicircular deviation is minimized by keeping the B and C magnets as far away from the quadrantal correctors as practicable, and any deviation that does exist is removed by means of these magnets. The quadrantal deviation is removed by means of the quadrantal correctors themselves. The compass magnets of most modern compasses have little effect upon the quadrantal correctors.

Because of the interaction between the various correctors, it is good practice to insert the required amount of Flinders bar, and to install the quadrantal correctors and heeling magnet at their approximate positions before adjusting the compass. If a radical change is subsequently made in any of these adjustments, the settings of the B and C magnets should be checked and altered if necessary.

Analysis of Deviation

726. Nature and purpose of analysis.—An analysis consists of determining the approximate value of each of the six coefficients, and studying the results. The purpose of the analysis is to give the compass adjuster an understanding of the magnetic properties of the vessel. This provides the basis for the approximate placement of the various correctors, and suggests possibilities for further refinement in the adjustment. Without an analysis, compass adjustment is a more-or-less mechanical process. Fewer mistakes are likely to be made by the person who understands the nature of the magnetic field he seeks to neutralize.

727. The analysis.—The first step in an analysis is to record the deviation on each cardinal and intercardinal heading *by the compass to be analyzed.* For the purpose of analysis, easterly deviation is considered positive (+), and westerly deviation negative (−). Approximate values of the various coefficients are:

Coefficient A—mean of deviation on all headings.

Coefficient B—mean of deviation on headings 090° and 270°, with sign at 270° reversed.

Coefficient C—mean of deviation on headings 000° and 180°, with sign at 180° reversed.

Coefficient D—mean of deviation on intercardinal headings, with signs at headings 135° and 315° reversed.

Coefficient E—mean of deviation on cardinal headings, with signs at 090° and 270° reversed.

Coefficient J—change of deviation for a heel of 1° while the vessel heads 000° by compass. It is considered *positive* if the north end of the compass card is drawn toward the *low* side, and *negative* if toward the *high* side.

Example.—A magnetic compass which has not been adjusted has deviation on cardinal and intercardinal compass headings as follows:

Compass heading	*Deviation*	*Compass heading*	*Deviation*
000°	1°5 W	180°	8°0 E
045°	34°0 E	225°	1°5 W
090°	31°0 E	270°	29°0 W
135°	13°5 E	315°	36°0 W

On heading compass north the deviation is 13°5 W when the vessel heels 10° to starboard.

Required.—The approximate value of each coefficient.

Solution.—

$$A=\frac{-1^\circ.5+34^\circ.0+31^\circ.0+13^\circ.5+8^\circ.0-1^\circ.5-29^\circ.0-36^\circ.0}{8}=(+)\ 2^\circ.3$$

$$B=\frac{31^\circ.0+29^\circ.0}{2}=(+)\ 30^\circ.0$$

$$C=\frac{-1^\circ.5-8^\circ.0}{2}=(-)\ 4^\circ.8$$

$$D=\frac{34^\circ.0-13^\circ.5-1^\circ.5+36^\circ.0}{4}=(+)\ 13^\circ.8$$

$$E=\frac{-1^\circ.5-31^\circ.0+8^\circ.0+29^\circ.0}{4}=(+)\ 1^\circ.1$$

$$J=\frac{-13^\circ.5+1^\circ.5}{10}=(-)\ 1^\circ.2$$

Answers.—*A* (+) 2°.3, *B* (+) 30°.0, *C* (−) 4°.8, *D* (+) 13°.8, *E* (+) 1°.1, *J* (−) 1°.2.

On any compass heading (CH) the deviation (d) from each coefficient acting alone is:

Coefficient A: $d_A=A$
Coefficient B: $d_B=B \sin CH$
Coefficient C: $d_C=C \cos CH$
Coefficient D: $d_D=D \sin 2CH$
Coefficient E: $d_E=E \cos 2CH$
Coefficient J: $d_J=J \cos CH$.

For a vessel on an even keel, the total deviation on any compass heading is the algebraic sum of the deviation due to each of the first five coefficients:

$$d=d_A+d_B+d_C+d_D+d_E=A+B \sin CH+C \cos CH+D \sin 2CH+E \cos 2CH.$$

For the compass of the example given above, the deviation due to each component, and the total, on various headings is:

CH	A	B	C	D	E	d
°	°	°	°	°	°	°
000	+2.3	0.0	−4.8	0.0	+1.1	−1.4
015	+2.3	+7.8	−4.6	+6.9	+1.0	+13.4
030	+2.3	+15.0	−4.2	+12.0	+0.6	+25.7
045	+2.3	+21.2	−3.4	+13.8	0.0	+33.9
060	+2.3	+26.0	−2.4	+12.0	−0.6	+37.3
075	+2.3	+29.0	−1.2	+6.9	−1.0	+36.0
090	+2.3	+30.0	0.0	0.0	−1.1	+31.2
105	+2.3	+29.0	+1.2	−6.9	−1.0	+24.6
120	+2.3	+26.0	+2.4	−12.0	−0.6	+18.1
135	+2.3	+21.2	+3.4	−13.8	0.0	+13.1
150	+2.3	+15.0	+4.2	−12.0	+0.6	+10.1
165	+2.3	+7.8	+4.6	−6.9	+1.0	+8.8
180	+2.3	0.0	+4.8	0.0	+1.1	+8.2
195	+2.3	−7.8	+4.6	+6.9	+1.0	+7.0
210	+2.3	−15.0	+4.2	+12.0	+0.6	+4.1
225	+2.3	−21.2	+3.4	+13.8	0.0	−1.7
240	+2.3	−26.0	+2.4	+12.0	−0.6	−9.9
255	+2.3	−29.0	+1.2	+6.9	−1.0	−19.6
270	+2.3	−30.0	0.0	0.0	−1.1	−28.8
285	+2.3	−29.0	−1.2	−6.9	−1.0	−35.8
300	+2.3	−26.0	−2.4	−12.0	−0.6	−38.7
315	+2.3	−21.2	−3.4	−13.8	0.0	−36.1
330	+2.3	−15.0	−4.2	−12.0	+0.6	−28.3
345	+2.3	−7.8	−4.6	−6.9	+1.0	−16.0

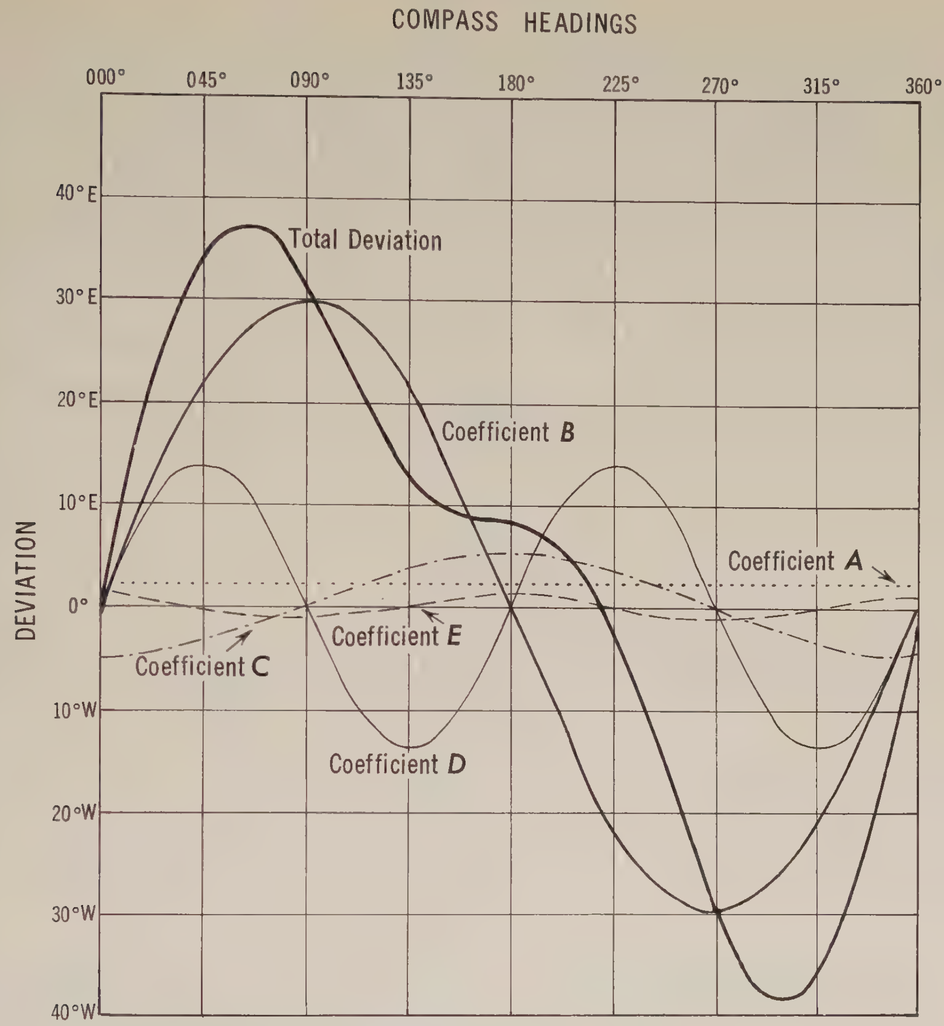

FIGURE 727.—Coefficients and total deviation of an unadjusted magnetic compass.

The various components and the total deviation are shown in graphical form in figure 727. Since the various coefficients are only approximated by the method given above, the curve of total deviation found in this way should not be expected to coincide exactly with a curve drawn from values found by measurement on the various headings.

The *shapes* of the curves of figure 727 are typical of those of an unadjusted compass of a large steel ship. However, an analysis of the results indicates the following:

Coefficient *A* is normally negligible. The presence of more than 2° of constant error indicates an abnormal condition which should be discovered and corrected. If the vessel has been in service for some time without major structural change, and no misalignment of the lubber's line of the compass or the pelorus or gyro compass used for measuring deviation has been noted previously, it is probable that a mistake has been made in determining the azimuth or bearing used for establishing deviation.

Coefficient *E* is normally negligible for a compass located on the center line of the vessel. This vessel has an excessive amount, which should be corrected by slewing the quadrantal correctors, using an *E*-link.

Since deviation is east on heading 090° and west on 000°, it is probable that the blue pole of the vessel's permanent field is on the port bow.

The compass being unadjusted, no Flinders bar is in place, and the large *B* deviation on heading 090° is a combination of deviation from induced magnetism in vertical soft iron and that due to the permanent magnetism of the vessel. Since the deviation on heading 270° is nearly the same as that on 090°, but of opposite sign, adjustment on one of these headings should result in nearly correct adjustment on the other. Since some *B* and *C* deviation occurs on intercardinal headings, while no *D* deviation occurs on cardinal headings, adjustment for *B* and *C* should be made before that for final *D* adjustment.

A second analysis made after adjustment may reveal possibilities for further refinement in the adjustment.

If heeling error is measured on any heading other than compass north or south, the value of coefficient *J* can be found by means of the formula:

$$\mathrm{d}=J\cos \mathrm{CH}$$

converted to

$$J=\frac{\mathrm{d}}{\cos \mathrm{CH}}$$

or

$$J=\mathrm{d}\sec \mathrm{CH}.$$

If HE is the total observed change of deviation (heeling error), and i is the angle of heel in degrees (for relatively small angles), the formula becomes

$$J=\frac{\mathrm{HE}\sec \mathrm{CH}}{i}.$$

If heeling error is sought, the formula becomes

$$\mathrm{HE}=Ji\cos \mathrm{CH}.$$

Adjustment Procedure

728. Preliminary steps.—Efficient and accurate adjustment is preceded by certain preliminary steps best made while a vessel is tied up or at anchor.

The magnetic environment of the compass should be carefully inspected. Stray magnetic influences such as those caused by tools, direct current electric appliances, personal equipment (such as keys, pocketknives, or steel belt buckles), nylon clothing, etc., should be eliminated. Permanently installed equipment of magnetic material (such as cargo booms, boat davits, cranes, or guns) should be placed in the positions they normally occupy at sea. The degaussing coils should be secured by the reversing process (art. 743) if this has not already been done.

The compass itself should be checked carefully for bubbles, and to be sure it is centered on the vertical axis of the binnacle. If it is, and the vessel is on an even keel, there is no change of reading as the heeling magnet is raised and lowered in its tube. An adjustment should be made to the gimbal rings if the compass is off center. There should be no play in the position of the compass once it is centered.

The lubber's line, too, should be checked to be sure it is in line with the longitudinal axis of the vessel. This can be done by sighting on the jackstaff if the compass is on the center line. If it is not, a batten might be erected at a distance from the center line equal to the distance from the center of the compass to the center line. Another way is to determine the distance from the compass to the center line and from this point to the jackstaff. The first distance divided by the second is the natural tangent of the

angle at the compass between the line of sight to the jackstaff and the line of sight through the lubber's line. If the compass is in an exposed position where bearings can be taken, and the true heading is known, the observed relative bearing of a distant object can be compared with that obtained by careful measurement on the chart. If the vessel is at anchor or underway, the method explained in article 723 can be used.

If a pelorus or gyro compass or repeater is to be used in determining deviation of the compass, its lubber's line should be checked in the same manner, or by comparing a relative bearing of a distant object taken by two instruments, the lubber's line of one having previously been checked. If a gyro compass is to be used, it is checked to see that it is synchronized with a repeater. With accurate synchronization, any error in one will also be present in the other. The speed and latitude adjustments of the gyro compass should be checked carefully.

All devices to be used in the adjustment should be checked to see that they are on hand and in good condition. The trays for *B* and *C* permanent magnets, the quadrantal correctors, and heeling magnet should be checked for freedom of motion. The Flinders bar and quadrantal correctors should be checked for permanent magnetism. The correct amount of Flinders bar should be placed in its tube. The quadrantal correctors should be placed in their approximate positions, being centered if no better information is available. The heeling magnet is generally placed with the red end uppermost in north magnetic latitude, and the blue end uppermost in south magnetic latitude. If no better information is available, the heeling magnet should be placed near the bottom of the tube.

Plans for the actual adjustment should be made carefully. A suitable time and location should be selected. If landmarks are to be used, suitable ones should be selected to provide the information desired. Areas of heavy traffic should be avoided. If azimuths of the sun are to be used, a time should be selected when the sun will not be too high in the sky for suitable observation. A curve of magnetic azimuths (art. 731) should be made, and just before adjustment begins a comparing watch should be checked and set, if possible, to correct time. Local variation should be checked carefully, and corrected for date, if necessary. Any necessary recording and work forms should be made up. Each person to participate in the adjustment should be instructed regarding the general plan and his specific duties.

729. Underway procedure.—When everything is in order and the vessel has arrived at its adjusting area, final adjustment can begin. Trim should be normal, and the vessel free from list, so that no heeling error is present.

All adjustment headings should be *magnetic*. Compass headings can be used, but this results in a slight turn being required every time an adjustment is altered. Also, the coefficients are not completely separated unless the vessel is on magnetic headings.

Turns to each new heading should be made slowly, swinging slightly beyond the desired heading before steadying on it. If steering is by gyro, the gyro error should be checked on each heading if time and facilities permit. The vessel should remain on each heading for at least two minutes before the deviation is determined or an adjustment made, to permit the compass card to come to rest and the magnetic condition of the vessel to become settled. If observations are made before the vessel's magnetism becomes settled, the reading will be incorrect by an amount called the **Gaussin error.**

Adjustments should be carried out in the correct order, as follows:

1. Steady on magnetic heading 090° (or 270°) and adjust the fore-and-aft permanent magnets until the compass heading coincides with the magnetic heading, thus

removing all coefficient B on this heading. Use magnets in pairs, from the bottom up, with the trays at the lowest point of travel. When overcorrection occurs, remove the two highest magnets and raise the trays until all deviation has been removed. If two magnets overcorrect, use a single magnet. It is not necessary to determine in advance which direction the red ends should occupy, for a mistake will be immediately apparent by an *increase* in the deviation.

2. Steady on magnetic heading 180° (or 000°) and adjust the athwartship permanent magnets until the compass heading coincides with the magnetic heading, thus removing all coefficient C on this heading. Use the same technique as in step 1.

3. Steady on magnetic heading 270° (090° if 270° was used in step 1) and remove *half* the deviation with the fore-and-aft magnets.

4. Steady on magnetic heading 000° (180° if 000° was used in step 2) and remove *half* the deviation with the athwartship magnets.

5. Steady on any intercardinal magnetic heading and adjust the position of the quadrantal correctors until the compass heading coincides with the magnetic heading, thus removing all coefficient D on this heading. Leave the quadrantal correctors at equal distances from the compass.

6. Steady on either intercardinal magnetic heading 90° from that used in step 5 and remove *half* the deviation by adjusting the positions of the quadrantal correctors, leaving them at equal distances from the compass.

7. Secure all correctors in their final positions and record their number, size, positions, and orientation, as appropriate, on the bottom of the deviation table form (if a standard form such as that shown in fig. 710 is used).

8. **Swing ship** for residual deviation. That is, determine the remaining deviation on a number of headings at approximately equal intervals. Every 15° is preferable, but if the maximum deviation is small, every 45° (cardinal and intercardinal headings) may suffice.

9. If the vessel has degaussing, energize the degaussing coils and repeat the swing.

10. Make a deviation table (art. 710) for each condition (degaussing off and on), giving values for headings at 15° intervals if the maximum deviation is large (more than about 2°), or at 45° intervals if the maximum deviation is small. Record values to the nearest half degree.

If preferred, the adjustment may be started on a north or south heading, thus reversing steps 1 and 2 and also 3 and 4.

With patience and skill, the readings can be made at exact headings. However, if some of the headings are off slightly during the swing, this need not invalidate the results. The exact headings should be recorded, and the deviation determined for these values. The results can then be plotted on cross-section paper with the deviation being one coordinate and the heading the other. The deviation at each heading to be recorded can then be read from the curve. This is good practice even when readings are made at exact headings, for if any large errors have been made, the fact will be immediately apparent. Also, such a curve may be of assistance in making an analysis. If a reason cannot be found for any marked irregularity in the curve, readings might be made again at the headings involved.

The deviation of all compasses aboard the vessel can be determined from a single swing if the heading by each compass is recorded at the moment the magnetic direction is noted. If deviation of one compass is determined by means of a magnetic bearing or azimuth (arts. 733–735), the readings of this compass can then be used to establish the magnetic headings for determining the deviation of each other compass (art. 732).

Compass adjustment is best made when the sea is relatively smooth, so that steady headings can be steered, and heeling error is absent. The setting of the heeling magnet can be checked later, preferably at the next time that the vessel is on a north or south heading and rolling moderately.

An analysis of deviation can be made either before or after adjustment. If this reveals an excessive amount of *A* (constant) deviation, the source of the error should be found and corrected (art. 723), if mechanical or mathematical. If an appreciable amount of *E* deviation is present, *E*-links should be used and the spheres slewed. This is particularly to be anticipated for compasses which are not on the center line.

The procedure outlined above is for initial adjustment aboard a new or radically modified vessel. Deviation on the heading being used for navigation should be checked from time to time and any important differences from the values shown on the deviation table should be investigated. At sea, it is good practice to compare the magnetic and gyro compasses at intervals not exceeding half an hour. The error of one or both of these compasses should be checked twice a day when means are available. In pilot waters deviation checks should be made as convenient opportunities present themselves.

Whenever there is reason to question the accuracy of the deviation table, the ship should be swung at the first opportunity and a new table made up if there are significant changes in the old one. Suitable occasions for swinging ship would be after a deviation check indicates a significant error or after any event that might result in changes in the magnetic field of the vessel (art. 712). Intervals of swing should not exceed three months even when there is no reason to question the accuracy of the deviation table.

If a swing indicates the presence of large maximum deviation, the compass should be readjusted. Unless there is reason to change it, the Flinders bar length should remain the same. Other adjustments are altered as needed, none of the correctors being removed at the beginning of adjustment. Whenever the vessel crosses the magnetic equator, the opportunity should be used to check the deviation on magnetic headings east and west. Any adjustment needed should be made by means of the fore-and-aft (*B*) magnets. Upon crossing the magnetic equator, the heeling magnet should be inverted.

The Flinders bar and quadrantal correctors should be checked for permanent magnetism at intervals of about a year, or oftener if such magnetism is suspected.

Finding the Deviation

730. Placing a vessel on a desired magnetic heading.—As indicated in article 729, compass adjustment is best made with the vessel on *magnetic* headings. The compass being adjusted cannot be used for placing the vessel on a desired magnetic heading because its deviation is unknown, and is subject to change during the process of adjustment. A number of methods are available, including use of (1) another magnetic compass of known deviation, (2) a gyro compass, (3) bearing of a distant object, and (4) azimuth (art. 1428) of a celestial body.

Magnetic compass. The deviation at the desired magnetic heading is determined from the deviation table for that compass, and applied to the magnetic heading to determine the equivalent compass heading.

Example 1.—It is desired to place a vessel on magnetic heading east, using the standard compass. The deviation table for this compass is shown in figure 710. Degaussing is off.

Required.—Heading per standard compass (psc).

Solution.—From figure 710 the deviation on heading 090° magnetic with degaussing

off is found to be 2°.5E. Therefore, the equivalent compass heading is 090°−2°.5=087°.5.

Answer.—Hpsc 087°.5.

Gyro compass. The variation is applied to the desired magnetic heading, to determine the equivalent true heading. Any gyro error is then applied to determine the equivalent gyro heading. This is the method commonly used by vessels equipped with a reliable gyro compass.

Example 2.—It is desired to place a vessel on magnetic heading north, using the gyro compass. The variation in this area is 6° W, and the gyro error is 1° E.

Required.—Heading per gyro compass (pgc).

Solution.—The equivalent true heading is 000°−6°=354°. The gyro heading is 354°−1°=353°.

Answer.—Hpgc 353°.

Bearing of distant object. If a vessel remains within a small area during compass adjustment, the bearing of a distant object is essentially constant. The required distance of the object in miles is found by multiplying the cotangent of the maximum tolerable error by the *radius* in miles of the maneuvering circle. Thus, if the maximum error that can be tolerated is 0°.5 (cotangent 114.6), and the vessel can be maneuvered within 200 yards (0.1 mile) of a fixed position such as a buoy, the object selected should be at least 114.6×0.1=11.5 miles away. The 200-yard limit is within radial lines centered at the distant object and tangent to a circle having a radius of 200 yards and its center at the center of the maneuvering area. Thus, a vessel has considerable maneuvering space along the line of sight, but very limited room across this line. However, it is not necessary that the vessel *stay* within the required area, but only that it be there when readings are made. Thus, if the center of the area is marked by a buoy, the vessel might steady on each heading while still some distance away, and note the required readings as the buoy is passed. In this way, a small radius may be practical even for a large vessel.

The object selected should be conspicuous and should have a clearly defined feature of small visible width upon which to observe bearings. The object having been selected, its true bearing from the center of the maneuvering area should be measured on the chart. To this, the variation *at the center of the maneuvering area* should be applied to determine the equivalent magnetic bearing. The desired magnetic heading should be set at the lubber's line of the pelorus, and the far vane set at the magnetic bearing of the distant object. The vessel should then be maneuvered until the object is in line with the vanes.

Example 3.—It is desired to place a vessel on magnetic heading northeast in an area where the variation is 4° E. The true bearing of a distant object is 219°.

Required.—The setting of the pelorus.

Solution.—Set 045° at the lubber's line, and set the far vane at 219°−4°=215°.

If preferred, 000° can be set at the lubber's line, and the far vane at the relative bearing, 170° (magnetic bearing minus desired magnetic heading). If a gyro repeater or a magnetic compass is used instead of a pelorus, the true (or magnetic) bearing should be converted to the equivalent gyro (or compass) bearing.

If the distant object selected is not charted, or the position of the vessel is not known accurately, the approximate magnetic bearing of the object can be determined by measuring its *compass* bearing on each cardinal and intercardinal compass heading, and finding the mean of these readings. The value so determined will be incorrect by the amount of any constant deviation (coefficient *A*).

Example 4.—The compass bearings of a distant object are as shown below.

Required.—The magnetic bearing of the object, assuming no constant deviation (coefficient A).

Solution.—

CH °	*CB* °
000	324. 8
045	320. 7
090	312. 6
135	306. 8
180	304. 9
225	310. 8
270	316. 2
315	320. 0
sum	2516. 8
mean	314. 6

Answer.—MB 314°6.

Azimuth of celestial body. The true azimuth of the celestial body selected should be computed (arts. 2125–2127) for the time of observation. The magnetic variation should then be applied to determine the equivalent magnetic azimuth. The desired magnetic heading should then be set at the lubber's line of the pelorus, and the far vane set at the magnetic azimuth of the celestial body. The vessel should then be maneuvered until the body is in line with the vanes.

Example 5.—It is desired to place a vessel on magnetic heading west in an area where the variation is 17° W, and at a time when the computed true azimuth of the sun is 098°.

Required.—The setting of the pelorus.

Solution.—Set 270° at the lubber's line, and set the far vane at 098°+17°=115°.

If preferred, 000° can be set at the lubber's line, and the far vane at the relative azimuth (magnetic azimuth minus desired magnetic heading). If a gyro repeater or a magnetic compass is used instead of a pelorus, the true (or magnetic) azimuth should be converted to the equivalent gyro (or compass) azimuth.

731. Curve of magnetic azimuths.—During the course of compass adjustment and swinging ship, a magnetic direction is needed many times, either to place the vessel on desired magnetic headings or to determine the deviation of the compass being adjusted. If a celestial body is used to provide the magnetic reference, the azimuth is continually changing as the earth rotates on its axis. Frequent and numerous computations can be avoided by preparing, in advance, a table or **curve of magnetic azimuths.** True azimuths at frequent intervals are computed by any of the methods of computation discussed in chapters XX and XXI. The variation at the center of the maneuvering area is then applied to determine the equivalent magnetic azimuths. These are plotted on cross-section paper, with time as the other argument, using any convenient scale. A curve is then faired through the points.

Points at intervals of half an hour (with a minimum of three) are usually sufficient unless the body is near the celestial meridian and relatively high in the sky, when additional points are needed. If the body *crosses* the celestial meridian, the direction of curvature of the line reverses.

Unless extreme accuracy is required, the Greenwich hour angle and declination can be determined for the approximate mid time, the same value of declination used for all computations, and the Greenwich hour angle considered to increase 15° per hour.

An illustration of a curve of magnetic azimuths of the sun is shown in figure 731. This curve is for the period 0700–0900 zone time on May 31, 1958, at latitude 23°09!5 N,

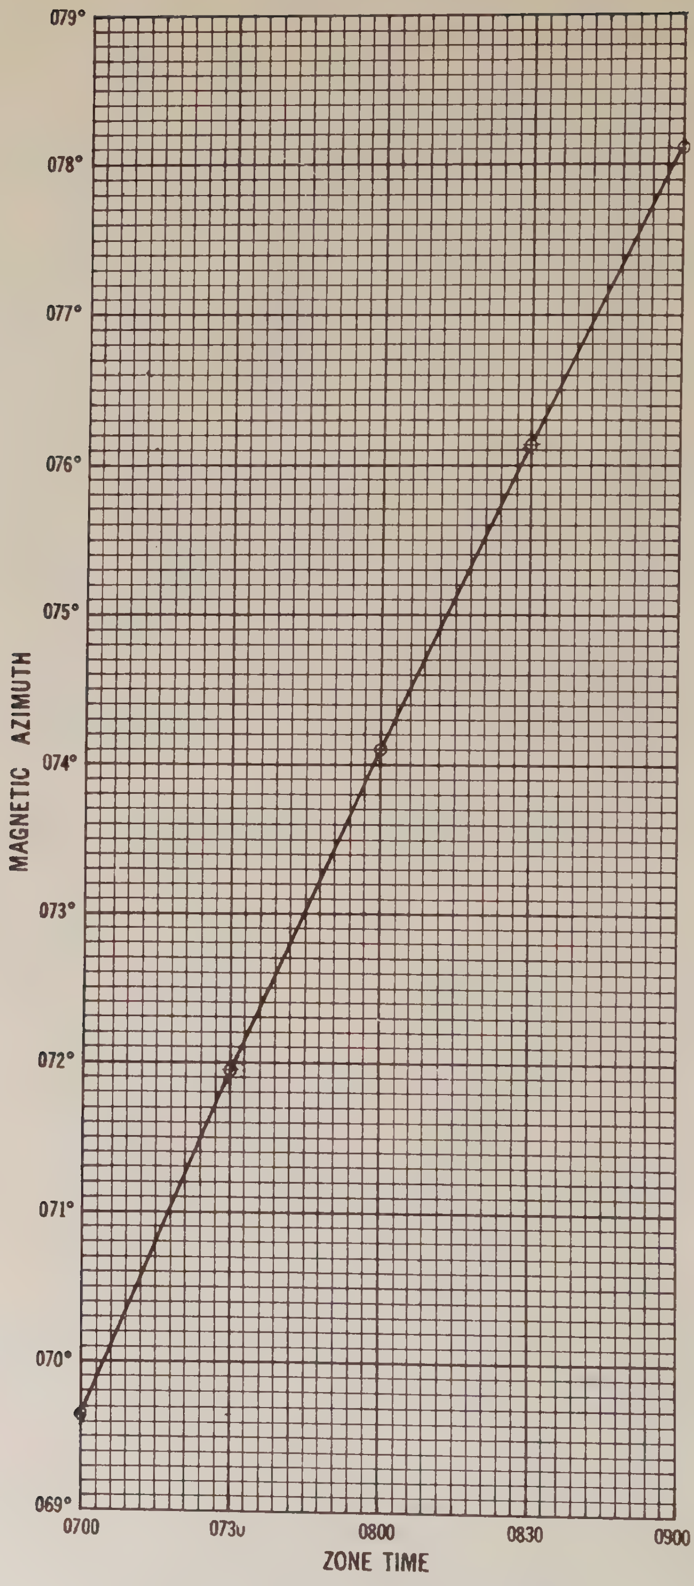

FIGURE 731.—Curve of magnetic azimuths.

longitude 82°24′.1 W, about a mile north of Battery No. 5, Havana, Cuba. The variation in this area is 2°47′ E. At the midtime, the meridian angle of the sun is 66°46′.9 E, and the declination is 21°53′.3 N. Azimuths were computed by H.O. Pub. No. 260 (art. 2126) at half-hour intervals, as follows:

Zone time	*Meridian angle* ° ′ (h m)	*Declination* °	*Latitude* °	*Magnetic azimuth* ° ′
0700	81 46.9 E (5 27.1 E)	21.9 N	23.2 N	069 39
0730	74 16.9 E (4 57.1 E)	21.9 N	23.2 N	071 57
0800	66 46.9 E (4 27.1 E)	21.9 N	23.2 N	074 06
0830	59 16.9 E (3 57.1 E)	21.9 N	23.2 N	076 08
0900	51 46.9 E (3 27.1 E)	21.9 N	23.2 N	078 07

This curve was constructed on the assumption that the vessel would remain in approximately the same location during the period of adjustment and swing. If the position changes materially, this should be considered in the computation.

732. Deviation by magnetic headings.—If the vessel is placed on a magnetic heading by any of the methods of article 730, compass deviation on that heading is the difference between the magnetic heading and the compass heading. If the compass heading is less than the magnetic heading, deviation is easterly, if the compass heading is greater than the magnetic heading, deviation is westerly.

Example.—A vessel is being maneuvered to determine the deviation of the magnetic steering compass on cardinal and intercardinal headings. The gyro compass, which has an error of 0°.5 W, is used for placing the vessel on each of the magnetic headings. Variation in the area is 27°.5 E.

Required.—Deviation on each magnetic heading, using the compass headings given below:

Solution.—

MH °	*V* °	*TH* °	*GE* °	*Hpgc* °	*CH* °	*Dev.* °
000	27.5 E	027.5	0.5 W	028	000.3	0.3 W
045	27.5 E	072.5	0.5 W	073	046.1	1.1 W
090	27.5 E	117.5	0.5 W	118	093.6	3.6 W
135	27.5 E	162.5	0.5 W	163	136.7	1.7 W
180	27.5 E	207.5	0.5 W	208	179.6	0.4 E
225	27.5 E	252.5	0.5 W	253	223.8	1.2 E
270	27.5 E	297.5	0.5 W	298	266.5	3.5 E
315	27.5 E	342.5	0.5 W	343	313.2	1.8 E

733. Deviation by magnetic bearing or azimuth.—Deviation can be found by comparing a magnetic bearing or azimuth with one measured by compass. The magnetic direction can be obtained as explained in articles 730–731. If the compass direction is less than the magnetic direction, deviation is easterly; if the compass direction is greater than the magnetic direction, deviation is westerly. This method is used for determining deviation on a given *compass* heading. The equivalent magnetic heading can be determined by applying the deviation thus determined. If this method is used for swinging ship, the values can be plotted as explained in article 729. For a well-adjusted compass, the deviation may be so small that the compass headings can be considered magnetic headings, without introducing significant errors.

Example.—The standard compass of a vessel has been adjusted, and the vessel is to be swung for residual deviation during the period and for the place for which the curve of magnetic azimuths of figure 731 has been constructed.

Required.—Find the deviation on each heading given below, at the times indicated.
Solution.—

CH °	*Time* h m s	*CZn* °	*MZn* °	*Deviation* °
000	7 35 20	073.2	072.4	0.8 W
045	7 41 12	074.0	072.8	1.2 W
090	7 50 15	074.2	073.4	0.8 W
135	7 57 36	074.0	073.9	0.1 W
180	8 04 44	073.7	074.4	0.7 E
225	8 10 10	073.5	074.8	1.3 E
270	8 16 33	074.3	075.2	0.9 E
315	8 24 51	075.8	075.7	0.1 W

The magnetic azimuth (MZn) is determined from figure 731, and the deviation from compass azimuth (CZn) and magnetic azimuth.

734. Deviation by a range is a special case of deviation by magnetic bearing. Two objects appearing in line, one behind the other, constitute a **range.** Range markers are established in many places to mark important channels, the extremities of measured miles, etc. In addition, numerous good ranges occur naturally, as when a lighthouse is in line with a tank, or a tower with a chimney. The true direction of such a range can be determined by measurement on the chart, and variation applied to determine the equivalent magnetic direction. In the case of a natural range, the objects should preferably be at least an inch apart as they appear on the chart, to minimize any plotting errors.

A range is superior to the bearing of a single object because it provides a critical indication of when the vessel is in the correct position to take a reading. The vessel crosses the range on various compass headings. At each crossing, the compass bearing of the range is observed, and also the compass heading. It is well to use two ranges nearly 90° apart, if available, because of the difficulty of crossing at small angles.

Example.—A vessel maneuvering to adjust its compass in the Lower Bay of New York Harbor finds the true direction of the range between West Bank Light and Coney Island Light to be 032°. The variation in this area is 11°2 W. The vessel steams across the range on various compass headings, noting the compass direction of the range at the times of crossing, as shown below.

Required.—The deviation on each compass heading indicated.

Solution.—The magnetic bearing of the range is 032°+11°2=043°2.

CH °	*MB Range* °	*CB Range* °	*Deviation* °
000	043.2	032.9	10.3 E
045	043.2	023.7	19.5 E
090	043.2	031.9	11.3 E
135	043.2	044.2	1.0 W
180	043.2	048.5	5.3 W
225	043.2	051.0	7.8 W
270	043.2	055.6	12.4 W
315	043.2	049.8	6.6 W

The analysis of these results (art. 727) indicates a constant error of 1°0 E. The mean compass bearing is 042°2, differing from the correct magnetic bearing by the amount of the constant error.

Ranges are widely used to check the deviation on the heading in use as a vessel

proceeds through pilot waters. In this manner several checks can be made without advance preparation as a vessel enters or leaves port.

735. Deviation by reciprocal bearings.—Another method of using magnetic bearings is by means of a compass on the beach. This method is particularly useful when no suitable distant object or range is available, or where it may not be practical to remain close to a given bearing line.

A reliable compass is taken ashore to a location which is free from magnetic disturbance. If the location is not marked by a conspicuous object, such as a beacon, flagpole, prominent tree, etc., a temporary marker should be erected. A staff with a flag or bunting should be adequate. The marker should be of sufficient size and nature to be conspicuous at the vessel. At suitable visual or radio signals from the vessel, bearings are observed simultaneously aboard the vessel and ashore. The bearings of the vessel observed by the shore compass are magnetic. The reciprocals of these can be considered magnetic bearings of the shore station from the vessel. The bearings measured aboard the vessel are compass bearings. The difference is deviation. To avoid confusion in the sequence of bearings, the time of each bearing is recorded. Timepieces should be synchronized before the start of observations.

Example.—Simultaneous bearings are observed by a shore compass and the standard compass aboard a vessel, as shown below.

Required.—The deviation of the standard compass on each heading.

Solution.—

CH	*Time*	*MB of vessel*	*MB of shore position*	*CB of shore position*	*Deviation*
°		°	°	°	°
000	1112	307	127	137	10 W
045	1120	309	129	131	2 W
090	1126	312	132	130	2 E
135	1018	296	116	113	3 E
180	1029	295	115	109	6 E
225	1039	288	108	096	12 E
270	1052	288	108	113	5 W
315	1104	289	109	115	6 W
		mean	118	118	

The analysis of these results indicates no constant deviation. This is further indicated by the fact that the means of the bearings aboard and ashore are equal.

Adjustment by Deflector

736. Principles involved.—As indicated in article 713, the magnetic field of a vessel causes deviation of a magnetic compass, and also alters its directive force, strengthening it on some headings and weakening it on others. The purpose of compass adjustment is to neutralize the effect of the vessel's magnetic field on the compass. If this is done completely, all deviation is removed, and the directive force is the same on all headings. The usual procedure, described earlier in this chapter, is to adjust by reducing or eliminating the deviation. By the deflector method, the various correctors are adjusted until the directive force is the same on all cardinal headings. Deviation is then a minimum.

The *relative* directive force on various headings is determined by means of an instrument called a **deflector.** Actual measurement is of the setting of the instrument when the compass card has been rotated or "deflected" through 90° under certain standard conditions. The units are arbitrary "deflector units" which are used only for comparison with readings on other headings.

The deflector method provides a quick adjustment with only four headings being needed, without need for bearings, azimuths, or comparison with other compasses. It is easy to use. However, it is not as thorough as the method described in article 729, and should not be used when the usual method is available. The deflector method makes no provision for determination of coefficient A (art. 716), the amount of Flinders bar needed, the setting of the heeling magnet, or the residual deviation. Coefficient E can be determined, but is usually ignored. The method has never been popular in the United States. It offers little or no advantage for a vessel equipped with a reliable gyro compass.

737. Adjustment by deflector.—The preliminary steps of adjustment are the same as indicated in article 728, omitting those relating to peloruses and other compasses. Preparations having been completed, the adjustment should be carried out as follows:

1. Steady on heading 000° (or 180°) *by the compass being adjusted.* Note the heading by another compass and keep the vessel on this heading, steering by means of the second compass. Put the deflector in place over the first compass, and deflect the compass card 90°. Record the reading on the deflector scale, and remove the deflector.

2. Steady on heading 090° (or 270°) by the compass being adjusted, and follow the procedure of step 1.

3. Steady on heading 180° (000° if 180° was used in step 1) by the compass being adjusted, and determine the deflector reading by the procedure of step 1. Leave the deflector in place and set it to the mean of the readings on headings 000° and 180°. Adjust the fore-and-aft permanent magnets until the deflection is 90°. This corrects for coefficient B, and the deflector readings on compass headings 000° and 180° should now be the same. Remove the deflector.

4. Steady on heading 270° (090° if 270° was used in step 2) by the compass being adjusted, and determine the deflector reading by the procedure of step 1. Leave the deflector in place and set it to the mean of the readings on headings 090° and 270°. Adjust the athwartship permanent magnets until the deflection is 90°. This corrects for coefficient C, and the deflector readings on compass headings 090° and 180° should now be the same.

5. Without changing the heading, set the deflector to the mean of the N–S and E–W means. Adjust the quadrantal correctors until the deflection is 90°. This corrects for coefficient D, and the deflector readings on all cardinal headings should be the same. Remove the deflector.

Adjustment is now complete. It can be checked by repeating the five steps, a procedure which is particularly recommended if the difference between deflector readings on opposite headings is more than ten units. If means are available, and time permits, the vessel should be swung for residual deviation. If preferred, a heading of east or west can be used, reversing steps 1 and 2 and also steps 3 and 4.

This method is particularly useful when a quick adjustment is needed following some change that affects the magnetic environment of the compass.

738. The Kelvin deflector was developed in Great Britain by Sir William Thomson (Lord Kelvin). It consists essentially of two permanent magnets hinged like a pair of dividers, with opposite poles at the hinge. The magnets are mounted vertically over the center of the compass, with the hinged end on top. The separation of the lower ends can be varied by means of a screw. The amount of separation, indicated by a scale and vernier drums, is the reading used in the adjustment.

The deflecting force increases as the separation becomes greater. When the deflector is in place over the compass, the blue pole is in line with the north (red) end

of the compass magnets, as indicated by a pointer. As the deflecting magnets are rotated around the vertical axis of the instrument, the compass card rotates in the same direction, but at a slower rate. The separation is adjusted until the rotation of the instrument is 170° when the deflection of the compass card is 90°. These are the standard conditions under which readings are made.

The Kelvin type deflector, which provides adjustment to an accuracy of 2° to 3°, is used on many British merchant vessels. Deflectors are seldom used on British Navy vessels.

739. The De Colong deflector was developed in Russia, and is standard equipment on naval vessels of the USSR. It provides an accuracy of 0°.5 to 1°.0. Essentially, this instrument consists of two horizontal magnets which are perpendicular to each other. The small magnet is held in a fixed position close to the compass card. The large magnet is mounted in a small tray which can be moved up and down along a vertical spindle mounted over the center of the compass. The red end of this magnet is placed toward the north. When it is positioned so that the directive force is exactly neutralized, the small magnet causes the compass card to be deflected 90°. The height of the large magnet is the deflector reading, the scale being on the vertical spindle, and the index on the movable tray.

Provision is made for mounting the large magnet vertically, to measure the vertical force of the magnetic field at the compass. A separate scale is provided for this purpose. Additional magnets are generally provided for use near the magnetic equator, where the vertical intensity is very small.

In practice, a separate deflector is provided for each compass, and they are not interchangeable. By the addition of an auxiliary scale, the instrument could be made usable for any compass.

Degaussing Compensation

740. Degaussing.—As indicated in article 712, a steel vessel has a certain amount of permanent magnetism in its "hard" iron, and induced magnetism in its "soft" iron. Whenever two or more magnetic fields occupy the same space, the total field is the vector sum (art. O18) of the individual fields. Thus, within the effective region of the field of a vessel, the total field is the combined total of the earth's field and that due to the vessel. Consequently, the field due to earth's magnetism alone is altered or distorted due to the field of the vessel. This is indicated by a tendency of the lines of force to crowd into the metal of the vessel (art. 703), as shown in figure 741a.

Certain mines and other explosive devices are designed to be triggered by the magnetic influence of a vessel passing near them. It is therefore desirable to reduce to a practical minimum the magnetic field of a vessel. One method of doing this is to neutralize each component by means of an electromagnetic field produced by direct current of electricity in electric cables installed so as to form coils around the vessel. A unit sometimes used for measuring the strength of a magnetic field is the **gauss**. The reduction of the strength of a magnetic field decreases the number of gauss in that field. Hence, the process is one of **degaussing** the vessel.

When a vessel's degaussing coils are energized, the magnetic field of the vessel is completely altered. This introduces large deviation in the magnetic compasses. This is removed, as nearly as practicable, by introducing at each compass an equal and opposite force of the same type—one caused by direct current in a coil—for each component of the field due to the degaussing currents. This is called **compass compensation.** When there is a possibility of confusion with compass adjustment to neutralize the effects of the natural magnetism of the vessel, the expression **degaussing compensation** is used. Since the neutralization may not be perfect, a small amount

of deviation due to degaussing may remain on certain headings. This is the reason for swinging ship twice—once with degaussing off and once with it on—and having two separate columns in the deviation table (fig. 710).

741. A vessel's magnetic signature.—A simplified diagram of the distortion of the earth's magnetic field in the vicinity of a steel vessel is shown in figure 741a. The strength of the field is indicated by the spacing of the lines, being stronger as the lines are closer together. If a vessel passes over a device for detecting and recording the strength of the magnetic field, a certain pattern is traced, as shown in figure 741b. Since the magnetic field of each vessel is different, each has a distinctive trace, known as its **magnetic signature.** The simplified signature shown in figure 741b is one that might result from an uncomplicated field such as that shown in figure 741a.

Several degaussing stations have been established to determine magnetic signatures and recommend the currents needed in the various degaussing coils. Since a vessel's induced magnetism varies with heading and magnetic latitude, the current settings of the coils which neutralize induced magnetism need to be changed to suit the conditions. A "degaussing folder" is provided each vessel to indicate the changes, and to give other pertinent information.

A vessel's permanent magnetism changes somewhat with time and the magnetic history of the vessel. Therefore, the information given in the degaussing folder should be checked from time to time by a return to the magnetic station.

742. Degaussing coils.—For degaussing purposes, the total field of the vessel is divided into three components: (1) vertical, (2) horizontal fore-and-aft, and (3) horizontal athwartships. The positive directions are considered downward, forward, and to port, respectively. These are the normal directions for a vessel headed north or east in north latitude. Each component is opposed by a separate degaussing field just strong enough to neutralize it. Ideally, when this has been done, the earth's field passes through the vessel smoothly and without distortion. The opposing degaussing fields are produced by direct current flowing in coils of wire. Each of the degaussing coils is placed so that the field it produces is directed to oppose one component of the ship's field.

The number of coils installed depends upon the magnetic characteristics of the vessel, and the degree of safety desired. The ship's permanent and induced magnetism may be neutralized separately so that control of induced magnetism can be varied as heading and latitude change, without disturbing the fields opposing the vessel's permanent field. The principal coils employed are the following:

Main (M) coil. The *M*-coil is placed horizontal, and completely encircles the vessel, usually at or near the water line. Its function is to oppose the vertical component of the vessel's permanent and induced fields combined. Generally the induced field predominates. Current in the *M*-coil is varied or reversed according to the change of the *induced* component of the vertical field with latitude.

Forecastle (F) and quarterdeck (Q) coils. The *F*- and *Q*-coils are placed horizontal just below the forward and after thirds (or quarters), respectively, of the weather deck. The designation "*Q*" for quarterdeck is reminiscent of the days before World War II when the "quarterdeck" of naval vessels was aft along the ship's quarter. These coils, in which current can be individually adjusted, remove much of the fore-and-aft component of the ship's permanent and induced fields. More commonly, the combined *F*- and *Q*-coils consist of two parts; one part the *FP*- and *QP*-coils, to take care of the permanent fore-and-aft field, and the other part, the *FI*- and *QI*-coils, to neutralize the induced fore-and-aft field. Generally, the forward and after coils of each type are connected in series, forming a split-coil installation and designated *FP-PQ* coils and *FI-QI* coils. Current in the *FP-QP* coils is generally constant, but in the *FI-QI* coils

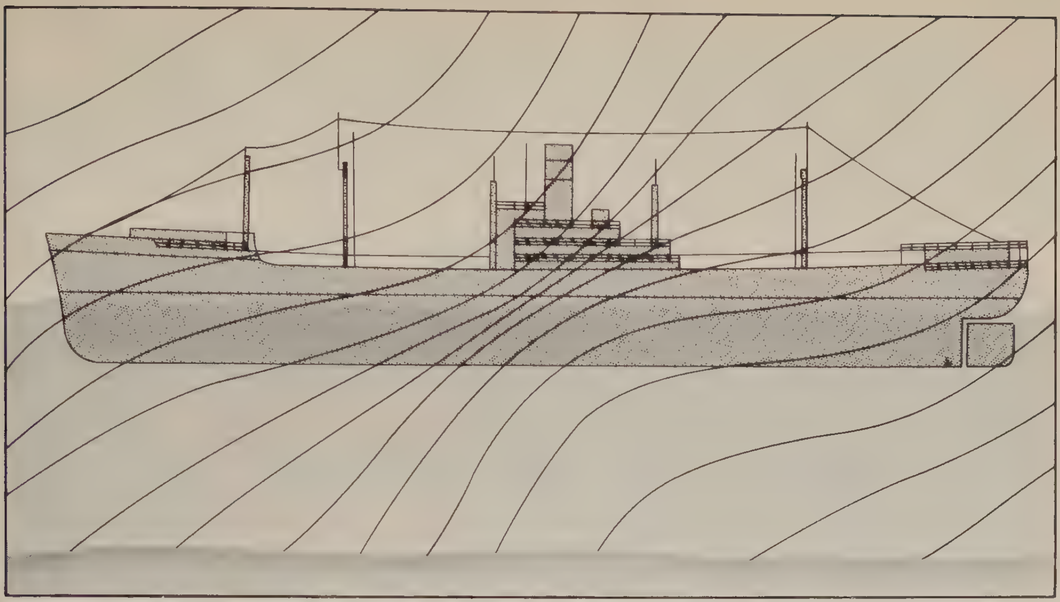

Figure 741a.—Simplified diagram of distortion of earth's magnetic field in the vicinity of a steel vessel.

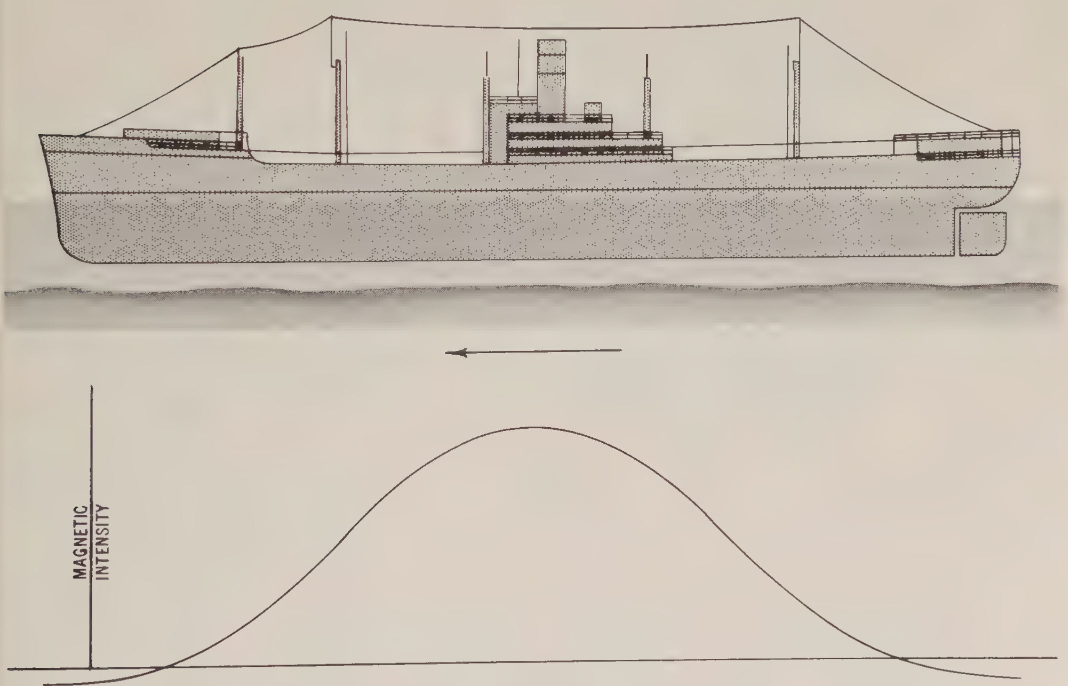

Figure 741b.—Simplified signature of vessel of figure 741a.

is varied according to the heading and magnetic latitude of the vessel. In split-coil installations, the coil designations are often contracted to P-coil and I-coil.

Longitudinal (L) *coil.* Better control of the fore-and-aft components, but at greater installation expense, is provided by placing a series of vertical, athwartships coils along the length of the ship. It is the *field*, not the coils, which is longitudinal. Current in an L-coil is varied as with the FI-QI coils. It is maximum on north and south headings, and zero on east and west headings.

Athwartship (A) *coil.* The A-coil is in a vertical fore-and-aft plane, thus producing a horizontal athwartship field which neutralizes the athwartship component of the vessel's field. In most vessels, this component of the permanent field is small and can be ignored. Since the A-coil neutralizes the induced field, primarily, the current is changed with magnetic latitude and with heading, being maximum on east or west headings, and zero on north or south headings.

The strength and direction of the current in each coil is indicated and adjusted at a control panel which is normally accessible to the navigator. Current may be controlled directly by rheostats at the control panel or remotely by push buttons which operate rheostats in the engine room.

Since degaussing fields oppose the vessel's fields, the positive directions of the degaussing fields are upward, aft, and to starboard. For positive fields in M, F, FI, FP, Q, QI, and QP coils, current flows forward on the starboard side of the vessel; and the north end of a small compass placed *above* any of these coils is deflected outboard. For a positive field in the L-coil, current flows upward on the starboard side, and the north end of a compass is deflected aft when placed *below* an upper, athwartship portion of the coil. For a positive field in the A-coil, current in the upper, fore-and-aft portion flows aft, and the north end of a compass is deflected to starboard when placed *below* this portion of the coil. The FI-QI coils are generally connected so that the field in the FI-coil is negative when that in the QI-coil is positive.

Appropriate values of the current in each coil are determined at a degaussing station, the various currents being adjusted until the vessel's signature is made as flat as possible. Recommended current values and directions for all headings and magnetic latitudes are set forth in the vessel's degaussing folder. This document is normally retained by the navigator, whose responsibility it is to see that the recommended settings are maintained whenever the degaussing system is energized.

743. Securing the degaussing system.—Unless the degaussing system is properly secured, residual magnetism may remain in the metal of the vessel. During degaussing compensation and at other times, as recommended in the degaussing folder, the "reversal" method is used. The steps in the reversal process are as follows:

1. Start with maximum degaussing current used since the system was last energized.
2. Decrease current to zero and increase it in the opposite direction to the same value as in step 1.
3. Decrease the current to zero and increase it to three-fourths maximum value in the original direction.
4. Decrease the current to zero and increase it to one-half maximum value in the opposite direction.
5. Decrease the current to zero and increase it to one-fourth maximum value in the original direction.
6. Decrease the current to zero and increase it to one-eighth maximum value in the opposite direction.
7. Decrease the current to zero and open switch.

744. Magnetic treatment of vessels.—In some instances, the degaussing can be made more effective by changing the magnetic characteristics of the vessel by a process known as **deperming.** Heavy cables are wound around the vessel in an athwartship direction, forming vertical loops around the longitudinal axis of the vessel. The loops are run beneath the keel, up the sides, and over the top of the weather deck at closely-spaced equal intervals along the entire length of the vessel. Predetermined values of direct current are then passed through the coils. When the desired magnetic characteristics have been acquired, the cables are removed.

A vessel which does not have degaussing coils, or which has a degaussing system which is inoperative, can be given some temporary protection by a process known as **flashing.** A horizontal coil is placed around the outside of the vessel and energized with large predetermined values of direct current. When the vessel has acquired a vertical field of permanent magnetism of the correct magnitude and polarity to reduce to a minimum the resultant field below the vessel for the particular magnetic latitude involved, the cable is removed. This type protection is not as satisfactory as that provided by degaussing coils because it is not adjustable for various headings and magnetic latitudes, and also because the vessel's magnetism slowly readjusts itself following treatment.

During magnetic treatment it is a wise precaution to remove all magnetic compasses and Flinders bars from the vessel. Permanent adjusting magnets and quadrantal correctors are not materially affected, and need not be removed. If for any reason it is impractical to remove a compass, the cables used for magnetic treatment should be kept as far as practical from it.

745. Degaussing compensation.—The magnetic fields created by the degaussing coils would render the vessel's magnetic compasses useless unless compensated. This is accomplished by subjecting the compass to compensating fields along three mutually perpendicular axes. These fields are provided by small compensating coils adjacent to the compass. In nearly all installations, one of these coils, the heeling coil, is horizontal and on the same plane as the compass card. Current in the heeling coil is adjusted until the vertical component of the total degaussing field is neutralized. The other compensating coils provide horizontal fields perpendicular to each other. Current is varied in these coils until their resultant field is equal and opposite to the horizontal component of the degaussing field. In early installations, these horizontal fields were directed fore-and-aft and athwartships by placing the coils around the Flinders bar and the quadrantal spheres. Compactness and other advantages are gained by placing the coils on perpendicular axes extending 045°–225° and 315°–135° relative to the heading. A frequently used compensating installation, called the type "K," is shown in figure 745. It consists of a heeling coil extending completely around the top of the binnacle, four "intercardinal" coils, and three control boxes. The intercardinal coils are named for their positions relative to the compass when the vessel is on a heading of north, and also for the compass headings on which the current in the coils is adjusted to the correct amount for compensation. The NE–SW coils operate together as one set, and the NW–SE coils operate as another. One control box is provided for each set, and one for the heeling coil.

The compass compensating coils are connected to the power supply of the degaussing coils, and the currents passing through the compensating coils are adjusted by series resistances so that the compensating field is equal to the degaussing field. Thus, a change in the degaussing currents is accompanied by a proportional change in the compensating currents. Each coil has a separate winding for each degaussing circuit it compensates.

Degaussing compensation is carried out while the vessel is moored at the shipyard where the degaussing coils are installed. This is usually done by personnel of the yard, using the following procedure:

1. The compass is removed from its binnacle and a dip needle is installed in its place. The *M*-coil and heeling coil are then energized, and the current in the heeling coil is adjusted until the dip needle indicates the correct value for the magnetic latitude of the vessel. The system is then secured by the reversing process.

2. The compass is restored to its usual position in the binnacle. By means of auxiliary magnets, the compass card is deflected until the compass magnets are parallel to one of the compensating coils or set of coils used to produce a horizontal field. The compass magnets are then perpendicular to the field produced by that coil. One of the degaussing circuits producing a horizontal field, and its compensating winding, are then energized, and the current in the compensating winding is adjusted until the compass reading returns to the value it had before the degaussing circuit was energized. The system is then secured by the reversing process. The process is repeated with each additional circuit used to create a horizontal field. The auxiliary magnets are then removed.

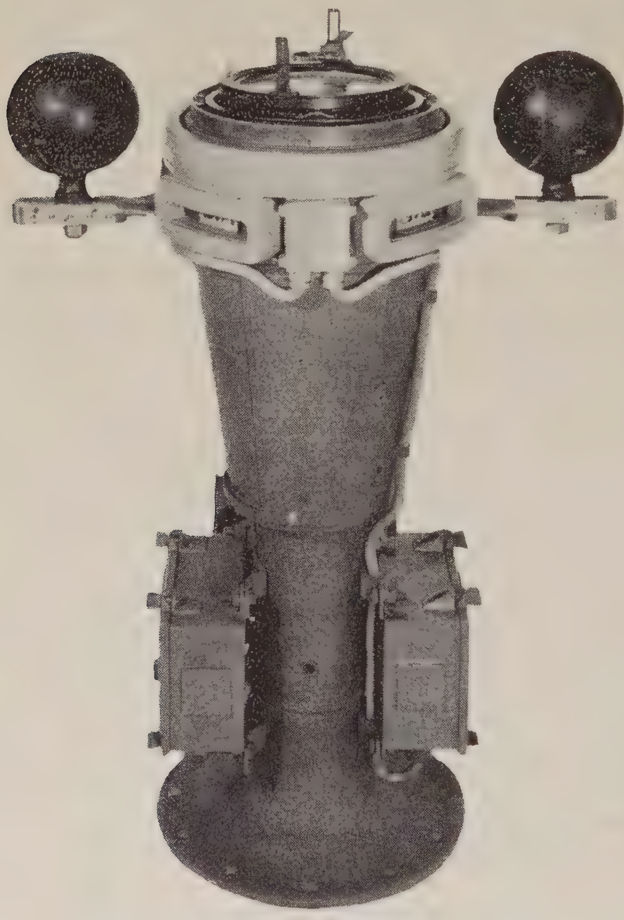

FIGURE 745.—Type "K" degaussing compensation installation.

3. The auxiliary magnets are placed so that the compass magnets are parallel to the other compensating coils or set of coils used to produce a horizontal field. The procedure of step 2 is then repeated for each circuit producing a horizontal field.

When the vessel gets under way, it proceeds to a suitable maneuvering area. The vessel is then headed so that the compass magnets are parallel first to one compensating coil or set of coils and then the other, and any needed adjustment is made in the compensating circuits to reduce the error to a minimum. The vessel is then swung for residual deviation, first with degaussing off and then with degaussing on, and the correct current settings for each heading at the magnetic latitude of the vessel. From the values thus obtained, the "DG OFF" and "DG ON" columns of the deviation table (fig. 710) are filled in. If the results indicate satisfactory compensation, a record is made of the degaussing coil settings and the resistances, voltages, and currents in the compensating coil circuits. The control boxes are then secured.

Under normal operating conditions, the settings need not be changed unless changes are made in the degaussing system, or unless an alteration is made in the amount of Flinders bar or the setting of the quadrantal correctors. However, it is possible for a ground to occur in the coils or control box if the circuits are not adequately protected from sea water or other moisture. If this occurs, it should be reflected by a change in deviation with degaussing on, or by a decreased installation resistance. Under these conditions, compensation should be carried out again. If the compass is to be needed with degaussing on before the ship can be returned to a shipyard where the compensation can be made by experienced personnel, the compensation should be made at sea on the actual headings needed, rather than by deflection of the compass needles by magnets. More complete information related to this process is given in H.O. Pub. No. 226 and the degaussing folder.

If a vessel has been given magnetic treatment, its magnetic properties have been changed. This necessitates readjustment of each magnetic compass. This is best delayed for several days to permit stabilization of the magnetic characteristics of the vessel. If this cannot be delayed, the vessel should be swung again for residual deviation after a few days. Degaussing compensation should not be made until after compass adjustment has been completed.

Problems

711a. Fill in the blanks in the following:

	TC °	*V* °	*MC* °	*D* °	*CC* °	*CE* °
(1)	105	15 E	—	5 W	—	—

(7)	—	2 W	—	6 E	015	—
(8)	—	—	210	—	214	1 W

Answers.—(1) MC 090°, CC 095°, CE 10°E; (2) TC 229°, V 10°E, MC 219°; (3) TC 060°, MC 072°, D 5°E; (4) V 10°W, D 6°E, CE 4°W; (5) V 6°E, CC 219°, CE 3°E; (6) V 12°E, D 2°W, CC 359°; (7) TC 019°, MC 021°, CE 4°E; (8) TC 213°, V 3°E, D 4°W.

711b. A vessel is on course 150° by compass in an area where the variation is 19°E. The deviation is as shown in figure 710. Degaussing is on.

Required.—(1) Deviation.

(2) Compass error.

(3) Magnetic heading.

(4) True heading.

Answers.—(1) D 1°E, (2) CE 20°E, (3) MH 151°, (4) TH 170°.

711c. A vessel is on course 055° by gyro and 041° by magnetic compass. The gyro error is 1°W. The variation is 15°E.

Required.—The deviation on this heading.

Answer.—D 2°W.

711d. A vessel is on course 177° by gyro. The gyro error is 0.°5 E. A beacon bears 088° by magnetic compass in an area where variation is 11°W. The deviation is as shown in figure 710, degaussing off.

Required.—The true bearing of the beacon.

Answer.—TB 076°.

721a. A magnetic compass is adjusted on the magnetic equator, without any Flinders bar being used. The residual deviation on heading 090° magnetic is 1° E. Some days later, at latitude 37° N, dip 70°, the deviation on heading 090° is 12° W.

Required.—The length and location of Flinders bar required to restore a residual deviation of 1° E (using fig. 721, A) if the magnetic properties of the vessel are unchanged.

Answer.—Fifteen inches of Flinders bar forward of the compass.

721b. The deviation of a magnetic compass of a vessel on heading 270° magnetic is 2° E at Sydney, Australia (south magnetic latitude) and 12° W at Seattle, Wash. (north magnetic latitude). At Sydney, H=0.258 and Z=0.51. At Seattle, H=0.188 and Z=0.53. The shielding factor is 0.9.

Required.—The length of Flinders bar to use if (1) no Flinders bar is in place during observations, (2) 12 inches of Flinders bar is in place forward of the compass during observations.

Answers.—(1) 8¼ inches (8.5 inches by computation) of Flinders bar aft of the compass, (2) nine inches (8.8 inches by computation) of Flinders bar forward of the compass.

727. A magnetic compass which has not been adjusted has deviation on cardinal and intercardinal compass headings as follows:

Compass heading °	*Deviation* °	*Compass heading* °	*Deviation* °
000	2.0 E	180	6.0 E
045	20.5 E	225	5.5 W
090	18.5 E	270	22.0 W
135	8.0 E	315	23.5 W

On heading compass north the deviation is 6°0 W when the vessel heels 7° to starboard.

Required.—(1) The approximate value of each coefficient.

(2) The total deviation to be expected on compass heading 300°, with the vessel on an even keel.

(3) Heeling error on compass heading 060°, with a heel of 10°.

Answers.—(1) *A* (+)0°5, *B* (+)20°2, *C* (−)2°0, *D* (+)7°6, *E* (+)2°9, *J* (−)1°1; (2) d 26°0 W; (3) HE 5°5.

730a. It is desired to place a vessel on magnetic heading west, using the magnetic steering compass. The deviation table for this compass is shown in figure 710. Degaussing is on.

Required.—Heading per steering compass (p stg c).

Answer.—$H_{p\ stg\ c}$ 272°.

730b. It is desired to place a vessel on magnetic heading south, using the gyro compass. The variation in this area is 12° E, and the gyro error is 0°5 E.

Required.—Heading per gyro compass.

Answer.—H_{pgc} 191°5.

730c. It is desired to place a vessel on magnetic heading southeast in an area where the variation is 6° W. The true bearing for a distant object is 047°.

Required.—(1) The magnetic bearing of the object.

(2) The relative bearing of the object when the vessel is on the desired magnetic heading.

Answers.—(1) MB 053°, (2) RB 278°.

730d. The compass bearings of a distant object are as follows:

CH °	*CB* °	*CH* °	*CB* °
000	358	180	002
045	357	225	006
090	351	270	012
135	353	315	009

Required.—The magnetic bearing of the object, assuming no constant deviation (coefficient *A*).

Answer.—MB 001°.

730e. It is desired to place a vessel on magnetic heading east in an area where the variation is 13° E, and at a time when the computed true azimuth of the sun is 218°.

Required.—(1) The magnetic azimuth of the sun.

(2) The relative azimuth when the vessel is on the desired magnetic heading.

(3) The azimuth by a magnetic compass having deviation as shown in figure 710 (DG on).

(4) The azimuth by a gyro compass having a gyro error of 1° W.

Answers.—(1) MZn 205°, (2) RZn 115°, (3) CZn 202°, (4) Zn_{pgc} 219°.

732. A vessel is being maneuvered to determine the residual deviation of a magnetic compass. The gyro compass, which has an error of 1° E, is used for placing the vessel on the magnetic headings indicated below. Variation in the area is 7.°8 W. The following readings are obtained:

MH °	*CH* °	*MH* °	*CH* °
000	000.0	180	180.1
045	044.1	225	225.8
090	088.5	270	271.4
135	134.2	315	315.9

Required.—Gyro heading and deviation on each magnetic heading.

Answers.—

MH °	*Hpgc* °	*Dev.* °	*MH* °	*Hpgc* °	*Dev.* °
000	351.2	0.0	180	171.2	0.1 W
045	036.2	0.9 E	225	216.2	0.8 W
090	081.2	1.5 E	270	261.2	1.4 W
135	126.2	0.8 E	315	306.2	0.9 W

733. A vessel is being swung for residual deviation during the period and at the place for which the curve of magnetic azimuths of figure 731 has been constructed. The following readings are obtained:

CH °	*Time* h m s	*CZn* °	*CH* °	*Time* h m s	*CZn* °
000	7 56 13	73.7	180	8 16 36	75.2
045	8 01 22	72.9	225	8 22 19	76.8
090	8 04 55	71.9	270	8 27 12	78.7
135	8 11 01	74.0	315	8 33 27	77.2

Required.—Deviation on each compass heading.

Answers.—

CH °	*Deviation* °	*CH* °	*Deviation* °
000	0.1 E	180	0.0
045	1.3 E	225	1.2 W
090	2.6 E	270	2.8 W
135	0.9 E	315	0.8 W

734. A vessel being swung for residual deviation crosses a range on various compass headings as indicated below, the compass bearing of the range being observed at each crossing. The true direction of the range is 255°. The variation in the vicinity is 24°5 E.

CH °	*CB* °	*CH* °	*CB* °
000	230.3	180	230.6
045	228.7	225	232.4
090	227.4	270	233.8
135	228.0	315	232.3

Required.—Deviation on each compass heading.

Answers.—

CH °	*Deviation* °	*CH* °	*Deviation* °
000	0.2 E	180	0.1 W
045	1.8 E	225	1.9 W
090	3.1 E	270	3.3 W
135	2.5 E	315	1.8 W

735. Bearings of a vessel are taken by means of a compass ashore, and simultaneous bearings of the shore position are taken from the vessel, as follows:

CH °	*CB of shore position* °	*MB of vessel* °	*CH* °	*CB of shore position* °	*MB of vessel* °
000	020	198	180	003	184
045	013	189	225	009	194
090	004	174	270	013	204
135	001	172	315	017	205

Required.—(1) Deviation on each heading.
(2) The value of coefficient *A*.

Answers.—

(1)

CH °	*Deviation* °	*CH* °	*Deviation* °
000	2 W	180	1 E
045	4 W	225	5 E
090	10 W	270	11 E
135	9 W	315	8 E

(2) Coefficient *A* is zero.

CHAPTER VIII

DEAD RECKONING

801. Introduction.—**Dead reckoning** (**DR**) is the determination of position by advancing a known position for courses and distances. It is reckoning relative to something stationary or "dead" in the water, and hence applies to courses and speeds *through the water*. Because of leeway due to wind, inaccurate allowance for compass error, imperfect steering, or error in measuring speed, the actual motion through the water is seldom determined with complete accuracy. In addition, if the water itself is in motion, the course and speed over the bottom differ from those through the water. It is good practice to use the true course *steered* and the best determination of *measured* speed, which is normally speed *through the water*, for dead reckoning. Hence, geographically, a **dead reckoning position** is an approximate one which is corrected from time to time as the opportunity presents itself. Although of less than the desired accuracy, dead reckoning is the only method by which a position can be determined at *any* time and therefore might be considered *basic* navigation, with all other methods only appendages to provide means for correcting the dead reckoning. The prudent navigator keeps his direction- and speed- or distance-measuring instruments in top condition and accurately calibrated, for his dead reckoning is no more accurate than his measurement of these elements.

If a navigator can accurately assess the disturbing elements introducing geographical errors into his dead reckoning, he can determine a better position than that established by dead reckoning alone. This is properly called an **estimated position** (**EP**). It may be established either by applying an estimated correction to a dead reckoning position, or by estimating the course and speed being made good over the bottom. The expression "dead reckoning" is sometimes applied loosely to such reckoning, but it is better practice to keep this "estimated reckoning" distinct from dead reckoning, if for no other reason than to provide a basis for evaluating the accuracy of one's estimates. When good information regarding current, wind, etc., is available, it should be used, but the practice of applying corrections based upon information of uncertain accuracy is, at best, questionable, and may introduce an error. Estimates should be based upon judgment and experience. Positional information which is incomplete or of uncertain accuracy may be available to assist in making the estimate. However, before adequate experience is gained, one should be cautious in applying corrections, for the estimates of the inexperienced are often quite inaccurate.

Dead reckoning not only provides means for continuously establishing an approximate position, but also is of assistance in determining times of sunrise and sunset, the celestial bodies available for observation, the predicted availability of electronic aids to navigation, the suitability and interpretation of soundings for checking position, the predicted times of making landfalls or sighting lights, estimates of arrival times, and in evaluating the reliability and accuracy of position-determining information. Because of the importance of accurate dead reckoning, a careful log is kept of all courses and speeds, times of all changes, and compass errors. These may be recorded directly in the log or first in a **navigator's notebook** for later recording in the log, but whatever the form, a careful record is important.

Modern navigators almost invariably keep their dead reckoning by plotting directly on the chart or plotting sheet, drawing lines to represent the direction and distance of

travel and indicating dead reckoning and estimated positions from time to time. This method is simple and direct. Large errors are often apparent as inconsistencies in an otherwise regular plot. Before the advent of power vessels, when frequent course and speed changes were common, and when charts were sometimes of questionable accuracy, it was common practice to keep the dead reckoning mathematically by one, or a combination, of the "sailings" (arts. 811–825). Except for great-circle sailing, and occasionally composite and Mercator sailings, these are of little more than historical interest to modern navigators, other than those of small boats.

In determining distance run in a given time, one may find table 19 useful. Similar information is given in a somewhat different form in an auxiliary table in H.O. Pub. No. 214.

802. Plotting position on the chart.—A position is usually expressed in units of latitude and longitude, generally to the nearest 0.′1, but it may be expressed as bearing and distance from a known position, such as a landmark or aid to navigation.

To plot a position on a Mercator chart, or to determine the coordinates of a point on such a chart, proceed as follows:

To plot a position when its latitude and longitude are known: Mark the given latitude on a convenient latitude scale along a meridian, being careful to note the unit of the smallest division on the scale. Place a straightedge at this point and parallel to a parallel of latitude (perpendicular to a meridian). Holding the straightedge in place, set one point of a pair of dividers at the given longitude on the longitude scale at the top or bottom of the chart (or along any parallel) and the other at a convenient printed meridian. Without changing the spread of the dividers, place one point on the same printed meridian at the edge of the straightedge, and the second point at the edge of the straightedge in the direction of the given longitude. This second point is at the given position. *Lightly* prick the chart. Remove first the straightedge and then the dividers, watching the point to be sure of identifying it. Make a dot at the point, enclose it with a small circle or square as appropriate (art. 805), and label it. If the dividers are set to the correct spread for longitude *before* the latitude is marked, one point of the dividers can be used to locate the latitude and place the straightedge, if one is careful not to disturb the setting of the dividers.

To determine the coordinates of a point on the chart: Place a straightedge at the given point and parallel to a parallel of latitude. Read the latitude where the straightedge crosses a latitude scale. Keeping the straightedge in place, set one leg of a pair of dividers at the given point and the other at the intersection of the straightedge and a convenient printed meridian. Without changing the spread of the dividers, place one end on a longitude scale, at the same printed meridian, and the other point on the scale, in the direction of the given point. Read the longitude at this second point.

Several variations of these procedures may suggest themselves. That method which seems most natural and is least likely to result in error should be used.

803. Measuring direction on the chart.—Since the Mercator chart, commonly used by the marine navigator, is *conformal* (art. 302), directions and angles are correctly represented. It is customary to orient the chart with 000° (north) at the top; other directions are in their correct relations to north and each other.

As an aid in measuring direction, **compass roses** are placed at convenient places on the chart or plotting sheet. A desired direction can be measured by placing a straightedge along the line from the center of a compass rose to the circular graduation representing the desired direction. The straightedge is then in the desired direction, which may be transferred to any other part of the chart by parallel motion, as by parallel rulers or two triangles (art. 603). The direction between two points is determined by transferring that direction to a compass rose. If a drafting machine (art. 606) or some

form of plotter (art. 605) or protractor (art. 604) is used, measurement can be made directly at the desired point, without using the compass rose.

Measurement of direction, whether or not by compass rose, can be made at any convenient place on a Mercator chart, since meridians are parallel to each other and a line making a desired angle with any one makes the same angle with all others. Such a line is a **rhumb line,** the kind commonly used for course lines, except in polar regions. For direction on a chart having nonparallel meridians, measurement can be made at the meridian involved if the chart is conformal, or by special technique if it is not conformal. Explanation of the former is given in article 2511. The only nonconformal chart commonly used by navigators is the gnomonic, and instructions for measuring direction on this chart are usually given on the chart itself.

Compass roses for both true and magnetic directions may be given. A drafting machine can be oriented to any reference direction—true, magnetic, compass, or grid. When a plotter or protractor is used for measuring an angle with respect to a meridian, the resulting direction is true unless other than true meridians are used. For most purposes of navigation it is good practice to plot true directions only, and to label them in true coordinates.

804. Measuring distance on the chart.—The length of a line on a chart is usually measured in nautical miles, to the nearest 0.1 mile. For this purpose it is customary to use the latitude scale, considering one minute of latitude equal to one nautical mile. The error introduced by this assumption is not great over distances normally measured. It is maximum near the equator or geographical poles. Near the equator a ship traveling 180 miles by measurement on the chart would cover only 179 miles over the earth. Near the pole a run of 220 miles by chart measurement would equal 221 miles over the earth.

Since the latitude scale on a Mercator chart expands with increased latitude, measurement should be made at approximately the mid latitude. For a chart covering a relatively small area, such as a harbor chart, this precaution is not important because of the slight difference in scale over the chart. On such charts a separate mile scale may be given, and it may safely be used over the entire chart. However, habit is strong, and mistakes can probably be avoided by *always* using the mid latitude.

For long distances the line should be broken into a number of parts or *legs*, each one being measured at its mid latitude. The length of a line that should be measured in a single step varies with latitude, decreasing in higher latitudes. No realistic numerical value can be given, since there are too many considerations. With experience a navigator determines this for himself. On the larger scale charts this is not a problem because the usual dividers used for this purpose will not span an excessively long distance.

In measuring distance, the navigator spans with his dividers the length of the line to be measured and then, without altering the setting, transfers this length to the latitude scale, carefully noting the graduations so as to avoid an error in reading. This precaution is needed because of the difference from chart to chart. In measuring a desired length along a line, the navigator spans this length on the latitude scale opposite the line and then transfers his dividers to the line, without changing the setting. For a long line the navigator sets his dividers to some convenient distance and steps off the line, counting the number of steps, multiplying this by the length of the step, and adding any remainder. If the line extends over a sufficient spread of latitude to make scale difference a factor, he resets his dividers to the scale for the approximate mid latitude of each leg. The distance so measured is the length of the rhumb line.

For measuring distance on a nearly-constant-scale chart, such as the Lambert conformal, the mid-latitude precaution is usually unnecessary. Such charts generally

have a mile scale independent of the latitude scale. On a gnomonic chart a special procedure is needed, and this is usually explained on the chart.

805. Plotting and labeling the course line and positions.—**Course** is the intended horizontal direction of travel. A **course line** is a line extending in the direction of the course. From a known position of the ship the course line is drawn in the direction indicated by the course. It is good practice to label all lines and points of significance as they are drawn, for an unlabeled line or point can easily be misinterpreted later. Any simple, clear, logical, unambiguous system of labels is suitable. The following is widely used and might well be considered standard.

Label a course line with direction and speed. *Above* the course line place a capital C followed by three figures to indicate the course steered. It is customary to label and steer courses to the nearest whole degree, although they are generally computed to the nearest 0°1. The course label should indicate *true* direction, starting with 000° at true north and increasing clockwise through 360°. *Below* the course line, and under the direction label, place a capital S followed by figures representing the speed in knots. Since the course is *always* given in degrees true and the speed in knots, it is not necessary to indicate the units or the reference direction (fig. 805).

A point to be labeled is enclosed by a small circle in the case of a **fix** (an accurate position determined without reference to any former position) or dead reckoning position, and by a small square in the case of an estimated position. It is labeled with the time, usually to the nearest minute, and the nature of the position (FIX, EP, DR). Time is usually expressed in four figures without punctuation, on a 24-hour basis (art. 1903). Zone time (art. 1907) is usually used, but Greenwich mean time (art. 1907) may be employed. A course line is a succession of an infinite number of dead reckoning positions. Only selected points are labeled.

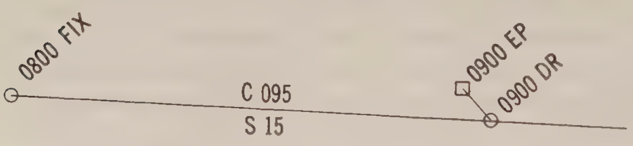

FIGURE 805.—A course line with labels.

The labels of a *line* are placed *along* the line, and those of a *point* are at an *angle to the line.*

806. Dead reckoning by plot.—As a vessel clears a harbor and proceeds out to sea, the navigator obtains one last good fix while identifiable landmarks are still available. This is called **taking departure,** and the position determined is called the **departure.** Piloting (ch. IX) comes to an end and the course is set for the open sea. The course line is drawn and labeled, and some future position is indicated as a DR position. The number of points selected for labeling depends primarily upon the judgment and individual preference of the navigator. It is good practice to label each point where a change of course or speed occurs. If such changes are frequent, no additional points need be labeled. With infrequent changes, it is good practice to label points at some regular interval, as every two hours. From departure, the dead reckoning plot continues unbroken until a new well-established position is obtained, when both DR and fix are shown. The fix serves as the start of a new dead reckoning plot. Although estimated positions are shown, it is generally not good practice to begin a new DR at these points.

A typical dead reckoning plot is shown in figure 806, indicating procedures both when there are numerous changes of course and speed and when there is a long continuous course. It is assumed that no fix is obtained after the initial one at 0800 on September 8. Note that course lines are not extended beyond their limits of usefulness. One should keep a neat plot and leave no doubt as to the meaning of each line and

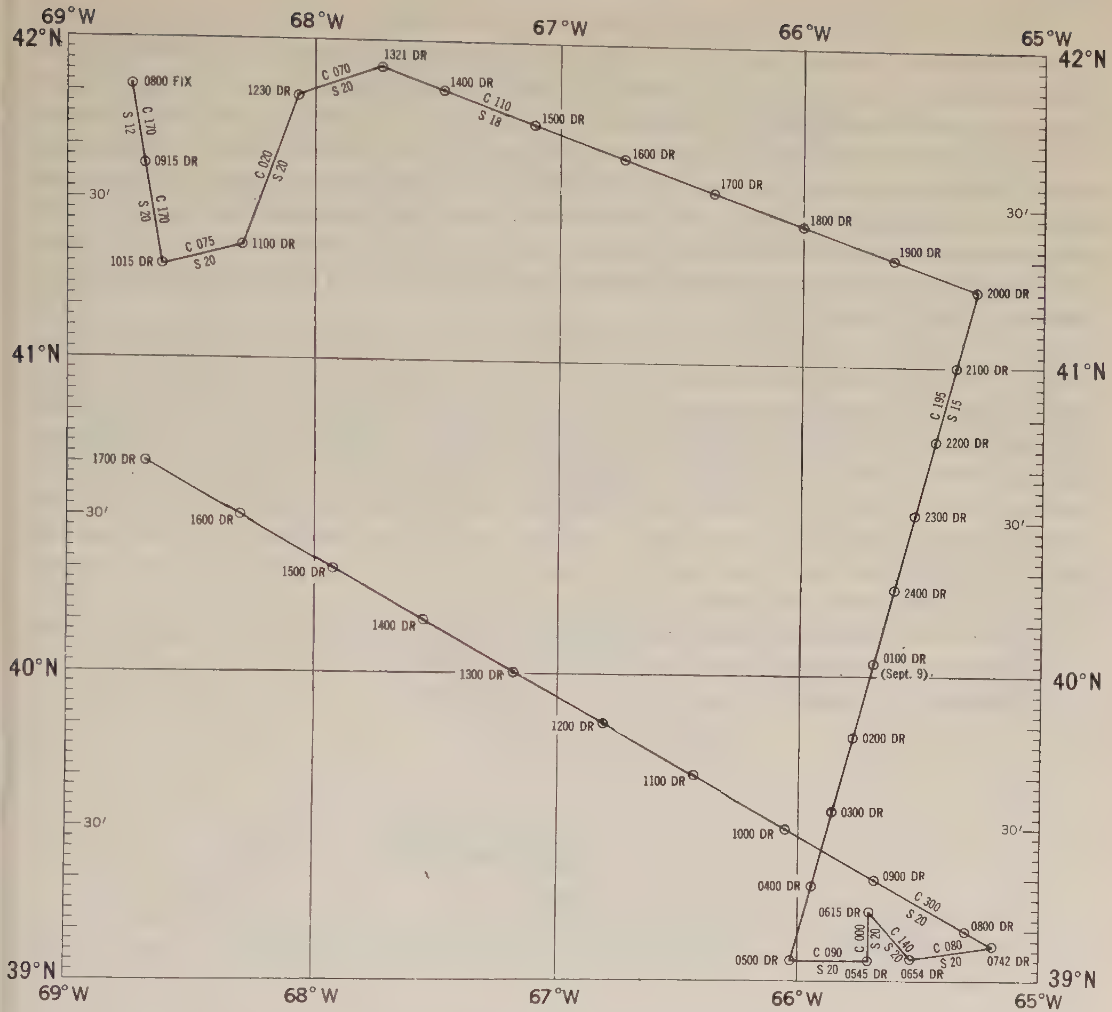

FIGURE 806.—A typical dead reckoning plot.

marked point. *A neat, accurate plot is the mark of a good navigator.* The plot should be kept extended to some future time. A good navigator is always ahead of his ship. In shoal water or when near the shore, aids to navigation, dangers, etc., it is customary to keep the dead reckoning plot on a chart. A chart overprinted with loran or other electronic position lines may be used at a considerable distance from shore. But on the open sea, with only dead reckoning and celestial navigation available, it is good practice to use a plotting sheet (art. 323).

807. Current.—Water in essentially horizontal motion over the surface of the earth is called **current.** The direction in which the water is moving is called the **set,** and the speed is called the **drift.** In navigation it is customary to use the term "current" to include all factors introducing geographical error in the dead reckoning, whether their immediate effects are on the vessel or the water. When a fix is obtained, one assumes that the current has set *from* the DR position at the same time *to* the fix, and that the drift is equal to the distance in miles between these positions, divided by the number of hours since the last fix. This is true regardless of the number of changes of course or speed since the last fix.

If set and drift since the last fix are known, or can be estimated, a better position can be obtained by applying a correction to that obtained by dead reckoning. This is conveniently done by drawing a straight line in the direction of the set for a distance equal to the drift multiplied by the number of hours since the last fix, as shown in figure 805. The direction of a straight line from the last fix to the EP is the estimated **course made good,** and the length of this line divided by the time is the estimated **speed made good.** These estimated values are sometimes called the **course of advance** (**COA**) and **speed of advance** (**SOA**), respectively. The course and speed actually made good over the ground are then called the **course over the ground** (COG) and **speed over the ground** (SOG), respectively.

If a current is setting in the same direction as the course, or its reciprocal, the course over the ground is the same as that through the water. The effect on the speed can be found by simple arithmetic. If the course and set are in the same direction, the speeds are added; if in opposite directions, the smaller is subtracted from the larger. This situation is not unusual when a ship encounters a tidal current while entering or leaving port. If a ship is *crossing* a current, solution can be made graphically by vector diagram (arts. O17, O18) since velocity over the ground is the vector sum of velocity *through* the water and velocity *of* the water. Although *distances* can be used, it is generally easier to use *speeds.*

Example 1.—A ship on course 080°, speed ten knots, is steaming through a current having an estimated set of 140° and drift of two knots.

Required.—Estimated course and speed made good.

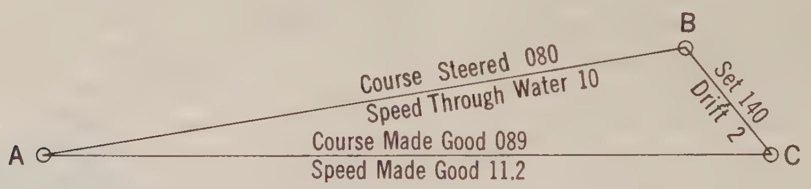

FIGURE 807a.—Finding course and speed made good through a current.

Solution (fig. 807a).—(1) From *A*, any convenient point, draw *AB*, the course and speed of the ship, in direction 080°, for a distance of ten miles.

(2) From *B* draw *BC*, the set and drift of the current, in direction 140°, for a distance of two miles.

(3) The direction and length of *AC* are the estimated course and speed made good. Determine these by measurement.

Answers.—Estimated course made good 089°, estimated speed made good 11.2 kn.

If it is required to find the course to steer at a given speed to make good a desired course, plot the current vector from the origin, *A*, instead of from *B*.

Example 2.—The captain desires to make good a course of 095° through a current having a set of 170° and a drift of 2.5 knots, using a speed of 12 knots.

Required.—The course to steer and the speed made good.

Solution (fig. 807b).—(1) From *A*, any convenient point, draw line *AB* extending in the direction of the course to be made good, 095°.

(2) From *A* draw *AC*, the set and drift of the current.

(3) Using *C* as a center, swing an arc of radius *CD*, the speed through the water (12 knots), intersecting line *AB* at *D*.

(4) Measure the direction of line *CD*, 083°5. This is the course to steer.

(5) Measure the length *AD*, 12.4 knots. This is the speed made good.

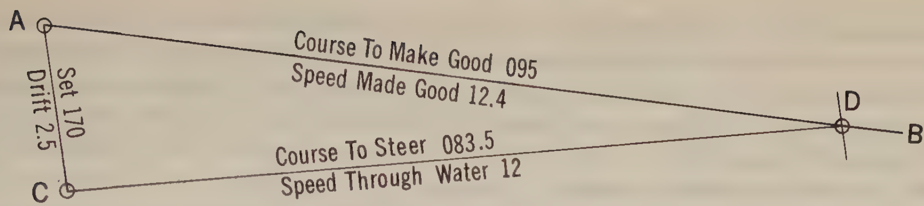

FIGURE 807b.—Finding the course to steer at a given speed to make good a given course through a current.

Answers.—Course to steer 083°5, speed made good 12.4 kn.

If it is required to find the course to steer and the speed to use to make good a desired course and speed, proceed as follows:

Example 3.—The captain desires to make good a course of 265° and a speed of 15 knots through a current having a set of 185° and a drift of three knots.

Required.—The course to steer and the speed to use.

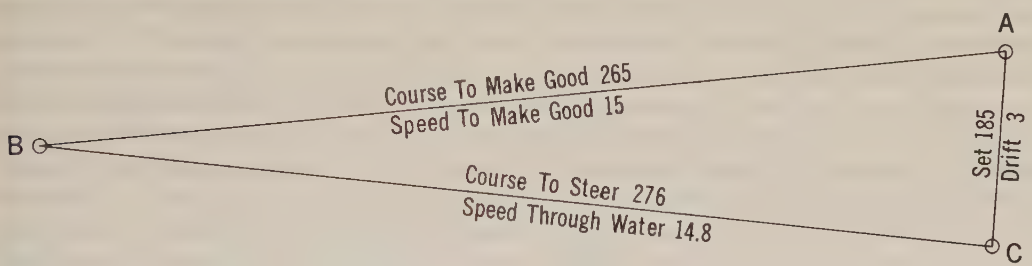

FIGURE 807c.—Finding the course to steer and the speed to use to make good a given course and speed through a current.

Solution (fig. 807c).—(1) From *A*, any convenient point, draw *AB* in the direction of the course to be made good, 265°, and for a length equal to the speed to be made good, 15 knots.

(2) From *A* draw *AC*, the set and drift of the current.

(3) Draw a straight line from *C* to *B*. The direction of this line, 276°, is the required course to steer; and the length, 14.8 knots, is the required speed.

Answers.—Course to steer 276°, speed to use 14.8 kn.

Such vector solutions can be made to any convenient scale and at any convenient place, such as the center of a compass rose, an unused corner of the plotting sheet, a separate sheet, or directly on the plot.

808. Leeway is the leeward motion of a vessel due to wind. It may be expressed as distance, speed, or angular difference between course steered and course through the water. However expressed, its amount varies with the speed and relative direction of the wind, type of vessel, amount of freeboard, trim, speed of the vessel, state of the sea, and depth of water. If information on the amount of leeway to be expected under various conditions is not available for the type vessel involved, it should be determined by observation. When sufficient data have been collected, suitable tables or graphs can be made for quick and convenient estimate. The accuracy of the information should be checked whenever convenient, and corrections made when sufficient evidence indicates the need.

Leeway is most conveniently applied by adding its effect to that of current and other elements introducing geographical error in the dead reckoning. It is customary to consider the combined effect of all such elements as current, and to make allowance

for this as explained in article 807. In sailing ship days it was common practice to consider leeway in terms of its effect upon the course only, and to apply it as a correction in the same manner that variation and deviation are applied. While this method has merit even with power vessels, it is generally considered inferior to that of considering leeway as part of current.

809. Automatic dead reckoning.—Several types of devices are in use for performing automatically all or part of the dead reckoning. Perhaps the simplest is the automatic **course recorder,** which provides a graphical record of the various courses steered. In its usual form this device is controlled by the gyro compass, and so indicates gyro courses.

Dead reckoning equipment receives inputs from the compass, usually the gyro compass, and a mechanical log or engine revolution counter. It determines *change* in latitude and longitude, the latter by first determining departure and then mechanically multiplying this by the secant of the latitude. The device is provided with counters on which latitude and longitude can be set. As the vessel proceeds, the changes are then mechanically added to or subtracted from these readings to provide a continuous, instantaneous indication of the dead reckoning position. The navigator or an assistant reads these dials at intervals, usually each hour, and records the values in a notebook. Most models of dead reckoning equipment are provided, also, with a tracer for keeping a graphical record of dead reckoning in the form of a plot by moving a pencil or pen across a chart or plotting sheet. This part of the device is called a **dead reckoning tracer.** Whatever the form, dead reckoning equipment is a great convenience, particularly when a ship is maneuvering. However, such mechanical equipment is subject to possible failure. The prudent navigator keeps a hand plot and uses the dead reckoning equipment as a check. In navigation it is never wise to rely upon a single method if a second method is available as a check.

If it were possible to measure, with complete accuracy, the direction and distance traveled *with respect to the earth,* an accurate geographical position could be known at all times. Several methods of doing so have been suggested, and while developments along these lines relate principally to aircraft and guided missiles, it is possible that from these or other developments may come some method suitable for shipboard use. The two methods most prominently suggested are (1) Doppler and (2) inertial. By the **Doppler** method one or more beams of radiant energy are directed downward at an angle. The return echo from the bottom is of a slightly different frequency due to the motion of the craft. The amount of the change, or Doppler, is proportional to the speed. By proper selection of beams, it is possible to measure speed in a lateral direction as well as in a forward direction. Distance can be determined by mechanical or electronic integration of these measurements, and this can be converted into position. By the **inertial** method, accelerometers measure the acceleration in various directions, and by double integration this is converted to distance, from which position can be determined. Either of these methods can provide considerable accuracy over a period of several hours, but since the error increases with time, they are not yet suitable for general shipboard use over long distances.

810. Dead reckoning by computation.—Dead reckoning involves the determination of position by means of course and distance from a known position. A closely related problem is that of finding the course and distance from one point to another. Although both of these problems are customarily solved by plotting directly on the chart, it occasionally becomes desirable to solve by computation, usually by logarithms (arts. O10–O15) or traverse table (art. 812). The various methods of solution are

collectively called the **sailings.** Computation should be carried to the precision shown in the examples, even though this in some instances exceeds the usable precision, and sometimes the accuracy.

811. The sailings.—In the solution of problems involved in the sailings, the following quantities are used:

1. *Latitude* (L). The latitude of the point of departure is designated L_1; that of the point of arrival or the destination, L_2; mid latitude, Lm; latitude of the vertex of a great circle, L_v; and latitude of any point on a great circle, L_x.
2. *Difference of latitude* (l).
3. *Meridional parts* (M). The meridional parts of the point of departure are designated M_1, and of the point of arrival or the destination, M_2.
4. *Meridional difference* (m).
5. *Longitude* (λ). The longitude of the point of departure is designated λ_1; that of the point of arrival or the destination, λ_2; of the vertex of a great circle, λ_v; and of any point on a great circle, λ_x.
6. *Difference of longitude* (DLo).
7. *Departure* (p).
8. *Course* or *course angle* (Cn or C).
9. *Distance* (D).

The various kinds of sailings are:

1. **Plane sailing.** The earth, or that part traversed, is regarded as a plane surface. A single course and distance, difference of latitude, and departure are the only items involved. Hence, the method provides solution for latitude of the point of arrival, but not for longitude of this point, one of the spherical sailings being needed for this problem. Because of the basic assumption that the earth is flat, this method should not be used for distances of more than a few hundred miles.
2. **Traverse sailing** combines the plane sailing solutions when there are two or more courses.
3. **Parallel sailing** is the interconversion of departure and difference of longitude when a vessel is proceeding due east or due west. This was a common occurrence when the sailings were first employed several hundred years ago, but only an incidental situation now.
4. **Middle-** (or **mid-**) **latitude sailing** involves the use of the mid latitude for converting departure to difference of longitude when the course is not due east or due west.
5. **Mercator sailing** provides a mathematical solution of the plot as made on a Mercator chart. It is similar to plane sailing, but uses meridional difference and difference of longitude in place of difference of latitude and departure, respectively.
6. **Great-circle sailing** involves the solution of courses, distances, and points along a great circle between two points, the earth being regarded as a sphere.
7. **Composite sailing** is a modification of great-circle sailing to limit the maximum latitude.

In addition, **meridian sailing** might be added to this list to cover the special case of a vessel following a course of due north or due south (true). However, no solution is needed for this case because there is no departure or difference of longitude, and the distance is considered equal to the difference of latitude in minutes. The true course is 000° or 180°.

Except for great-circle sailing and the great-circle part of composite sailing, the various problems normally arising under the sailings can be solved (1) by plane trigonometry, either using natural functions (tab. 31) or logarithms (tabs. 32 and 33);

(2) by traverse table (tab. 3), or (3) graphically. For the graphical solution, cross-section paper is helpful. The triangle of each method is drawn, and the parts are measured. Solution by computation is most accurate.

In the mathematical solution of navigational problems, the use of standard work forms is desirable to provide orderly computations and to minimize errors. This subject is further discussed in appendix Q, which gives recommended forms for many of the common problems of navigation.

Great-circle sailing and occasionally composite sailing and Mercator sailing are the only ones commonly used, except by small-boat navigators.

812. Traverse tables, such as table 3, providing a solution for any plane right triangle, can be used in the solution of the usual problems encountered in any of the sailings except great-circle and composite. A separate table is given for each degree of course if the lower line of column headings is used, and for each degree of latitude if the upper line of column headings is used. For intermediate values interpolation should be made between tables. The main part of each table involves solution for the various sides of a plane triangle. The auxiliary table to the right of each main table provides a tabulated solution for the course. The manner of using the table in specific problems is illustrated in the examples given in the explanations of the various sailings.

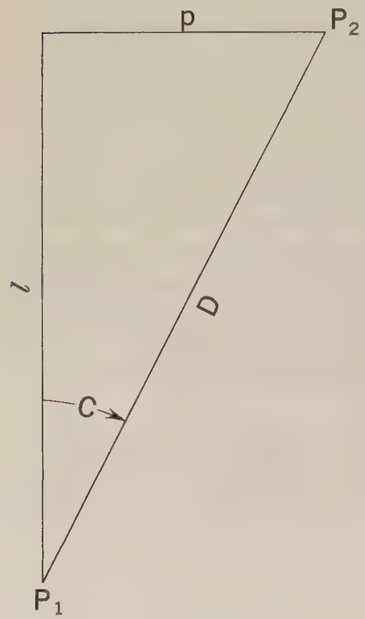

FIGURE 813.—The plane sailing triangle.

813. Plane sailing.—In plane sailing the figure formed by the meridian through the point of departure, the parallel through the point of arrival, and the course line is considered a plane right triangle. This is illustrated in figure 813, in which P_1 and P_2 are the points of departure and arrival, respectively. The course angle and the three sides are as labeled. From this triangle:

$$\cos C=\frac{l}{D} \qquad \sin C=\frac{p}{D} \qquad \tan C=\frac{p}{l}$$

From the first two of these formulas the following relationships can be derived:

$$l=D\cos C \qquad D=l\sec C \qquad p=D\sin C$$

The usual problems solved by plane sailing are: (1) given the course and distance, find the difference of latitude and the departure; and (2) the reverse of this. It is good practice to label l, N or S, and p, E or W, to aid in identification of the quadrant of the course. Logarithmic and traverse table solutions are illustrated in the following examples:

Example 1.—A vessel steams 188.4 miles on course 005°.

Required.—(1) Difference of latitude, (2) departure.

Solution.—By computation:

	D 188.4 mi.	log 2.27508	log 2.27508
	C 005°	l cos 9.99834	l sin 8.94030
(1)	l 187′.7 N	log 2.27342	
(2)	p 16.4 mi. E		log 1.21538

By traverse table:

D	l	p
100.0	99.6	8.7
80.0	79.7	7.0
8.0	8.0	0.7
0.4	0.4	0.0
188.4	(1) 187.7 N	(2) 16.4 E

Example 2.—A ship has steamed 136.6 miles north and 203.1 miles west.

Required.—(1) Course, (2) distance.

Solution.—*By computation:*

p 203.1 mi. W	log	2.30771		
l 136′.6 N	log (−)	2.13545	log	2.13545
C N 56°04′.6 W	l tan	0.17226	l sec	0.25330
(2) D 244.8 mi.			log	2.38875
(1) Cn 303°.9				

By traverse table:

			l	D (303°)	D (304°)
p 203.1 mi. W	log	2.30771	100.0	183.6	178.8
l 136′.6 N	log (−)	2.13545	30.0	55.1	53.6
p÷l 1.487	log	0.17226	6.0	11.0	10.7
C N 56°.1 W			0.6	1.1	1.1
(1) Cn 303°.9			136.6	250.8	244.2
(2) D 244.9 mi.					

In the solution, the navigational form (art. O11) is used, with the basic quantity being on the left, and related information on the same line. Thus, 2.27508 is the logarithm ("log") of 188.4, and 9.99834 is the logarithmic cosine ("l cos") of 5°.

The labels (N, S, E, W) of l, p, and C are determined by noting the direction of motion or the relative positions of the two places.

In the solution of example 2 by traverse table, it is first necessary to solve for p÷l. If this is done by logarithms, as shown above, the solution is similar to that by computation, with one additional step. Solution for p÷l can be made by any method, or course can be found as shown in the first solution, and this value used for entering the traverse table to determine the distance.

The distance in the traverse table solution is found by interpolation between the values for 303° and 304°.

When the course is near 090° or 270°, the solution of C to the nearest 0°.1 only, as by traverse table, may introduce a large error in distance.

814. Traverse sailing.—A **traverse** is a series of courses, or a track consisting of a number of course lines, as might result from a sailing vessel beating into the wind. **Traverse sailing** is the finding of a single equivalent course and distance. If the effect of an estimated current is to be considered, the set is treated as an additional course, the drift times the number of hours involved being used as the distance. If direction and distance from some point, such as a lighthouse, other than the point of departure is desired, the bearing of the point of departure from the selected position is used as the first course and the distance between these points as the first distance.

Solution is usually made by means of the traverse tables, the distance to the north or south and that to the east or west on each course being tabulated, the algebraic sum of difference of latitude and departure being found, and the result being converted to course and distance.

Example.—A ship steams as follows: course 158°, distance 15.5 miles; course 135°, distance 33.7 miles; course 259°, distance 16.1 miles; course 293°, distance 39.0 miles; course 169°, distance 40.4 miles.

Required.—Equivalent single (1) course, (2) distance.

Solution.—Solve for each leg as in example 1, article 813. Tabulate the answers as follows:

Course	Dist.	N	S	E	W
°	*mi.*	*mi.*	*mi.*	*mi.*	*mi.*
158	15.5		14.4	5.9	
135	33.7		23.8	23.8	
259	16.1		3.0		15.8
293	39.0	15.2			35.9
169	40.4		39.7	7.7	
		15.2	80.9	37.4	51.7
(1)	(2)		15.2		37.4
192.3	67.2		65.7		14.3

Convert *l* 65′.7 S, p 14.3 mi.W to equivalent single course and distance as shown in example 2, article 813.

815. Parallel sailing consists of the interconversion of departure and difference of longitude. It is the simplest form of spherical sailing (other than meridional sailing). The formulas for these transformations are:

$$\text{DLo} = \text{p sec L} \qquad\qquad \text{p} = \text{DLo cos L}$$

When solution is made by table 3, enter the table for the latitude and use the *upper* line of column headings.

Example 1.—The DR latitude of a ship on course 090° is 49°40′.2 N.

Required.—The change in longitude if the ship steams for 136.4 miles.

Solution.—By computation:

p	136.4 mi. E	log	2. 13481
L	49°40′.2 N	*l* sec	0. 18897
DLo	210′.8 E	log	2. 32378
DLo	3°30′.8 E		

By traverse table:

p	DLo (49°)	DLo (50°)
100. 0	152. 4	155. 6
30. 0	45. 7	46. 7
6. 0	9. 1	9. 3
0. 4	0. 6	0. 6
136. 4	207. 8	212. 2

DLo for L 49°40′.2 N: 210′.7=3°30′.7 E.

Example 2.—The DR latitude of a ship on course 270° is 37°50′.1 S. The ship steams on this course until the longitude changes 4°33′.5W.

Required.—The distance steamed.

Solution.—By computation:

DLo	273′.5W	log	2. 43696
L	37°50′.1S	*l* cos	9. 89751
p	216.0 mi.W	log	2. 33447

By traverse table:

DLo	p (37°)	p (38°)
200. 0	159. 7	157. 6
70. 0	55. 9	55. 2
3. 0	2. 4	2. 4
0. 5	0. 4	0. 4
273. 5	218. 4	215. 6

p for L 37°50′.1 S: 216.1 mi. W.

The labels (E or W) of p and DLo agree with the direction of motion.

816. Middle-latitude sailing, popularly called **mid-latitude sailing,** combines plane sailing and parallel sailing. Plane sailing is used to find difference of latitude and departure when course and distance are known, or vice versa. Parallel sailing is used to interconvert departure and difference of longitude, the middle or mean latitude (Lm) being used. If a course line crosses the equator, that part on each side (the north latitude and south latitude portions, respectively) should be solved separately.

This sailing, like most elements of navigation, contains certain simplifying approximations which produce answers somewhat less accurate than those yielded by more rigorous solutions. For ordinary purposes, however, the results are more accurate than the navigation of the vessel using them. From time to time suggestions have been made that a correction be applied to eliminate the error introduced by assuming that the meridians of the point of departure and of the destination converge uniformly (as the two sides of a plane angle), rather than as the sine of the latitude (approximately). The proposed correction usually takes the form of some quantity to be added to or subtracted from the middle latitude to obtain a "corrected middle latitude" for use in the solution. Tables giving such a correction have been published for both spherical and spheroidal earths. However, the actual correction is not a simple function of the middle latitude and the difference of longitude, as assumed, because the basic formulas of the sailing are themselves based upon a sphere, rather than a spheroid. Hence, the use of such a correction is misleading, and may introduce more error than it eliminates. The use of any correction is not considered justified; if highly accurate results are required, a different method should be used.

Example 1.—A vessel steams 1,253.4 miles on course 070° from lat. 15°17′.4 N, long. 151°37′.8 E.

Required.—(1) Latitude and (2) longitude of the point of arrival.

Solution.—By computation:

D	1253.4 mi.	log 3.09809	log 3.09809
C	070°	l cos 9.53405	l sin 9.97299
l	428.7 N	log 2.63214	
p	1177.8 mi. E		log 3.07108
Lm	18°51′.8 N		l sec 0.02397
DLo	1244′.7 E		log 3.09505

L_1	15°17′.4 N	L_1	15°17′.4 N
l	7°08′.7 N	½ l	3°34′.4 N
(1) L_2	22°26′.1 N	Lm	18°51′.8 N

λ_1	151°37′.8 E
DLo	20°44′.7 E
(2) λ_2	172°22′.5 E

By traverse table:

D	l	p
1000.0	342.0	940.0
200.0	68.4	187.9
50.0	17.1	47.0
3.0	1.0	2.8

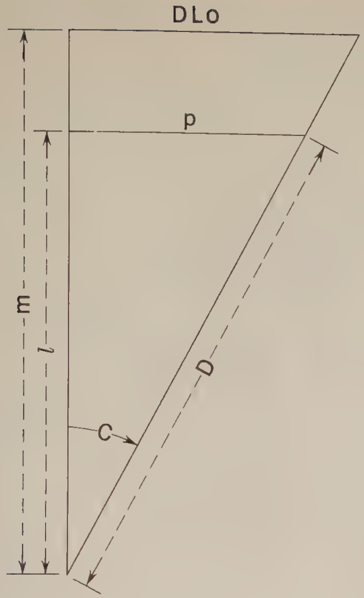

FIGURE 817.—Mercator sailing relationships.

The labels (N, S, E, W) of l, p, DLo, and C are determined by noting the direction of motion or the relative positions of the two places.

When the course is near 090° or 270°, the solution of C to the nearest 0°.1 only, as by traverse table, may introduce a large error in distance.

817. Mercator sailing problems are solved graphically when measurement is made on a Mercator chart. Graphical solution can also be made as shown in figure 817. The lower part is identical with the plane sailing triangle, figure 813. For mathematical solution the formulas of Mercator sailing are:

$$\tan C = \frac{DLo}{m} \qquad D = l \sec C$$

$$l = D \cos C \qquad DLo = m \tan C$$

Another formula sometimes of use is:

$$p = \frac{l \times DLo}{m}$$

Solution can be made by computation or by traverse table.

Example 1.—A ship at lat. 32°14′.7 N, long. 66°28′.9 W is to head for Chesapeake Lightship, lat. 36°58′.7 N, long. 75°42′.2 W.

Required.—(1) Course, (2) distance.

Solution.—By computation:

L_1	32°14′.7 N	M_1	2033.3	λ_1	66°28′.9 W
L_2	36°58′.7 N	M_2	2377.0	λ_2	75°42′.2 W

(1) Cn	301°.8			284.0	551.4	535.9
(2) D	539.0 mi.					

Example 2.—A ship at lat. 75°31′.7 N, long. 79°08′.7 W, in Baffin Bay, steams 263.5 miles on course 155°.

Required.—(1) Latitude and (2) longitude of point of arrival.

Solution.—By computation:

D 263.5 mi.	log 2.42078	
C 155°	l cos 9.95728	l tan 9.66867
l 238′.8 S	log 2.37806	
m 846.3		log 2.92752
DLo 394′.6 E		log 2.59619

L_1 75°31′.7 N	M_1 7072.4	λ_1 79°08′.7 W
l 3°58′.8 S		DLo 6°34′.6 E
(1) L_2 71°32′.9 N	M_2 6226.1	(2) λ_2 72°34′.1 W
	m 846.3	

By traverse table:

D	l	m	DLo
200.0	181.3	800.0	373.0
60.0	54.4	40.0	18.6
3.0	2.7	6.0	2.8
0.5	0.5	0.6	0.3
263.5	238.9	846.6	394.7

L_1 75°31′.7 N	M_1 7072.4	λ_1 79°08′.7 W
l 3°58′.9 S		DLo 6°34′.7 E
(1) L_2 71°32′.8 N	M_2 6225.8	(2) λ_2 72°34′.0 W
	m 846.6	

The labels (N, S, E, W) of l, DLo, and C are determined by noting the direction of motion or the relative positions of the two places.

If the course is near 090° or 270°, a small error in C introduces a large error in DLo. The solution for C to the nearest 0°.1 only, as by traverse table, may introduce a large error in distance if the course is near 090° or 270°.

818. Rhumb lines and great circles.—The principal advantage of a **rhumb line** is that it maintains constant true direction. A ship following the rhumb line between two places does not change true course. A rhumb line makes the same angle with all meridians it crosses and appears as a straight line on a Mercator chart. It is adequate for most purposes of navigation, bearing lines (except long ones, as those obtained by radio) and course lines both being plotted on a Mercator chart as rhumb lines, except in high latitudes. The equator and the meridians are great circles, but may be considered special cases of the rhumb line. For any other case, the difference between the rhumb line and the great circle connecting two points increases (1) as the latitude increases, (2) as the difference of latitude between the two points decreases, and (3) as the difference of longitude increases. It becomes very great for two places widely separated on the same parallel of latitude far from the equator.

A **great circle** is the intersection of the surface of a sphere and a plane through the center of the sphere. It is the largest circle that can be drawn on the surface of the sphere, and is the shortest distance, along the surface, between any two points on the sphere. Any two points are connected by only one great circle unless the points are antipodal (180° apart on the earth), and then an infinite number of great circles passes through them. Thus, two points on the same meridian are not joined by any great circle other than the meridian, unless the two points are antipodal. If they are the

poles, *all* meridians pass through them. Every great circle bisects every other great circle. Thus, except for the equator, every great circle lies half in the northern hemisphere and half in the southern hemisphere. Any two points 180° apart on a great circle have the same latitude numerically, but contrary names, and are 180° apart in longitude. The point of greatest latitude is called the **vertex.** For each great circle there is one of these in each hemisphere, 180° apart. At these points the great circle is tangent to a parallel of latitude, and hence its direction is due east-west. On each side of these vertices the direction changes progressively until the intersection with the equator is reached, 90° away, where the great circle crosses the equator at an angle equal to the latitude of the vertex. As the great circle crosses the equator, its change in direction reverses, again approaching east-west, which it reaches at the next vertex.

On a Mercator chart a great circle appears as a sine curve extending equal distances each side of the equator. The rhumb line connecting any two points of the great circle on the same side of the equator is a chord of the curve, being a straight line nearer the equator than the great circle. Along any intersecting meridian the great circle crosses at a higher latitude than the rhumb line. If the two points are on opposite sides of the equator, the direction of curvature of the great circle relative to the rhumb line changes at the equator. The rhumb line and great circle may intersect each other, and if the points are equal distances on each side of the equator, the intersection takes place at the equator.

819. Great-circle sailing is used when it is desired to take advantage of the shorter distance along the great circle between two points, rather than to follow the longer rhumb line. The arc of the great circle between the points is called the **great-circle track.** If it could be followed exactly, the destination would be dead ahead throughout the voyage (assuming course and heading were the same). The rhumb line *appears* the more direct route on a Mercator chart because of chart distortion. The great circle crosses meridians at higher latitudes, where the distance between them is less.

The decision as to whether or not to use great-circle sailing depends upon the conditions. The saving in distance should be worth the additional effort, and of course the great circle should not cross land, or carry the vessel into dangerous waters or excessively high latitudes. A slight departure from the great circle or a modification called composite sailing (art. 825) may effect a considerable saving over the rhumb line track without leading the vessel into danger. If a fix indicates the vessel is a considerable distance to one side of the great circle, the more desirable practice often is to determine a new great-circle track, rather than to return to the original one.

Since a great circle is continuously changing direction as one proceeds along it, no attempt is customarily made to follow it exactly, except in polar regions (ch. XXV). Rather, a number of points are selected along the great circle, and rhumb lines are followed from point to point, taking advantage of the fact that for short distances a great circle and a rhumb line almost coincide.

The number of points to use is a matter of personal preference, a large number of points providing closer approximation to the great circle but requiring more frequent change of course. As a general rule, each 5° of longitude is a convenient length. Legs of equal length are not provided in this way, but this is not objectionable under normal conditions.

If a magnetic compass is used, the variation for the middle of the leg is usually used for the entire leg. In some areas the change in variation and the change in course due to convergence of the meridians are in opposite directions and of about the same magnitude. In these areas the same magnetic course can be used for relatively long distances. The change of deviation with change of heading may also be a consideration.

The problems of great-circle sailing can be solved by (1) chart (art. 820), (2) conversion angle (art. 821), (3) computation (art. 822), (4) table (art. 823), (5) graphically, or (6) mechanically. Of these, (5) and (6) are but graphical or mechanical solutions of (3). They usually provide solution only for initial course and the distance, and are not in common use.

820. Great-circle sailing by chart.—Problems of great-circle sailing, like those of rhumb line sailing, are most easily solved by plotting directly on a chart. For this purpose the U. S. Navy Hydrographic Office publishes a number of charts on the gnomonic projection (art. 317), covering the principal navigable waters of the world. On this projection any straight line is a great circle, but since the chart is not conformal (art. 302), directions and distances cannot be measured directly, as on a Mercator chart. An indirect method is explained on each chart.

The usual method of using a gnomonic chart is to plot the great circle and, if it provides a satisfactory track, to determine a number of points along the track, using the latitude and longitude scales in the immediate vicinity of each point. These points are then transferred to a Mercator chart or plotting sheet and used as a succession of destinations to be reached by rhumb lines. The course and distance for each leg is determined by measurement on the Mercator chart or plotting sheet. This method is illustrated in figure 820, which shows a great circle plotted as a straight line on a gnomonic chart and a series of points transferred to a Mercator chart. The arrows represent corresponding points on the two charts. The points can be plotted directly on plotting sheets without the use of a small-scale chart, but the use of the chart provides a visual check to avoid large errors, and a visual indication of the suitability of the track.

Since gnomonic charts are normally used only because of their great-circle properties, they are often popularly called **great-circle charts.**

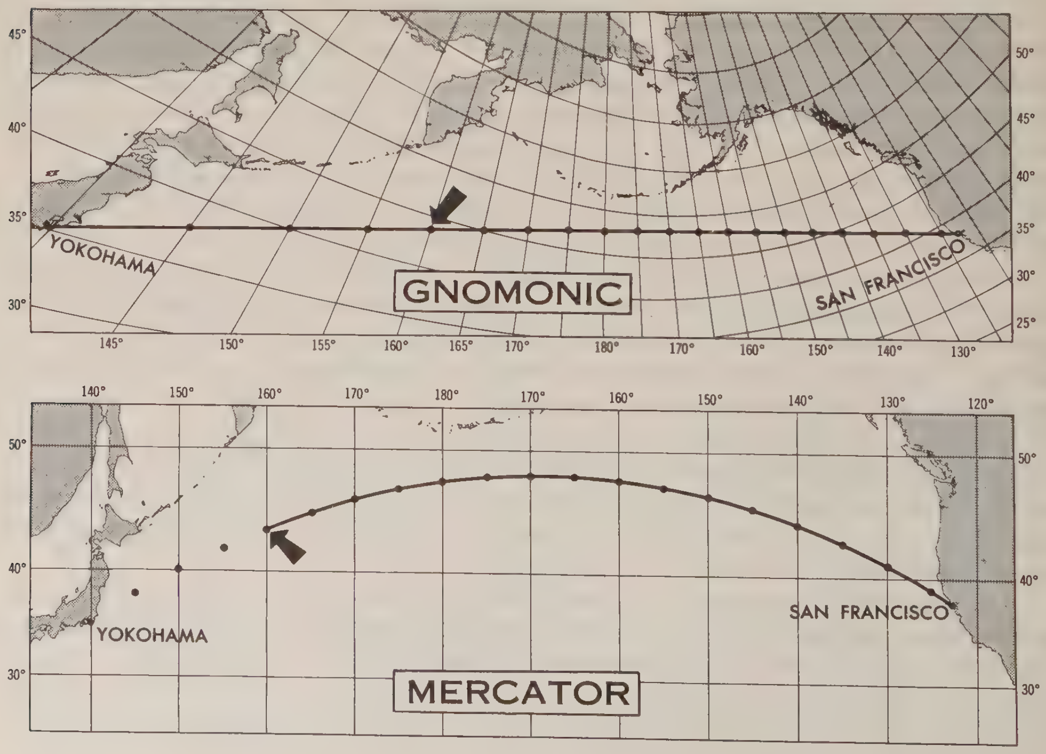

FIGURE 820.—Transferring great-circle points from a gnomonic chart to a Mercator chart.

A projection on which a straight line is *approximately* a great circle can be used in place of a gnomonic chart with negligible error. If such a projection is conformal, as in the case of the Lambert conformal (art. 314), measurement of course and distance of each leg can be made directly on the chart, as explained in article 2511.

Some great circles are shown on pilot charts and certain other charts, together with the great-circle distances. Where tracks are recommended on charts or in sailing directions, it is good practice to follow such recommendations.

821. Great-circle sailing by conversion angle.—The direction of the great circle at the point of departure is called the **initial great-circle course,** and its direction at the destination is called the **final great-circle course.** The *difference* between the initial great-circle course and the single rhumb line course is called **conversion angle.** This is usually about half the difference between initial and final great-circle courses.

Conversion angles for difference of longitude to 120°, sufficient for virtually all situations in which great-circle sailing is likely to be used by ships, are given in table 1. To use the table, measure the rhumb line course on a Mercator chart (or compute it by Mercator or mid-latitude sailing) and apply the conversion angle to find the initial great-circle course. The sign of the correction can be determined by means of the tabulation at the bottom of the table. With a little practice, one can determine the sign mentally by remembering that the great-circle course always lies nearer the pole (in the hemisphere of the point of departure) than the rhumb line course, except for those values given in italics.

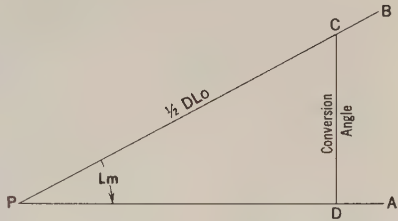

FIGURE 821.—Graphical solution for conversion angle.

The use of the conversion angle as taken directly from the table results in a course line tangent to the great circle (as plotted on a Mercator chart) and hence one that carries the vessel to higher latitudes than the great circle. To convert this to the corresponding chord, as in great-circle sailing by chart, divide the conversion angle by the number of legs, and *subtract* this value from the tabulated conversion angle before applying the correction to the rhumb line course. At the end of each leg make a new solution, using the position of the vessel as the point of departure.

This method does not indicate the suitability of the route unless the entire solution is made in advance and the results plotted on a chart.

Approximate values of conversion angle can be found by the formula:

$$\tan \text{conversion angle} = \frac{\sin \text{Lm} \tan \frac{1}{2} \text{DLo}}{\cos \frac{1}{2} l}$$

if both points are on the same side of the equator. For small differences of latitude, $\cos \frac{1}{2} l$ can be considered 1 without introducing a significant error. The tangent of a small angle equals, approximately, the angle itself (in radians). Therefore, for small values of DLo and l (up to 15° to 20°) the formula can be simplified:

$$\text{conversion angle} = \tfrac{1}{2} \text{DLo} \sin \text{Lm}.$$

This formula can be solved graphically (fig. 821). Draw any line *PA*, and from *P* draw *PB* making an angle with *PA* equal to Lm. Along *PB* measure ½ DLo, letting any convenient linear unit equal 1°. From *C*, the point thus found, draw *CD* perpendicular to *PA*. The length of *CD* in the units used for ½ DLo is the conversion angle in degrees. Conversion angle can also be determined by table 3, using mid latitude as course, ½ DLo as *D*, and conversion angle as p. The value found by formula, however solved, may not be accurate for large differences of latitude.

822. Great-circle sailing by computation.—In figure 822, 1 is the point of departure, 2 the destination, P the pole nearer 1, $1XV2$ the great circle through 1 and 2, V the vertex, and X any point on the great circle. The arcs $P1$, PX, PV, and $P2$ are the colatitudes of points 1, X, V, and 2, respectively. If 1 and 2 are on opposite sides of the equator, $P2$ is $90° + L_2$. The length of arc 1–2 is the great-circle distance between 1 and 2. Arcs 1–2, $P1$, and $P2$ form a spherical triangle. The angle at 1 is the initial great-circle course from 1 to 2, that at 2 the supplement of the final great-circle course (or the initial course from 2 to 1), and that at P the DLo between 1 and 2.

Great-circle sailing by computation usually involves solution for the initial great-circle course; the distance; latitude and longitude, and sometimes the distance, of the vertex; and the latitude and longitude of various points (X) on the great circle. The computation for initial course and the distance involves solution of an oblique spherical triangle, and any method of solving such a triangle can be used. If 2 is the **geographical position** (**GP**) of a celestial body (the point at which the body is in the zenith), this triangle is solved in celestial navigation, except that 90°−D (the altitude) is desired instead of D. The solution for the vertex and any point X usually involves the solution of right spherical triangles.

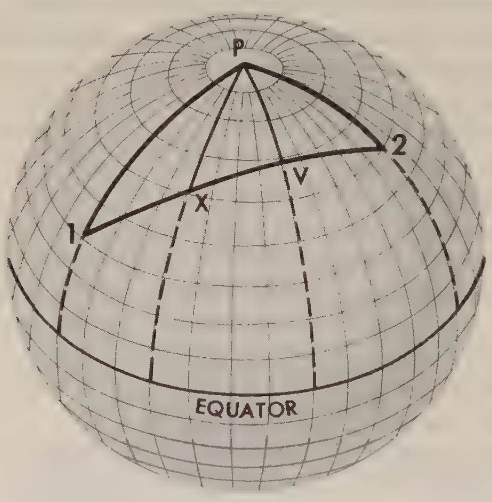

FIGURE 822.—The navigational triangle of great-circle sailing.

Although various formulas can be used, haversine formulas are considered most suitable for determining initial course and the distance, as these avoid the ambiguity that may arise through the use of trigonometric functions which do not indicate the quadrant in which the answer lies. In the formulas given below, the subscripts refer to the points indicated in figure 822. All terms without subscripts are from 1 to 2, D_v and DLo_v are from 1 to V, and D_{vx} and DLo_{vx} are from V to X. Other quantities can be computed by interchanging 1 and 2 in figure 822 and using the same formulas. The following formulas are suitable for great-circle sailing by computation:

$$\text{hav D} = \text{hav DLo} \cos L_1 \cos L_2 + \text{hav } l$$

which may be written $\text{hav D} = \text{hav } \theta + \text{hav } l$ (where $\text{hav } \theta = \text{hav DLo} \cos L_1 \cos L_2$)

$$\text{hav C} = \sec L_1 \csc D\,[\text{hav co}L_2 - \text{hav }(D \sim \text{co}L_1)]$$

$$\cos L_v = \cos L_1 \sin C$$

$$\sin DLo_v = \cos C \csc L_v$$

$$\sin D_v = \cos L_1 \sin DLo_v$$

$$\tan L_x = \cos DLo_{vx} \tan L_v$$

Example.—A ship is proceeding from Manila to Los Angeles. The captain wishes to use great-circle sailing from lat. 12°45′.2 N, long. 124°20′.1 E, off the entrance to San Bernardino Strait, to lat. 33°48′.8 N, long. 120°07′.1 W, five miles south of Santa Rosa Island.

Required.—(1) The initial great-circle course.

(2) The great-circle distance.

(3) The latitude and longitude of the vertex.

(4) The distance from the point of departure to the vertex.

(5) The latitude and longitude of points at DLo intervals of 12° each side of the vertex.

Solution.—

λ_1	124°20′.1 E					D	103°05′.9

(5) λ_x	148°34′.4 W	136°34′.4 W	124°34′.4 W	———	———	———

CoL_1 is always 90° − L_1. CoL_2 is 90° − L_2 if L_1 and L_2 are of same name, and 90° + L_2 if of contrary name.

D $\sim$ coL_1 is always the numerical difference between D and coL_1.

C is labeled N or S to agree with L_1 and E or W to agree with DLo. This is not the same as in rhumb line sailings. In great-circle sailing L_2 may be south of L_1, yet the initial course may have a northerly component.

L_v is always numerically equal to or greater than L_1 or L_2.

If C is less than 90°, the nearer vertex is toward L_2; but if C is greater than 90°, the nearer vertex is in the opposite direction.

DLo_v and D_v of the nearer vertex are never greater than 90°. However, when L_1 and L_2 are of contrary name, the other vertex, 180° away, may be the preferable one to use in the solution for various points along the great circle if it is nearer the mid point of the great circle.

The vertex nearer L_1 has the same name (N or S) as L_1.

L_x has the same name (N or S) as L_v if DLo_{vx} is less than 90°, but the opposite name if DLo_{vx} is greater than 90°.

The great circle is a symmetrical curve about the vertex. Hence, any given DLo can be applied to λ_v in both directions (E and W) to find two points having the same

latitude. However, if whole degrees of λ_x are desired, different E and W intervals are needed unless λ_v is a whole degree or an exact half degree.

Only those points on the portion of the great circle between the point of departure and destination are recorded.

The following formulas are sometimes useful in great-circle sailing:

$$\sin C = \sin DLo \cos L_2 \csc D$$

This offers a simpler solution than the haversine formula, but unless L_2 is of the same name and equal to or greater than L_1, it leaves doubt as to whether C is less or greater than 90°.

$$\cos C = \sin L_v \sin DLo_v$$

This offers an even simpler solution, but has the same limitations as those given above. Further, it requires a knowledge of the position of the vertex. It is particularly useful in determining the direction of the great circle at any given point along the circle.

$$\sin L_x = \sin L_v \cos D_{vx}$$

$$\sin DLo_{vx} = \sec L_x \sin D_{vx}$$

These formulas are useful for finding points at approximately equal *distances*, along the great circle, from the vertex, should this be considered more desirable than finding points of equal DLo. The method of selecting the longitude (or DLo_{vx}) and determining the latitude at which the great circle crosses the selected meridian provides shorter legs in higher latitudes and longer legs in lower latitudes, where the difference between the great circle and rhumb line is smaller. In using these formulas, D_{vx} is expressed in degrees. If it is greater than 90° (5,400 miles), L_x is of contrary name to L_v, and DLo_{vx} is greater than 90°.

$$\cos DLo_{vx} = \tan L_x \cot L_v$$

This formula is useful in determining the longitude (or DLo_{vx}) at which the great circle crosses selected parallels of latitude. If L_x is of contrary name to L_v, DLo_{vx} is greater than 90°. This formula is also used in composite sailing (art. 825).

823. Great-circle sailing by table.—Although tables designed to facilitate the computations of great-circle sailing have been published, no such table is in common use today. However, any method of solving the astronomical triangle of celestial navigation can be used for solving great-circle sailing problems. When such an adaptation is made, the point of departure replaces the assumed position of the observer, the destination replaces the geographical position of the body, difference of longitude replaces meridian angle, initial course angle replaces azimuth angle, and great-circle distance replaces zenith distance (90°−altitude). Therefore, any table of azimuths (if the entering values are meridian angle, declination, and latitude) can be used for determining initial great-circle course. H.O. Pubs. Nos. 208, 211, 214, 249, 260, and 261 are examples of tables that can be used for this purpose. Tables which provide solution for altitude, such as H.O. Pubs. Nos. 208, 211, 214, and 249, can be used for determining great-circle distance. The required distance is 90°−altitude (90°+negative altitudes).

In inspection tables such as H.O. Pubs. Nos. 214, 249, 260, and 261, the given combination of L_1, L_2, and DLo may not be tabulated. In this case reverse the name of L_2 and use 180°—DLo for entering the table. The required course angle is then 180° minus the tabulated azimuth, and distance is 90° plus the altitude. If neither com-

bination can be found, solution cannot be made by that method. By interchanging L_1 and L_2, one can find the supplement of the final course angle.

Solution by table often provides a rapid approximate check, but accurate results usually require triple interpolation (art. P4). Inspection tables do not provide solution for points along the great circle, and therefore are of limited usefulness.

An example of the use of H.O. Pub. No. 214 for great-circle sailing is given as example 8, near the front of each volume.

824. Altering a great-circle track to avoid obstructions.—Great-circle sailing cannot be used unless the great-circle track is free from obstructions. It does not start until one clears the harbor and takes his departure (art. 806), and often ends near the entrance to the destination. However, islands, points of land, or other obstructions may prevent the use of great-circle sailing over the entire distance. One of the principal advantages of solution by great-circle chart is that the presence of any obstructions is immediately apparent.

Often a relatively short run by rhumb line is sufficient to reach a point from which the great-circle track can be followed. Where a choice is possible, the rhumb line selected should conform as nearly as practicable to the direct great circle.

If the great circle crosses a small island, one or more legs may be altered slightly, or perhaps the drift of the vessel will be sufficient to make any planned alteration unnecessary. The possible use of the island in obtaining an en route fix should not be overlooked. If a larger obstruction is encountered, as in the case of the Aleutian Islands on a great circle from Seattle to Yokohama, some judgment may be needed in selecting the track. It may be satisfactory to follow a great circle to the vicinity of the obstruction, one or more rhumb lines along the edge of the obstruction, and another great circle to the destination. Another possible solution is the use of composite sailing (art. 825), and still another the use of two great circles, one from the point of departure to a point near the maximum latitude of unobstructed water, and the second from this point to the destination.

It is sometimes desirable to alter a great-circle track to avoid unfavorable winds or currents. The shortest route is not always the quickest.

Whatever the problem, a great-circle chart can be helpful in its solution.

825. Composite sailing.—When the great circle would carry a vessel to a higher latitude than desired, a modification of great-circle sailing, called **composite sailing,** may be used to good advantage. The composite track consists of a great circle from the point of departure and tangent to the limiting parallel, a course line along the parallel, and a great circle tangent to the limiting parallel and through the destination.

Solution of composite sailing problems is most easily made by means of a great-circle chart. Lines from the point of departure and the destination are drawn tangent to the limiting parallel. The coordinates of various selected points along the composite track are then measured and transferred to a Mercator chart, as in great-circle sailing (art. 820).

Composite sailing problems can also be solved by computation. For this purpose the last formula of article 822 is used:

$$\cos DLo_{vx} = \tan L_x \cot L_v.$$

In the computation, the point of departure and the destination are used successively as point X.

Example.—A ship leaves Baltimore, bound for Bordeaux (Royan), France. The captain desires to use composite sailing from lat. 36°57′.7 N, long. 75°42′.2 W, one mile

south of Chesapeake Lightship, to lat. 45°39′.1 N, long. 1°29′.8 W, near the entrance to Grande Passe de l'Ouest, limiting the maximum latitude to 47° N.

Required.—(1) The longitude at which the limiting parallel is reached. (2) The longitude at which the limiting parallel should be left.

Solution.—

L_1	36°57′.7 N	l tan 9.87651	
L_2	45°39′.1 N		l tan 0.00988
L_v	47°00′.0 N	l cot 9.96966	l cot 9.96966
DLo_{v1}	45°26′.1 E	l cos 9.84617	
DLo_{v2}	17°27′.0 W		l cos 9.97954
(1) λ_{v1}	30°16′.1 W		
(2) λ_{v2}	18°56′.8 W		

Composite sailing applies only when the vertex lies between the point of departure and the destination.

The remainder of the problem is one of solving the two great circles by great-circle sailing and the east-west portion by parallel sailing. Since both great circles have vertices at the same parallel, computation for C, D, and DLo_{vx} can be made by considering them parts of the *same* great circle with L_1, L_2, and L_v as given and $DLo = DLo_{v1} + DLo_{v2}$. The total distance is the sum of the great-circle and parallel distances. In finding λ_x be careful to apply DLo_{vx} to the correct vertex and in the correct direction.

Problems

806a. Draw a small area plotting sheet by either method explained in article 324, covering the area between latitude 32°-34° N and longitude 118°-122° W. Plot the following points:

A	L 33°49′.1 N	λ 120°52′.0 W	*C*	L 33°38′.0 N	λ 118°38′.6 W
B	L 32°17′.4 N	λ 121°28′.0 W	*D*	L 32°30′.6 N	λ 118°36′.2 W

Required.—(1) The bearings of *B*, *C*, and *D* from *A*.

(2) The course and distance of *A*, *B*, and *C* from *D*.

Answers.—(1) B_{AB} 198°.5, B_{AC} 095°.5, B_{AD} 124°; (2) C_{DA} 304°, D_{DA} 138.8 mi., C_{DB} 264°.5, D_{DB} 145.7 mi., C_{DC} 358°.5, D_{DC} 67.2 mi.

806b. Use the plot of problem 806a. A ship starts from *A* at 1200, and steams as follows:

Time	*Course*	*Speed*
1200	120°	15 kn.
1330	240°	15 kn.
1500	240°	17 kn.
1800	125°	20 kn.
2000	090°	20 kn.
2300	015°	10 kn.
0500		

Plot and label the dead reckoning course line and DR positions.

Required.—(1) The dead reckoning position of the ship at 0500.

(2) The bearing and distance of *D* from the 2300 DR position.

(3) The course and distance from the 0500 DR position to *C*.

(4) Estimated time of arrival (ETA), to the nearest minute, at *C* if the ship proceeds directly from the 0500 DR position at 20 knots.

Answers.—(1) 0500 DR: L 33°35′.1 N, λ 119°35′.8 W; (2) B 096°, D 66.0 mi.; (3) C 086°, D 48.1 mi.; (4) ETA 0724.

807a. A ship on course 120°, speed 12 knots, is steaming through a current having a set of 350° and a drift of 1.5 knots.

Required.—Course and speed made good.

Answers.—Course made good 114°, speed made good 11.1 kn.

807b. The captain desires to make good a course of 180° through a current having a set of 090° and a drift of two knots, using a speed of 11 knots.

Required.—The course to steer and the speed made good.

Answers.—Course to steer 190°.5, speed made good 10.8 kn.

807c. The captain desires to make good a course of 325° and a speed of 20 knots through a current having a set of 270° and a drift of one knot.

Required.—The course to steer and the speed to use.

Answers.—Course to steer 327°, speed to use 19.4 kn.

813a. A vessel steams 117.3 miles on course 214°.

Required.—(1) Difference of latitude, (2) departure, by plane sailing.

Answers.—(1) l 97′.2 S, (2) p 65.6 mi. W.

813b. A steamer is bound for a port 173.3 miles south and 98.6 miles east of the vessel's position.

Required.—(1) Course, (2) distance, by plane sailing.

Answers.—(1) C 150°.4; (2) D 199.4 mi. by computation, 199.3 mi. by traverse table.

814a. A ship steams as follows: course 359°, distance 28.8 miles; course 006°, distance 16.4 miles; course 266°, distance 4.9 miles; course 144°, distance 3.1 miles; course 333°, distance 35.8 miles; course 280°, distance 19.3 miles.

Required.—(1) Course, (2) distance, by traverse sailing.

Answers.—(1) C 334°.4, (2) D 86.1 mi.

814b. A lightship bears 020°, distant 3.4 miles from a ship standing out to sea at a speed of 12 knots. The ship steams on the following courses for the times indicated: course 090° for 18^m, course 114° for 1^h12^m, course 070° for 3^h45^m, course 095° for 54^m, course 050° for 36^m. The navigator estimates that during this entire time the ship has been in a current having a set of 315° and a drift of 0.5 knot.

Required.—The bearing and distance of the estimated position from the lightship, by traverse sailing.

Answers.—B 080°.3, D 73.0 mi. by computation, 73.1 mi. by traverse table.

815a. The 1530 DR position of a ship is lat. 44°36′.3 N, long. 31°18′.3 W. The ship is on course 270°, speed 17 knots.

Required.—The 2000 DR position, by parallel sailing.

Answer.—2000 DR: L 44°36′.3 N, λ 33°05′.7 W.

815b. The captain of the ship of problem 815a desires to change course when the ship arrives at long. 38°00′.0 W.

Required.—Estimated time of arrival (ETA) at the turning point, by parallel sailing.

Answer.—ETA 0819 the following day.

816a. A vessel steams 263.3 miles on course 340° from lat. 16°32′.2 S, long. 1°04′.4 E.

Required.—(1) Latitude and (2) longitude of the point of arrival, by middle-latitude sailing.

Answer.—By computation or traverse table: (1) L 12°24′.8 S, (2) λ 0°28′.6 W.

816b. A vessel leaves lat. 45°00′.0 N, long. 150°00′.0 W and arrives at lat. 38°18′.7 N, long. 137°14′.6 W.

Required.—(1) Course made good, (2) distance made good, by middle-latitude sailing.

Answers.—(1) C 125°.1; (2) D 698.6 mi. by computation, 697.9 mi. by traverse table.

816c. A vessel is at lat. 1°08′.3 S, long. 175°24′.5 E. It steams at 13.5 knots on course 075° for 22^h15^m. Twenty-four hours after that it is at lat. 0°06′.6 S, long. 174°20′.0 W.

Required.—(1) Latitude and (2) longitude of the point of arrival after 22^h15^m; (3) course and (4) distance made good during the last 24 hours of steaming; and (5) course and (6) distance made good over entire period, by middle-latitude sailing.

Answers.—(1) L 0°09′.5 N by computation, 0°09′.4 N by traverse table; (2) λ 179°45′.3 W; (3) C 092°.8; (4) D 325.7 mi. by computation, 338.3 mi. by traverse table; (5) C 084°.3; (6) D 618.5 mi. by computation, 625.6 mi. by traverse table.

817a. A ship at lat. 33°53′.3 S, long. 18°23′.1 E, leaving Cape Town, heads for Ambrose Lightship, lat. 40°27′.1 N, long. 73°49′.4 W.

Required.—(1) Course and (2) distance, by Mercator sailing.

Answers.—(1) C 310°.9; (2) D 6,811.5 mi. by computation, 6,812.8 mi. by traverse table. Compare these answers with those of problem 822, the great-circle sailing solution between the same points.

817b. A ship at lat. 15°03′.7 N, long. 151°26′.8 E steams 57.4 miles on course 035°.

Required.—(1) Latitude and (2) longitude of the point of arrival, by Mercator sailing.

Answers.—(1) L 15°50′.7 N, λ 152°00′.7 E.

821. Point *A* is at lat. 35°24′.2 N, long. 125°02′.6 W. Point *B* is at lat. 41°09′.2 N, long. 147°22′.6 E.

Required.—The conversion angle from *A* to *B* (1) by table 1, (2) by complete formula, (3) by construction; (4) rhumb line course by Mercator sailing; (5) initial great-circle course (using table 1, conversion angle); (6) chord course for first leg, if there are to be 17 legs (using table 1, conversion angle).

Answers.—Conversion angle (1) 29°.8, (2) 30°.7, (3) 27°.1, (4) Cn 274°.8, (5) Cn 304°.6, (6) Cn 302°.8.

822. A ship leaves Cape Town bound for New York City. The captain decides to use great-circle sailing from lat. 33°53′.3 S, long. 18°23′.1 E (near Green Point Light) to Ambrose Lightship, lat. 40°27′.1 N, long. 73°49′.4 W.

Required.—(1) The initial great-circle course.

(2) The great-circle distance.

(3) The latitude and longitude of both vertices.

(4) The distance from the point of departure to each vertex.

(5) The latitude and longitude of points on the great circle at longitude 15° E and at each 5° of longitude thereafter to longitude 70° W.

Answers.—(1) C 304°.5. (2) D 6,762.7 mi. (3) L_v 46°49′.4 S, λ_v 69°18′.8 E; L_v 46°49′.4 N, λ_v 110°41′.2 W. (4) D 2,407.5 mi. to eastern hemisphere vertex, 8,392.5 mi. to western hemisphere vertex. (5) L_1 33°53′.3 S, λ_1 18°23′.1 E (point of departure); L_x 31°52′.2 S, λ_x 15°00′.0 E; L_x 28°32′.5 S, λ_x 10°00′.0 E; L_x 24°47′.7 S, λ_x 5°00′.0 E; L_x 20°37′.8 S, λ_x 0°00′.0; L_x 16°04′.5 S, λ_x 5°00′.0 W; L_x 11°10′.8 S, λ_x 10°00′.0 W; L_x 6°01′.7 S, λ_x 15°00′.0 W; L_x 0°43′.9 S, λ_x 20°00′.0 W; L_x 4°35′.0 N, λ_x 25°00′.0 W; L_x 9°47′.2 N, λ_x 30°00′.0 W; L_x 14°45′.7 N, λ_x 35°00′.0 W; L_x 19°25′.0 N, λ_x 40°00′.0 W; L_x 23°41′.5 N, λ_x 45°00′.0 W; L_x 27°33′.3 N, λ_x 50°00′.0 W; L_x 30°59′.8 N, λ_x 55°00′.0 W; L_x 34°01′.7 N, λ_x 60°00′.0 W; L_x 36°40′.1 N, λ_x 65°00′.0 W; L_x 38°56′.6 N, λ_x 70°00′.0 W; L_2 40°27′.1 N, λ_2 73°49′.4 W (destination).

825. A ship is to steam from Valparaiso, Chile, to Wellington, New Zealand. The captain wishes to use composite sailing from lat. 32°58′.0 S, long. 71°41′.2 W, off Punta Angeles Light, to lat. 42°00′.0 S, long. 175°00′.0 E, near Cape Palliser, limiting the maximum latitude to 50° S.

Required.—(1) The longitude at which the limiting parallel is reached.

(2) The longitude at which the limiting parallel should be left.

(3) The initial great-circle course.

(4) The total distance.

(5) The latitude and longitude of points along the great circles at intervals of 10° of DLo from the vertices.

Answers.—(1) λ_{v1} 128°42′.9 W. (2) λ_{v2} 144°04′.3 W. (3) C 230°.0. (4) D 5,024.6 mi. (5) L_1 32°58′.0 S, λ_1 71°41′.2 W (point of departure); L_x 37°27′.2 S, λ_x 78°42′.9 W; L_x 42°23′.6 S, λ_x 88°42′.9 W; L_x 45°54′.3 S, λ_x 98°42′.9 W; L_x 48°14′.2 S, λ_x 108°42′.9 W; L_x 49°34′.1 S, λ_x 118°42′.9 W; L_{v1} 50°00′.0 S, λ_{v1} 128°42′.9 W (first vertex); L_{v2} 50°00′.0 S, λ_{v2} 144°04′.3 W (second vertex); L_x 49°34′.1 S, λ_x 154°04′.3 W; L_x 48°14′.2 S, λ_x 164°04′.3 W; L_x 45°54′.3 S, λ_x 174°04′.3 W; L_x 42°23′.6 S, λ_x 175°55′.7 E; L_2 42°00′.0 S, λ_2 175°00′.0 E (destination).

CHAPTER IX

PILOTING

General

901. Introduction.—On the high seas, where there is no immediate danger of grounding, navigation is a comparatively leisurely process. Courses and speeds are maintained over relatively long periods, and fixes are obtained at convenient intervals. Under favorable conditions a vessel might continue for several days with no positions other than those obtained by dead reckoning, or by estimate, and with no anxiety on the part of the captain or navigator. Errors in position can usually be detected and corrected before danger threatens.

In the vicinity of shoal water the situation is different. Frequent or continuous positional information is usually essential to the safety of the vessel. An error which at sea may be considered small, may in pilot waters be intolerably large. Frequent changes of course and speed are common. The proximity of other vessels increases the possibility of collision. Navigation under these conditions is called **piloting** or **pilotage.**

No other form of navigation requires the continuous alertness needed in piloting. At no other time is navigational experience and judgment so valuable. The ability to work rapidly and to correctly interpret all available information, always keeping "ahead of the vessel," may mean the difference between safety and disaster.

In piloting, positions are commonly obtained by reference to nearby landmarks, or the bottom. Advancements in electronics have provided additional aids which are of particular value in piloting, and have extended the range of piloting techniques far to sea.

902. Preparation for piloting.—Because the time element is often of vital importance in piloting, adequate preparation is important. Long-range preparation includes the acquisition of a thorough knowledge of the methods and techniques of piloting, and the organization and training of those who will assist in any way. This includes the steersman, who will be granted less tolerance in straying from the prescribed course than when farther offshore.

The more immediate preparation includes a study of the charts and publications of the area to familiarize oneself with the channels, shoals, tides, currents, aids to navigation, etc. One seldom has time to seek such information once he is proceeding in pilot waters. The more detailed preparation required for leaving or entering port is given in chapter XXIII.

Position

903. Lines of position.—As in electronic and celestial navigation, piloting makes extensive use of **lines of position.** Such a line is one on some point of which the vessel may be presumed to be located, as a result of observation or measurement. It may be highly reliable, or of questionable accuracy. Lines of position are of great value, but one should always keep in mind that *they can be in error* because of imperfections in instruments used for obtaining them and human limitations in those who use the instruments and utilize the results. The extent to which one can have confidence in various lines of position is a matter of judgment acquired from experience.

A line of position might be a straight line (actually a part of a great circle), an arc of a circle, or part of some other curve such as a hyperbola (art. O34). An appropriate label should be placed on the plot of a line of position *at the time it is drawn*, to avoid possible error or confusion. A label should include all information essential for identification, but no extraneous information. The labels shown in this volume are recommended.

904. Bearings.—A **bearing** is the horizontal direction of one terrestrial point from another. It is usually expressed as the angular difference between a reference direction and the given direction. In navigation, north is generally used as the reference direction, and angles are measured clockwise through 360°. It is customary to express all bearings in three digits, using preliminary zeros where needed. Thus, north is 000° or 360°, a direction 7° to the right of north is 007°, east is 090°, southwest is 225°, etc.

For plotting, *true* north is used as the reference direction. A bearing measured from this reference is called a **true bearing (TB)**. A **magnetic, compass,** or **grid bearing (MB. CB,** or **GB)** results from using magnetic, compass, or grid north, respectively, as the reference direction. This is similar to the designation of courses. In the case of bearings, however, one additional reference direction is often convenient. This is the heading of the ship. A bearing expressed as angular distance from the heading is called a **relative bearing (RB)**. It is usually measured clockwise through 360°, but for some purposes it is more conveniently measured either clockwise or counterclockwise through 180°, and designated *right* or *left*, respectively. A relative bearing may be expressed in still another way, as indicated in figure 904. Except for dead ahead and points at 45° intervals from it, this method is used principally for indicating directions obtained visually, without precise measurement. An even more general indication of relative bearing may be given by such directions as "ahead," "on the starboard bow," "on the port quarter," "astern." The term *abeam* may be used as the equivalent of either the general "on the beam" or, sometimes, the more precise "broad on the beam." Degrees are sometimes used instead of points to express relative bearings by the system illustrated in figure 904. However, if degrees are used, a better practice is to use the 360° or 180° system. Thus, a relative bearing of "20° forward of the port beam" is better expressed as "290°," or "70° left."

True, magnetic, and compass bearings are interconverted by the use of variation and deviation, or compass error, in the same manner as courses. Interconversion of relative and other bearings is accomplished by means of the heading. If true heading is added to a relative bearing, true bearing results (RB+TH=TB). If magnetic, compass, or grid heading (MH, CH, GH) is added to relative bearing, the corresponding magnetic, compass, or grid bearing is obtained.

A **bearing line** extending in the direction of an observed bearing of a charted object is one of the most widely used lines of position. If one knows that an identified landmark has a certain bearing from his vessel, the vessel can only be on the line at which such a bearing might be observed, for at any other point the bearing would be different. This line extends outward from the landmark, along the *reciprocal* of the observed bearing. Thus, if a lighthouse is *east* of a ship, that ship is *west* of the lighthouse. If a beacon bears 156°, the observer must be on a line extending 156°+180°=336° from the beacon. Since observed bearing lines are great circles, this relationship is not strictly accurate, but the error is significant only where the great circle departs materially from the rhumb line, as in high latitudes (ch. XXV).

Bearings are obtained by compass, gyro repeater, pelorus, alidade, radar, etc. One type of bearing can be obtained by eye without measurement. When two objects appear directly in line, one behind the other, they are said to be "in range," and together they constitute a **range.** For accurately charted objects, a range provides the most

accurate line of position obtainable, and one of the easiest to observe. Tanks, steeples, towers, cupolas, etc., sometimes form natural ranges. A navigator should be familiar with prominent ranges in his operating area, particularly those which can be used to mark turning points, indicate limits of shoals, or define an approach heading or let-go point of the anchorage of a naval vessel. So useful is the range in marking a course that artificial ranges, usually in the form of two lighted beacons, have been installed in line with channels in many ports. A vessel proceeding along the channel has only

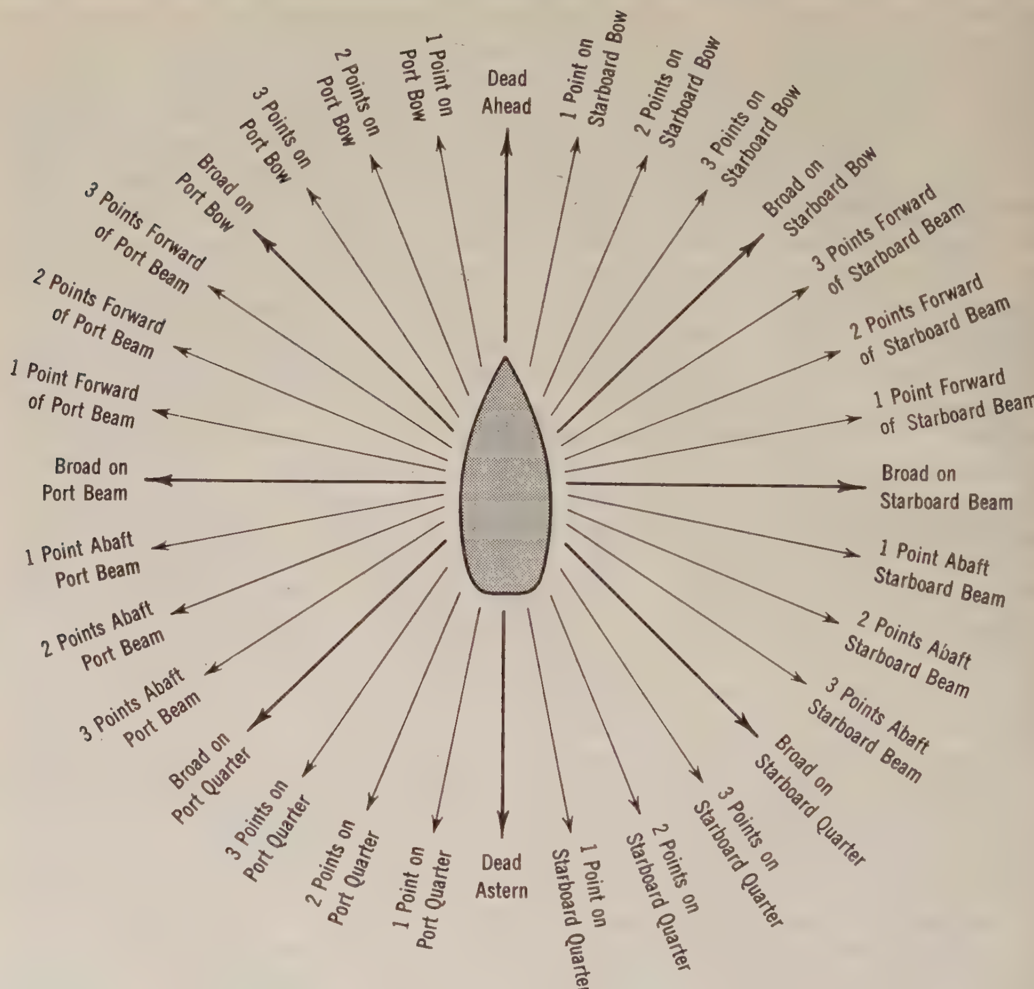

FIGURE 904.—One method of expressing relative bearings.

to keep the beacons in range to remain in the center of the channel. If the *farther* beacon (customarily the higher one) appears to "open out" (move) to the right of the forward (lower) beacon, one knows that he is to the right of his desired course line. Similarly, if it opens out to the left, the vessel is off course to the left.

It is good practice to plot only a short part of a line of position in the vicinity of the vessel, to avoid unnecessary confusion and to reduce the chart wear by erasure. Particularly, one should avoid the drawing of lines through the chart symbol indicating the landmark used. In the case of a range, a straightedge is placed along the two objects, and the desired portion of the line is plotted. One need not know the numerical

value of the bearing represented by the line. However, if there is any doubt as to the identification of the objects observed, the measurement of the bearing should prove useful.

A bearing line is labeled with the time above the line, and the bearing below the line. A range is labeled with the time only.

905. Distance.—If a vessel is known to be a certain distance from an identified point on the chart, it must be somewhere on a circle with that point as the center and the distance as the radius. An arc of the circle can be drawn and labeled with the time above the line and the distance below the line.

Distances are obtained by radar, range finder, stadimeter, synchronized sound and radio signals, synchronized air and water sounds, vertical sextant angles (table 9), etc. If vertical sextant angles are used, measurement should be made from the top of the object to the visible sea horizon, if it is available. If measurement is made to a water line not vertically below the top of the object, a problem may be encountered because distance from table 9 is to the point vertically below the top of the object, while the distance used for entering table 22 to determine dip short of the horizon is to the water line. Generally, any differences in these two distances can be determined from the chart. This problem may, in some cases, be avoided by decreasing the height of eye sufficiently to bring the horizon between the observer and the object.

906. The fix.—A line of position, however obtained, represents a series of possible positions, but not a single position. However, if *two simultaneous, nonparallel* lines of position are available, the only position that satisfies the requirements of being on both lines at the same time is the intersection of the two lines. This point is one form of **fix.** Examples of several types of fix are given in the illustrations. In figure 906a a fix is obtained from two bearing lines. The fix of figure 906b is obtained by two distance circles. Figure 906c illustrates a fix from a range and a distance. In figure 906d a bearing and distance of a single object are used.

Some consideration should be given to the selection of objects to provide a fix. It is essential, for instance, that the objects be identified. The angle between lines of position is important. The ideal is 90°. If the angle is small, a slight error in measur-

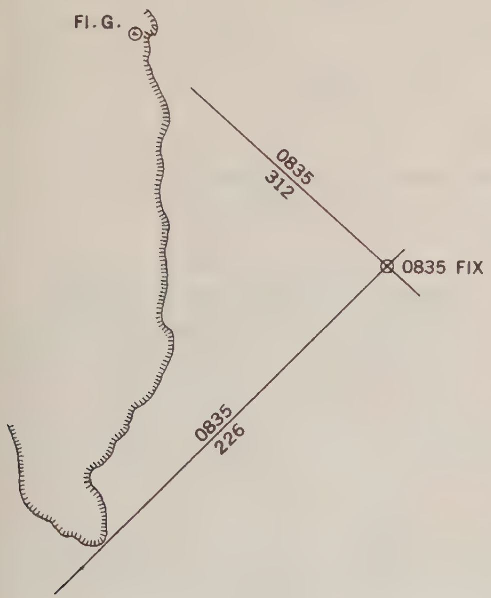

Figure 906a.—A fix by two bearing lines.

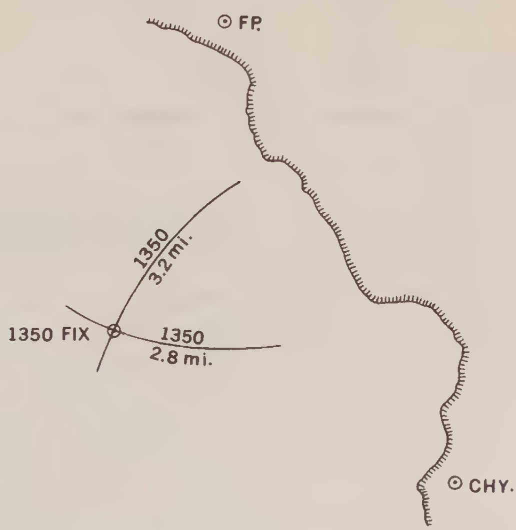

Figure 906b.—A fix by two distances.

ing or plotting either line results in a relatively large error in the indicated position. In the case of a bearing line, nearby objects are preferable to those at a considerable distance, because the linear (distance) error resulting from an angular error increases with distance. Thus, an error of 1° represents an error of about 100 feet if the object is one mile distant, 1,000 feet if the object is ten miles away, and one mile if the object is 60 miles from the observer.

Another consideration is the type of object. Lighthouses, spires, flagpoles, etc., are good objects because the point of observation is well defined. A large building, most nearby mountains, a point of land, etc., may leave some reasonable doubt as to the exact point used for observation. If a tangent is used (fig. 906a), there is a possibility that a low spit may extend seaward from the part observed. A number of towers, chimneys, etc., close together require careful identification. A buoy or a lightship may drag anchor and be out of position. Most buoys are secured by a single anchor and so have a certain radius of swing as the tide, current, and wind change.

Although two accurate nonparallel lines of position completely define a position, if they are taken at the same time, an element of doubt always exists as to the accuracy of the lines. Additional lines of position can serve as a check on those already obtained, and, usually, to reduce any existing error. If three lines of position cross at a common point, or form a small triangle, it is usually a reasonable assumption that the position is reliable, and defined by the center of the figure. However, this is not *necessarily* so, and one should be aware of the possibility of an erroneously indicated position. Some-

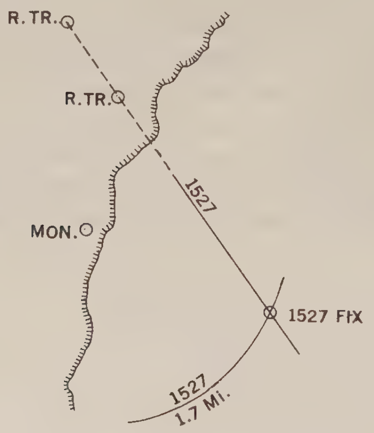

FIGURE 906c.—A fix by a range and distance.

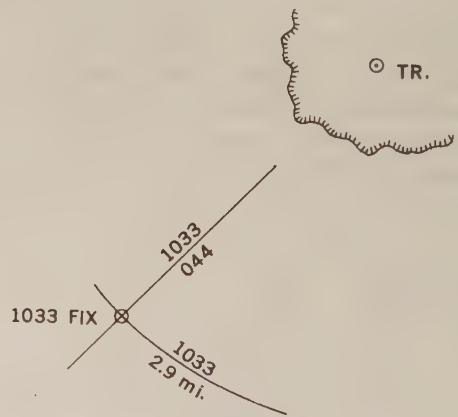

FIGURE 906d.—A fix by distance and bearing of single object.

times an error can be identified. For instance, if several fixes obtained by bearings on three objects produce triangles of about the same size, one might reasonably suspect a constant error in the observation of the bearings, particularly if the same instrument is used for all observations, or in the plotting of the lines. If the application of a constant error to all bearings results in a point, or near-point fix, the navigator is usually justified in applying such a correction. This situation is illustrated in figure 906e, where the solid lines indicate the original plot, and the broken lines indicate each line of position moved 3° in a clockwise direction. If different instruments are used for observation, one of them might be consistently in error. This might be detected by altering all bearings observed by that instrument by a fixed amount and producing good fixes. However, one seldom has time for much experimentation of this kind while piloting. If an error is suspected, such experiments might better be conducted while

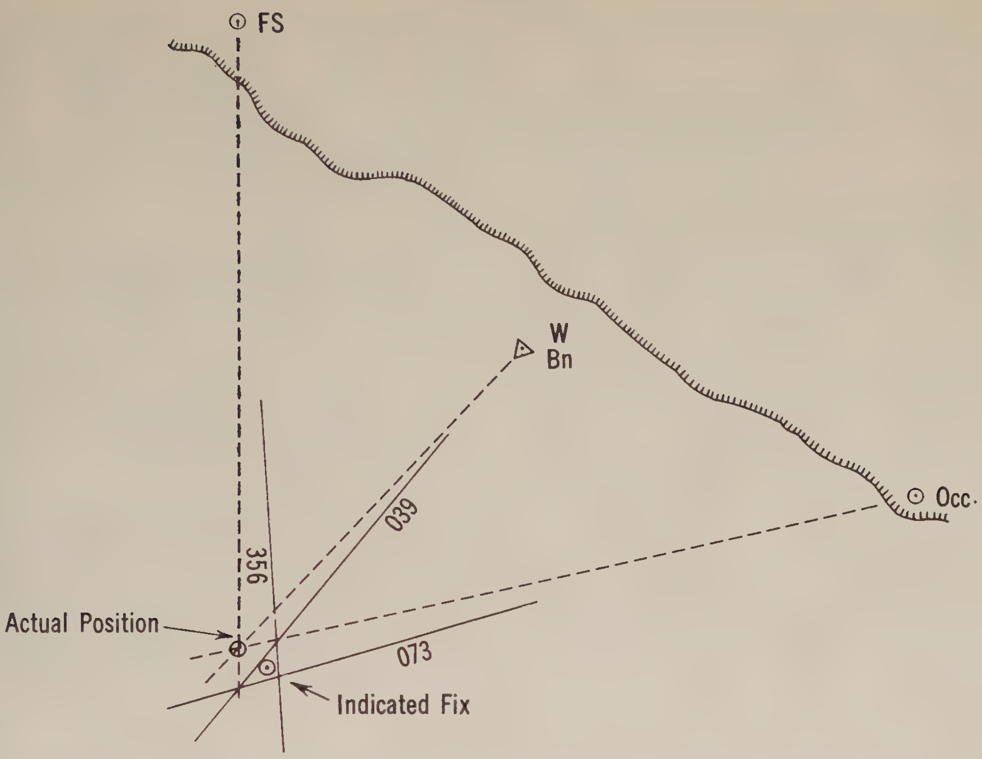

FIGURE 906e.—Adjusting a fix for inaccurate bearings.

at anchor or moored alongside a pier. Underway, other instruments, such as radar, or another method, such as that explained in article 907, might better be used.

Lines of position obtained by observation of bearings or distances can be used with lines of position obtained in any other manner, as by radio direction finder, loran, celestial navigation, etc. If an object such as a buoy is passed close aboard, a fix is obtained without plotting. Similarly, there should be no doubt as to the position of a vessel which is observed to be midway between two channel buoys a short distance apart.

907. Horizontal angles.—A fix may be obtained by means of the *difference* in bearing of several objects. If a constant error is present in the instrument used for measuring directions, it will not be reflected in the difference between bearings. Therefore, the differences may be more accurate than the bearings. Horizontal sextant angles, however, are usually the most accurate source of such information.

Customarily, two angles are obtained on three objects. These angles are then plotted from a single point on a sheet of transparent material, or set on a mechanical device called a **three-arm protractor** (fig. 4011c) in United States usage and a **station pointer** in British terminology. The three lines or arms are then fitted to the chart by trial and error until all three pass through the objects used for observation. The observer is then at the common intersection of the three lines. This method provides accurate results unless the three objects lie on or near a circle which passes through the observer. The best way to avoid this is to select objects nearly in a straight line, a group with the center one nearer than the other two, or objects so widely separated that the angle between the two end ones approaches or exceeds 180°.

Because of its high accuracy, this method is frequently used in hydrographic surveying (ch. XLI). It has fallen into virtual disuse in the ordinary course of navi-

gation because of the convenience and reliability of other methods. However, it may be used when a position of greater than normal accuracy is required, as for finding the position of letting go an anchor. Simultaneous angles are required for accurate results. These are customarily obtained by two observers, each with a sextant. If a single observer is available, he first observes the angle changing more slowly, then the other, and then makes a second observation of the first angle. The average of the two readings of the first angle is used with the second angle.

908. Nonsimultaneous observations.—For fully accurate results, observations made to fix the position of a moving vessel should be made simultaneously, or nearly so. On a slow-moving vessel, relatively little error is introduced by making several observations in quick succession. A wise precaution is to observe the objects more nearly ahead or astern first, since these are least affected by the motion of the observer. For more accurate results, all readings but the last can be repeated in reverse order, and the mean of each pair used. Thus, if three bearings (on objects *A*, *B*, and *C*) are to be used, five readings can be taken, as follows: *A*, *B*, *C*, *B*, *A*. The two *B* readings are averaged, and also the two *A* readings. The time of the *C* reading is considered the time of all readings. Approximately equal intervals should elapse between readings. An indication of the error introduced by *not* observing this precaution is the fact that at ten knots a vessel moves 1,000 feet in one minute. At 20 knots, this distance is doubled. If the angle between lines of position is small, and the earlier bearings are of objects near the beam, the position indicated by the fix might be in error by more than the motion of the vessel, particularly if the objects on which later bearings are taken are abaft those of earlier bearings.

Sometimes it is not possible or desirable to make simultaneous or nearly simultaneous observations. Such a situation may arise, for instance, when a single object is available for observation, or when all available objects are on nearly the same or reciprocal bearings, and there is no means of determining distance. Under such conditions, a period of several minutes or more may be permitted to elapse between observations to provide lines of position crossing at suitable angles. When this occurs, the lines can be adjusted to a common time to obtain a **running fix.** Refer to figure 908a. A ship is proceeding along a coast on course 020°, speed 15 knots. At 1505 lighthouse *L* bears 310°. If the line of position is accurate, the ship is somewhere on it at the time of observation. Ten minutes later the ship will have traveled 2.5 miles in direction 020°. If the ship was at *A* at 1505, it will be at *A′* at 1515. However, if the position at 1505 was *B*, the

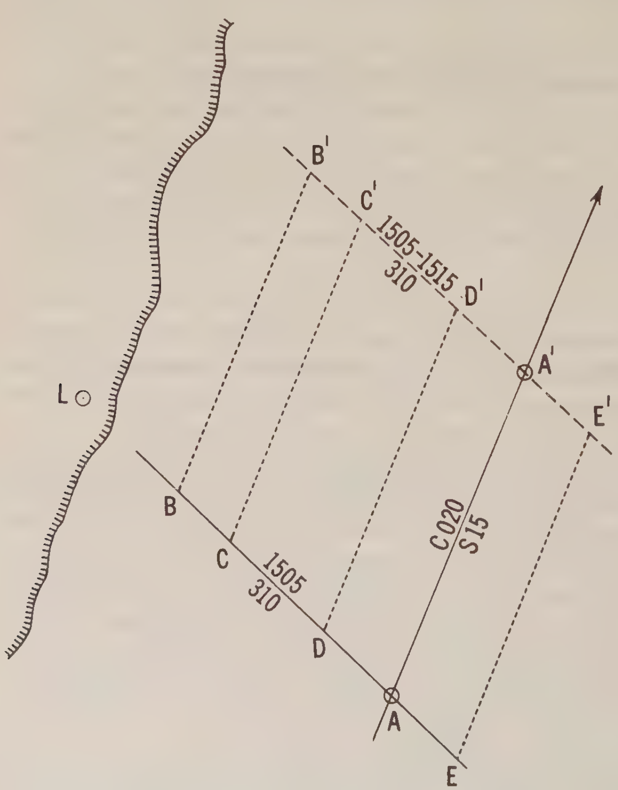

FIGURE 908a.—Advancing a line of position.

position at 1515 will be B'. A similar relationship exists between C and C', D and D', E and E', etc. Thus, if *any* point on the original line of position is moved a distance equal to the distance run, and in the direction of the motion, a line through this point, parallel to the original line of position, represents all possible positions of the ship at the later time. This process is called **advancing** a line of position. The moving of a line *back* to an *earlier* time is called **retiring** a line of position.

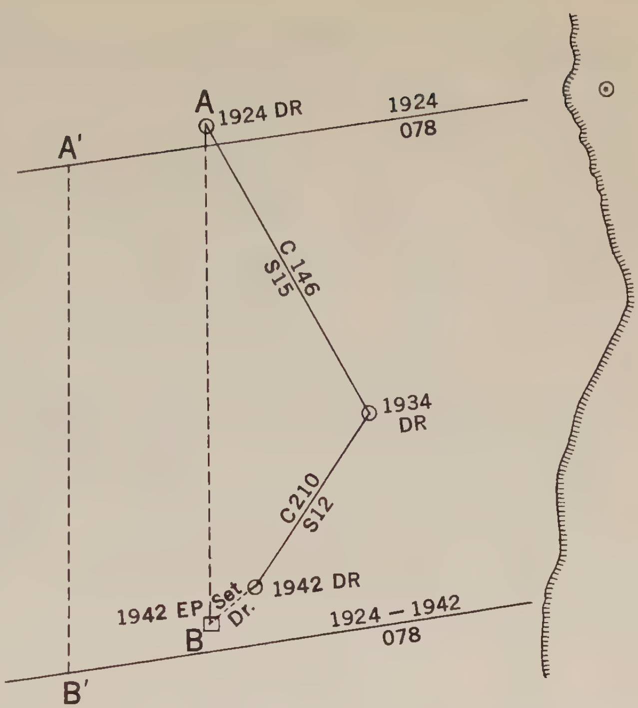

FIGURE 908b.—Advancing a line of position with a change in course and speed, and allowing for current.

The accuracy of an adjusted line of position depends not only upon the accuracy of the original line, but also upon the reliability of the information used in moving the line. A small error in the course made good has little effect upon the accuracy of a bearing line of an object near the beam, but maximum effect upon the bearing line of an object nearly ahead or astern. Conversely, the effect of an error in speed is maximum upon the bearing line of an object abeam. The opposite is true of circles of position. The best estimate of course and speed made good should be used in advancing or retiring a line of position.

If there are any changes of course or speed, these should be considered, for the motion of the line of position should reflect as accurately as possible the motion of the observer between the time of observation and the time to which the line is adjusted. Perhaps the easiest way to do this is to measure the direction and distance between dead reckoning or estimated positions at the two times, and use these to adjust some point on the line of position. This method is shown in figure 908b. In this illustration allowance is made for the estimated combined effect of wind and current, this effect being plotted as an additional course and distance. If courses and speeds made good over the ground are used, the separate plotting of the wind and current effect is not used. In the illustration, point A is the DR position at the time of observation, and point B is the estimated position (the DR position adjusted for wind and current) at the time to which the line of position is adjusted. Line $A'B'$ is of the same length and in the same direction as line AB.

Other techniques may be used. The position of the object observed may be advanced or retired, and the line of position drawn in relation to the adjusted position. This is the most satisfactory method for a circle of position, as shown in figure 908c. When the position of the landmark is adjusted, the advanced line of position can be laid down without plotting the original line, which need be shown only if it serves a useful purpose. This not only eliminates part of the work, but reduces the number of lines on the chart, and thereby decreases the possibility of error. Another method is

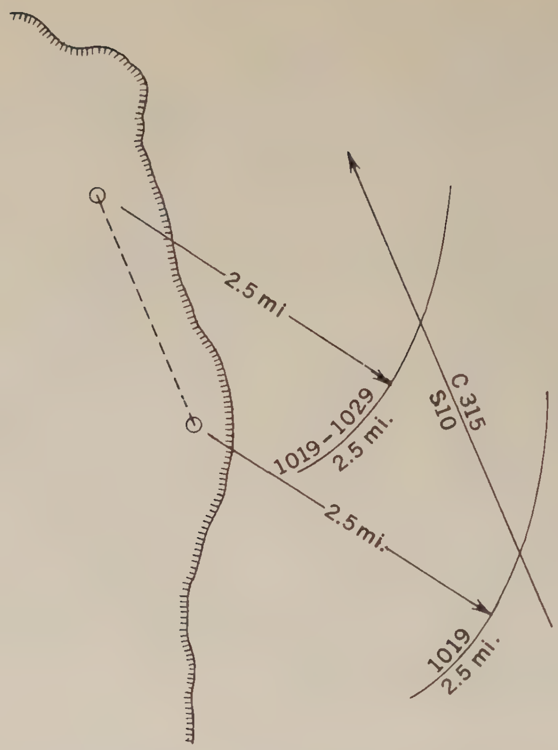

FIGURE 908c.—Advancing a circle of position.

to draw any line, such as a perpendicular, from the dead reckoning position at the time of observation to the line of position. A line of the same length and in the same direction, drawn from the DR position or EP at the time to which the line is adjusted, locates a point on the adjusted line, as shown in figure 908d. If a single course and speed is involved, common practice is to measure from the intersection of the line of position and the course line. If the dividers are set to the distance run between bearings and placed on the chart so that one point is on the first bearing line and the other point is on the second bearing line, and the line connecting the points is parallel to the course line, the points will indicate the positions of the vessel at the times of the bearings.

An adjusted line of position is labeled the same as an unadjusted one, except that both the time of observation and the time to which the line is adjusted are shown, as in the illustrations of this article and article 909. Because of additional sources of error in adjusted lines of position, they are not used when satisfactory simultaneous lines can be obtained.

909. The running fix.—As stated in article 908, a fix obtained by means of lines of position taken at different times and adjusted to a common time is called a **running fix.** In piloting, common practice is to *advance* earlier lines to the time of the last observation. Figure 909a illustrates a running fix obtained from two bearings of the same object. In figure 909b the ship changes course and speed between observations of two objects. A running fix by two circles of position is shown in figure 909c.

When simultaneous observations are not available, a running fix may provide the most reliable position obtainable. The time between observations should be no longer than necessary, for the uncertainty of course and distance made good increases with time.

The errors applicable to a running fix are those resulting from errors of the individual lines of position. However, a given error may have quite a different effect upon

the fix than upon the line of position. Consider, for example, the situation of an unknown head current. In figure 909d a ship is proceeding along a coast, on course 250°, speed 12 knots. At 0920 lighthouse *A* bears 190°, and at 0930 it bears 143°. If the earlier bearing line is advanced a distance of two miles (ten minutes at 12 knots) in the direction of the course, the running fix is as shown by the solid lines. However, if there is a head current of two knots, the ship is making good a speed of only ten knots, and in ten minutes will travel a distance of only 1⅔ miles. If the first bearing line is advanced this distance, as shown by the broken line, the actual position of the ship is at *B*. *This is nearer the beach than the running fix*, and therefore a dangerous situation. A following current gives an indication of position too far from the object. Therefore, if a current *parallel* to the course (either head or following) is suspected, a *minimum* estimate of speed made good will result in a possible margin of safety. If the second bearing is of a different object, a *maximum* estimate of speed should be made if the second object is on the same side and farther forward, or on the opposite side and farther aft, than the first object was when observed. All of these situations assume that danger is on the same side as the object observed first. If there is either a head or following current, a series of running fixes based upon a number of bearings of the same object will plot in a straight line parallel to the course line, as shown in figure 909e. The plotted line will be too close to the object observed if there is a following current, and too far out if there is a head current. The existence of the current will not be apparent unless the actual speed over the ground is known. The position of the plotted line relative to the dead reckoning course line is not a reliable guide.

A current oblique to the course will result in an incorrect position, but the direction of the error is indeterminate. In general, the effect of a current with a strong head or following component is similar to that of a head or following current, respectively. The existence of an oblique current, but not its amount, can be detected by observing and

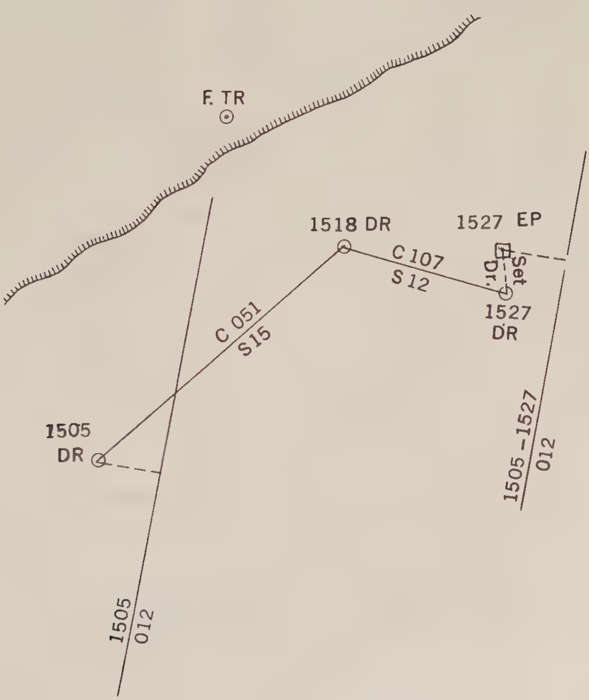

FIGURE 908d.—Advancing a line of position by its relation to the dead reckoning.

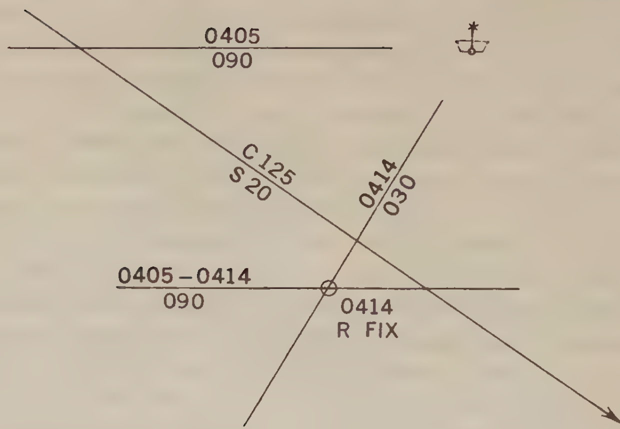

FIGURE 909a.—A running fix by two bearings on the same object.

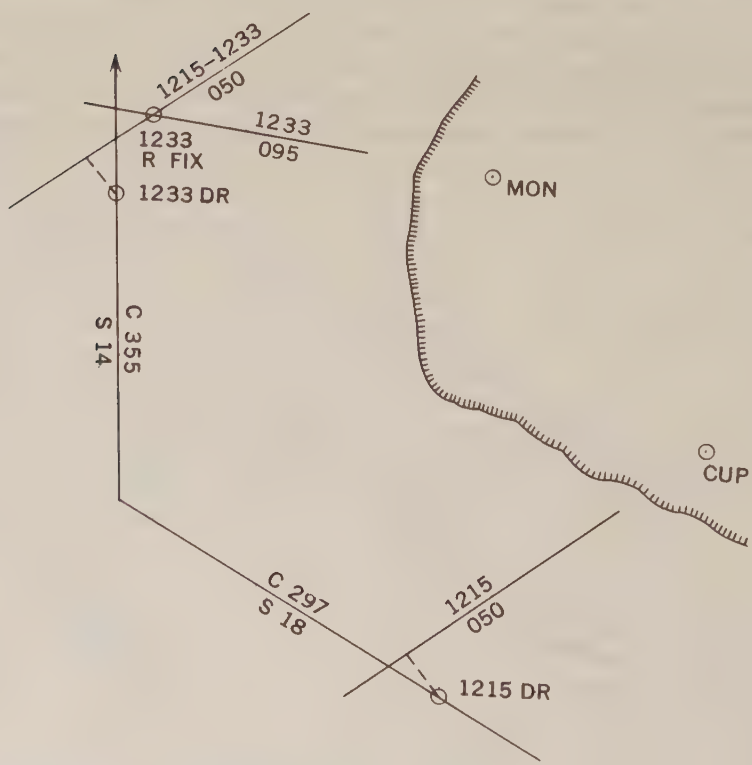

FIGURE 909b.—A running fix with a change of course and speed between observations on separate landmarks.

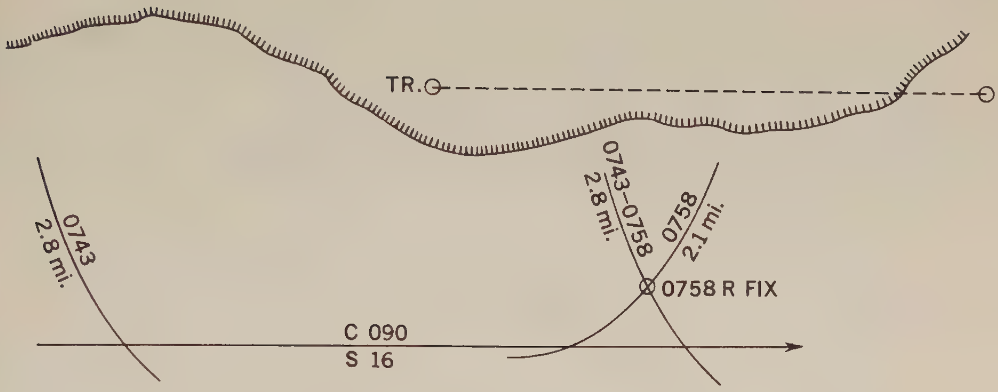

FIGURE 909c.—A running fix by two circles of position.

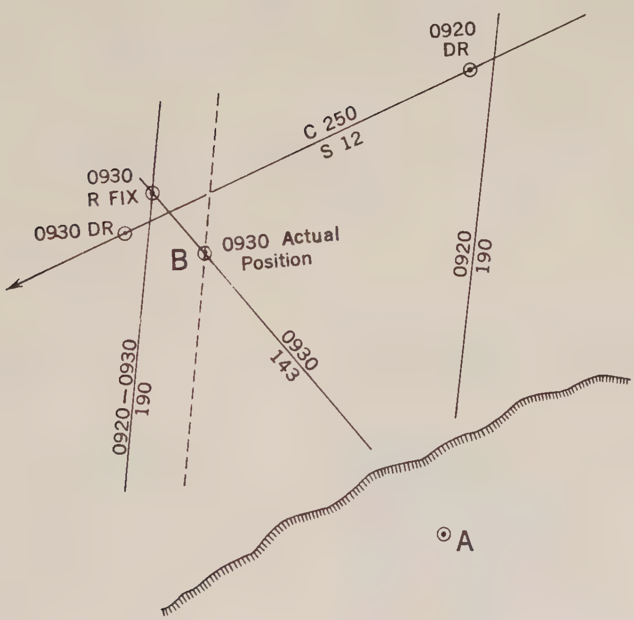

FIGURE 909d.—Effect of a head current on a running fix.

plotting several bearings of the same object. The running fix obtained by advancing one bearing line to the time of the next one will not agree with the running fix obtained by advancing an earlier line. Thus, if bearings *A*, *B*, and *C* are observed at five-minute intervals, the running fix obtained by advancing *B* to the time of *C* will not be the same as that obtained by advancing *A* to the time of *C*, as shown in figure 909f.

Whatever the current, the *direction* of the course made good (assuming constant current) can be determined. On the chart, plot the various bearing lines (fig. 909g, left). Draw a straight line on a piece of transparent material, and along it mark off the distances run (using any assumed speed) between bearings (fig. 909g, right). If transparent material is not available, mark off the distances along the edge of a piece

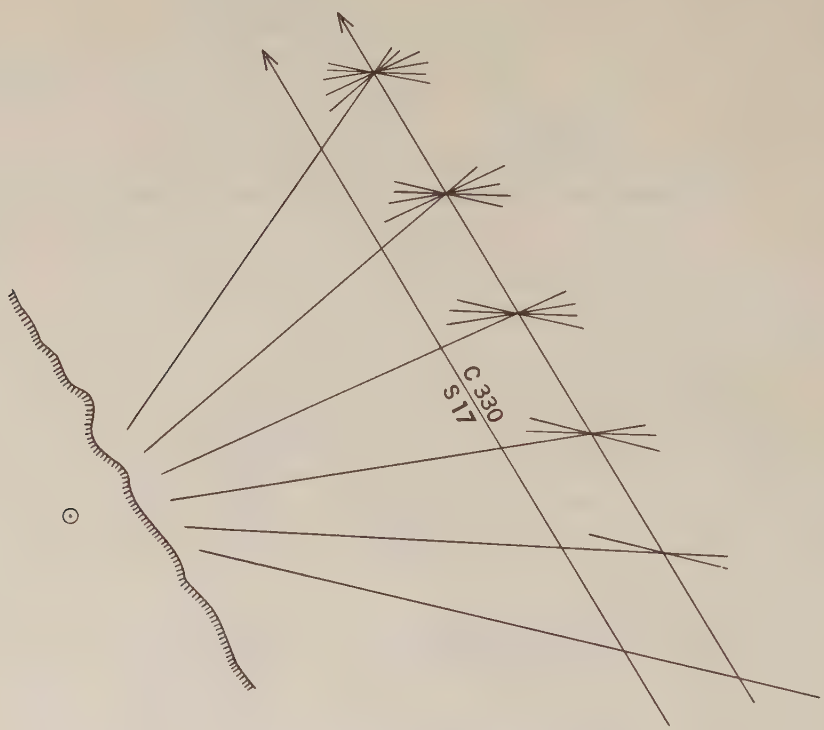

FIGURE 909e.—A number of running fixes with a following current.

of paper. By trial and error, fit the distances to the bearing lines on the chart, so that each mark falls on its bearing line (fig. 909h). The direction of the line is the course being made good. Its distance from the track is in error by an amount proportional to the ratio of the speed being made good to the speed assumed for the solution. If a good fix (not a running fix) is obtained at some time before the first bearing for the running fix, and the current has not changed, the track can be determined by drawing a line from the fix, in the direction of the course made good. The intersection of the track with any of the bearing lines is an actual position.

The current can be determined whenever a dead reckoning position and fix are available for the same time. The direction *from* the dead reckoning position *to* the fix is the set of the current. The distance between these two positions, divided by the time (expressed in hours and tenths) since the last fix, is the drift of the current in knots. For accurate results, the dead reckoning position must be run up from the previous fix without any allowance for current. Any error in either the dead reckoning

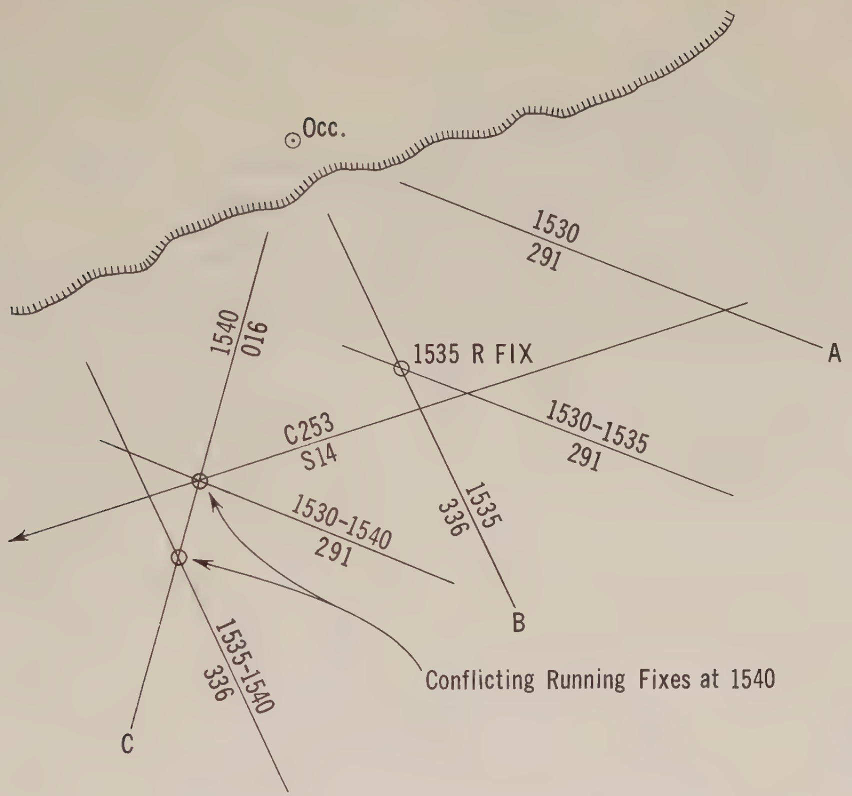

FIGURE 909f.—Detecting the existence of an oblique current, by a series of running fixes.

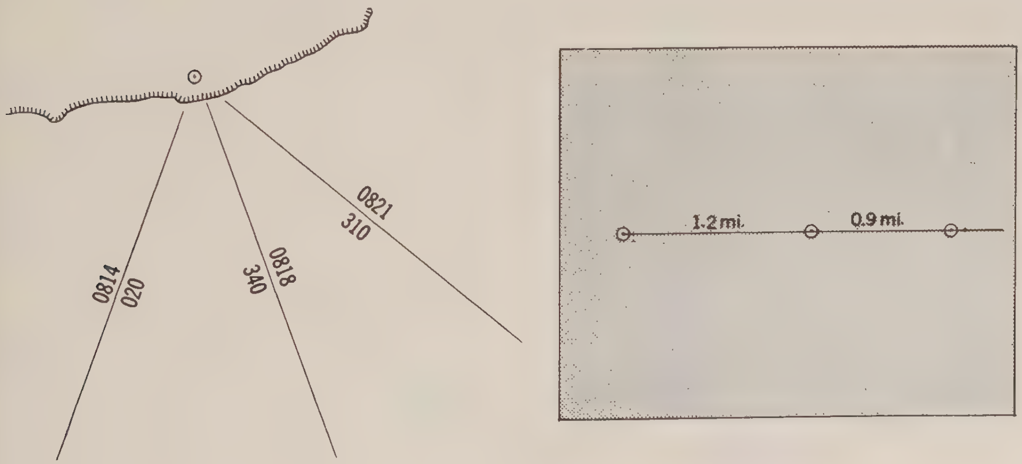

FIGURE 909g.—Preparing to determine the course made good.

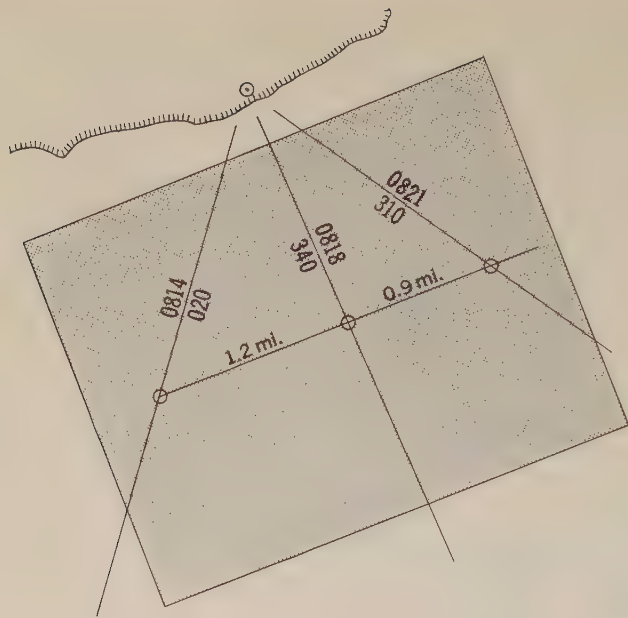

FIGURE 909h.—Determining the course made good.

position (such as poor steering, unknown compass error, inaccurate log, wind, etc.) or the fix will be reflected in the determination of current. When the dead reckoning position and fix are close together, a relatively small error in either may introduce a large error in the apparent set of the current.

910. Solution without a plot.—A running fix can be obtained by utilizing the mathematical relationships involved. Refer to figure 910. A ship steams past landmark *D*. At any point *A* a bearing of *D* is observed and expressed as degrees right or left of the course (a relative bearing if the ship is on course). At some later time, at *B*, a second bearing of *D* is observed and expressed as before. At *C* the landmark is broad on the beam. The angles at *A*, *B*, and *C* are known, and also the distance run between points. The various triangles could be solved by trigonometry (app. O) to find the distance from *D* at any bearing. Distance and bearing provide a fix.

Table 7 provides a quick and easy solution. The table is entered with the difference between the course and first bearing (angle *BAD* in fig. 910) along the top of the table, and the difference between the course and second bearing (angle *CBD*) at the left of the table. For each pair of angles listed, two numbers are given. To find the distance from the landmark at the time of the second bearing (*BD*), multiply the distance run between bearings by the first number from table 7. To find the distance when the object is abeam (*CD*), multiply the distance run between *A* and *B* by the second number from the table. If the run between bearings is exactly one mile, the tabulated values are the distances sought.

Example.—A ship is steaming on course 050°, speed 15 knots. At 1130 a lighthouse bears 024°, and at 1140 it bears 359°.

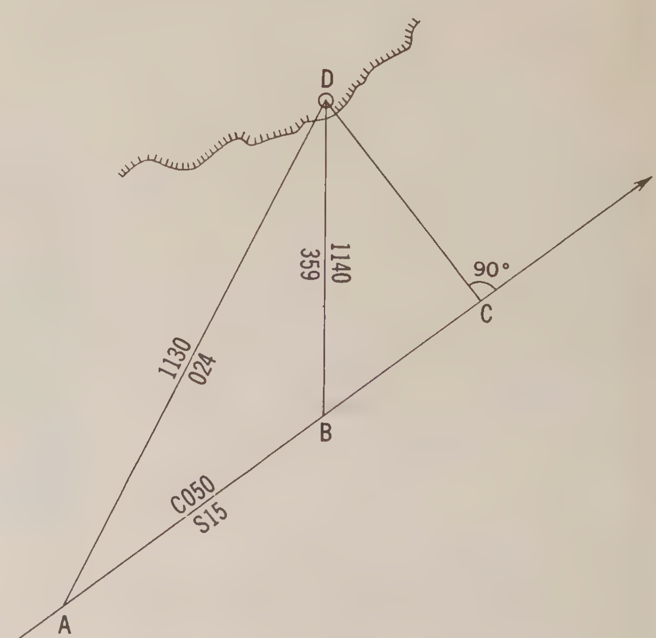

FIGURE 910.—Triangles involved in a running fix.

Required.—(1) Distance from the light at 1140.

(2) Distance from the light when it is broad on the port beam.

Solution (fig. 910).—(1) The difference between the course and the first bearing (050°–024°) is 26°, and the difference between the course and the second bearing (050°+360°−359°) is 51°.

(2) From table 7 the two numbers (factors) are 1.04 and 0.81, found by interpolation.

(3) The distance run between bearings is 2.5 miles (10 minutes at 15 knots).

(4) The distance from the lighthouse at the time of the second bearing is 2.5×1.04=2.6 miles.

(5) The distance from the lighthouse when it is broad on the beam is 2.5×0.81=2.0 miles.

Answers.—(1) D 2.6 mi., (2) D 2.0 mi.

Certain combinations of angles provide quick mental solution without the need for table 7. If the second difference (angle *CBD*) is double the first difference (angle *BAD*), triangle *BAD* is isosceles (art. O28), with equal angles at *A* and *D*. Therefore side *AB* (the run) is equal to side *BD* (the distance off at the time of the second bearing). This is called **doubling the angle on the bow.** If the first angle is 45° and the second 90°, the distance run equals the distance when broad on the beam. These are called **bow and beam bearings.** If the first angle is 63°.5 and the second 90°, the distance off when abeam is about twice the distance run. If the angles are 71°.5 and 90°, the distance off when abeam is about three times the distance run. If the first angle is 22°.5 and the second 45°, the distance at which the object will be passed abeam is about 7/10 of the distance run between bearings. If the angles are 22°.5 and 26°.5, the distance abeam will be about 7/3 of the distance run. If the angles are 30° and 60°, the distance of the object when abeam will be about 7/8 of the distance run between bearings. If the two angles are such that their natural cotangents differ by unity, the distance abeam will be equal approximately to the distance run between bearings. Some combinations having approximately this relationship are 22°–34°, 25°–41°, 27°–46°, 32°–59°, and 40°–79°.

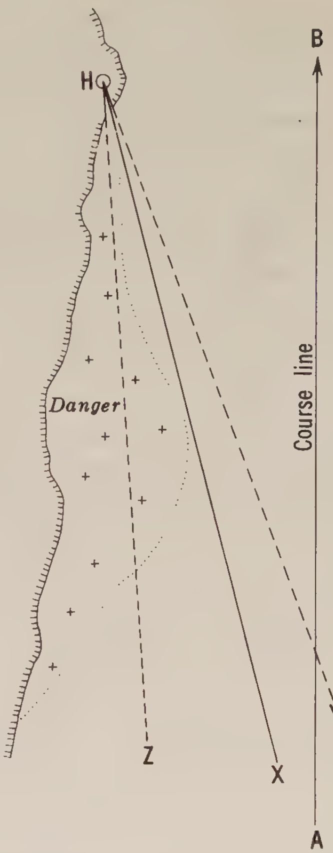

FIGURE 911a.—A danger bearing.

If either the course or speed is in error, the result will be inaccurate.

911. Safe piloting without a fix.—A fix or running fix is not always necessary to insure safety of the vessel. If a ship is proceeding up a dredged channel, for instance, the only knowledge needed to prevent grounding is that the ship is within the limits of the dredged area. This information might be provided by a range in line with the channel. A fix is not needed except to mark the point at which the range can no longer be followed with safety. Such a point is usually marked by a buoy.

Under favorable conditions a **danger bearing** might be used to insure safe passage past a shoal or other danger. Refer to figure 911a. A vessel is proceeding along a coast, on course line *AB*. A shoal is to be avoided. A line *HX* is drawn from lighthouse *H*, tangent to the outer edge of the danger. As long as the bearing of light *H* is

less than *XH*, the danger bearing, the vessel is in safe water. An example is *YH*, no part of the bearing line passing through the danger area. Any bearing *greater* than *XH*, such as *ZH*, indicates a *possible* dangerous situation. If the object is passed on the port side, the safe bearing is *less* than the danger bearing, as shown in figure 911a. If the object is passed on the starboard side, the danger bearing represents the minimum bearing, safe ones being *greater*. To be effective, a danger bearing should not differ greatly from the course, and the object of which bearings are to be taken should be easily identifiable and visible over the entire area of usefulness of the danger bearing. A margin of safety might be provided by drawing line *HX* through a point a short

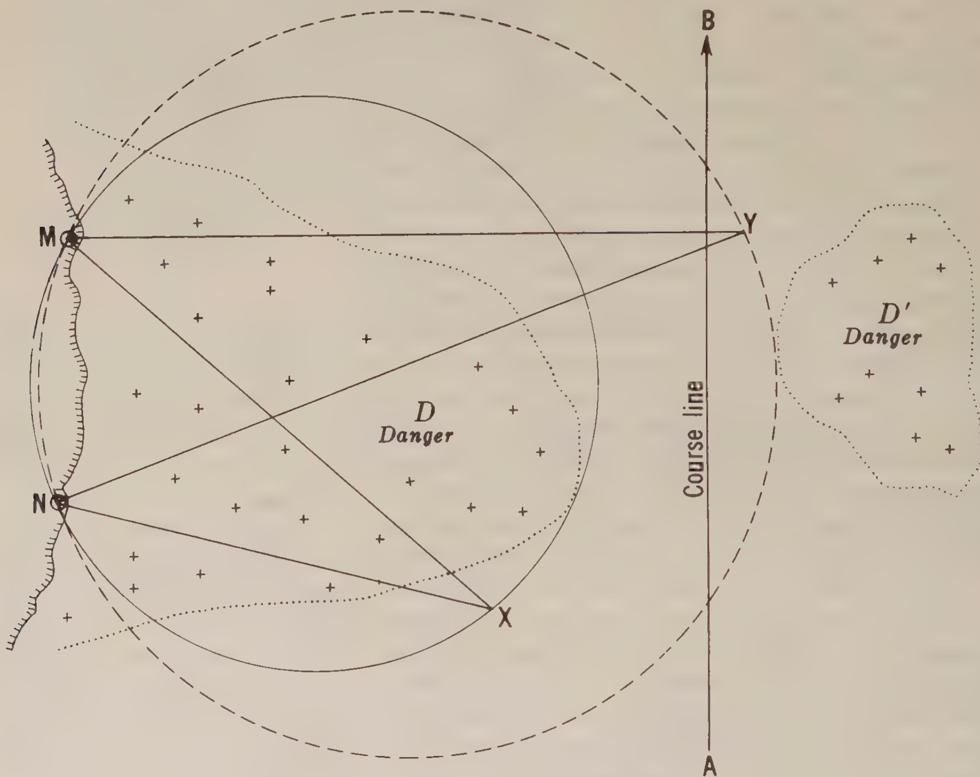

FIGURE 911b.—Horizontal danger angles.

distance off the danger. If a natural or artificial range is available as a danger bearing, it should be used.

A vessel proceeding along a coast may be in safe water as long as it remains a minimum distance off the beach. This information may be provided by any means available. One method useful in avoiding particular dangers is the use of a **danger angle.** Refer to figure 911b. A ship is proceeding along a coast on course line *AB*, and the captain wishes to remain outside a danger *D*. Prominent landmarks are located at *M* and *N*. A circle is drawn through *M* and *N* and tangent to the outer edge of the danger. If *X* is a point on this circle, angle *MXN* is the same as at any other point on the circle (except that part between *M* and *N*). Anywhere within the circle the angle is *larger* and anywhere outside the circle it is *smaller*. Therefore, any angle smaller than *MXN* indicates a safe position and any angle larger than *MXN* indicates possible danger. Angle *MXN* is therefore a maximum **horizontal danger**

angle. A minimum horizontal danger angle is used when a vessel is to pass *inside* an offlying danger, as at D' in figure 911b. In this case the circle is drawn through M and N and tangent to the *inner* edge of the danger area. The angle is kept larger than MYN. If a vessel is to pass *between* two danger areas, as in figure 911b, the horizontal angle should be kept smaller than MXN but larger than MYN. The minimum danger angle is effective only while the vessel is inside the larger circle through M and N. Bearings on either landmark might be used to indicate the entering and leaving of the larger circle. A margin of safety can be provided by drawing the circles through points a short distance off the dangers. Any method of measuring the angles, or difference of bearing of M and N, can be used. Perhaps the most accurate is by horizontal sextant angle. If a single landmark of known height is available, similar procedure can be used with a **vertical danger angle** between top and bottom of the object. In this case the charted position of the object is used as the center of the circles.

A vessel may sometimes be kept in safe water by means of a **danger sounding.** The value selected depends upon the draft of the vessel and the slope of the bottom. It should be sufficiently deep to provide adequate maneuvering room for the vessel to reach deeper water before grounding, once the minimum depth is obtained. In an area where the shoaling is gradual, a smaller margin of depth can be considered safe than in an area of rapid shoaling. Where the shoaling is very abrupt, as off Point Conception, California, no danger sounding is practical. It is good practice to prominently mark the danger sounding line on the chart. A colored pencil is useful for this purpose.

If it is desired to round a point marked by a prominent landmark, without approaching closer than a given minimum distance, this can be done by steaming until the minimum distance is reached and then immediately changing course so as to bring the landmark broad on the beam. Frequent small changes of course are then used to keep the landmark near, *but not forward of*, the beam. This method is not reliable if the vessel is being moved laterally by wind or current.

An approximation of the distance off can be found by noting the rate at which the bearing changes. If the landmark is kept abeam, the change is indicated by a change of heading. During a change of 57°5, the distance off is about the same as the distance run. For a change of 28°5, the distance is about twice the run; for 19° it is about three times the run; for 14°5 it is about four times the run; and for 11°5 it is about five times the run. Another variation is to measure the number of seconds required for a change of 16°. The distance off is equal to this interval multiplied by the speed in knots and divided by 1,000. That is, $D=\frac{St}{1{,}000}$, where D is the distance in nautical miles, S is the speed in knots, and t is the time interval in seconds. This method can also be used for straight courses (with bearings 8° forward and abaft the beam), but with somewhat reduced accuracy.

912. Soundings.—The most important use of soundings is to determine whether the depth is sufficient to provide a reasonable margin of safety for the vessel. For this reason, soundings should be taken continuously in pilot waters. A study of the chart and the establishment of a danger sounding (art. 911) should indicate the degree of safety of the vessel at any time.

Under favorable conditions, soundings can be a valuable aid in establishing the position of the vessel. Their value in this regard depends upon the configuration of the bottom, the amount and accuracy of information given on the chart, the type and accuracy of the sounding equipment available aboard ship, and the knowledge and skill of the navigator. In an area having a flat bottom devoid of distinctive features, or in an

area where detailed information is not given on the chart, little positional information can be gained from soundings. However, in an area where depth curves run roughly parallel to the shore, a sounding might indicate distance from the beach. In any area where a given depth curve is sharply defined and relatively straight, it serves as a line of position which can be used with other lines, such as those obtained by bearings of landmarks, to obtain a fix. The 100-fathom curve at the outer edge of the continental shelf might be crossed with a line of position from celestial observation or loran. The crossing of a sharply defined trench, ridge, shoal, or flat-topped seamount (a **guyot**) might provide valuable positional information.

In any such use, identification of the feature observed is important. In an area of rugged underwater terrain, identification might be difficult unless an almost continuous determination of position is maintained, for it is not unusual for a number of features within a normal radius of uncertainty to be similar. If the echo sounder produces a continuous recording of the depth, called a **bottom profile,** this can be matched to the chart in the vicinity of the course line. If no profile is available, a rough approximation of one can be constructed as follows: Record a series of soundings at short intervals, the length being dictated by the scale of the chart and the existing situation. For most purposes the interval might be each minute, or perhaps each half-mile or mile. Draw a straight line on transparent material and, at the scale of the chart, place marks along the line at the distance intervals at which soundings were made. For this purpose the line might be superimposed over the latitude scale or a distance scale of the chart. At each mark record the corresponding sounding. Then place the transparency over the chart and, by trial and error, match the recorded soundings to those indicated on the chart. Keep the line on the transparency parallel or nearly parallel to the course line plotted on the chart. A current may cause some difference between the plotted course line and the course made good. Also, speed over the bottom might be somewhat different from that used for the plot. This should be reflected in the match. This method should be used with caution, because it may be possible to fit the **line of soundings** to several places on the chart.

Exact agreement with the charted bottom should not be expected at all times. Inaccuracies in the soundings, tide, or incomplete data on the chart may affect the match, but general agreement should be sought. Any marked discrepancy should be investigated, particularly if it indicates less depth than anticipated. If such a discrepancy cannot be reconciled, the wisest decision might well be to haul off into deeper water or anchor and wait for more favorable conditions or additional information.

913. Most probable position (**MPP**).—Since information sufficient to establish an *exact* position is seldom available, the navigator is frequently faced with the problem of establishing the most probable position of the vessel. If three reliable bearing lines cross at a point, there is usually little doubt as to the position, and little or no judgment is needed. But when conflicting information or information of questionable reliability is received, a decision is required to establish the MPP. At such a time the experience of the navigator can be of great value. Judgment can be improved if the navigator will continually try to account for all apparent discrepancies, even under favorable conditions. If a navigator habitually analyzes the situation whenever positional information is received, he will develop judgment as to the reliability of various types of information, and will learn something of the conditions under which certain types should be treated with caution.

When complete positional information is lacking, or when the available information is considered of questionable reliability, the most probable position might well be considered an **estimated position** (**EP**). Such a position might be determined from a single line of position, from a line of soundings, from lines of position which are some-

what inconsistent, from a dead reckoning position with a correction for current or wind, etc.

Whether the most probable position is a fix, running fix, estimated position, or dead reckoning position, it should be kept continually in mind, together with some estimate of its reliability. The practice of continuing a dead reckoning plot from one good fix to another is advisable, whether or not information is available to indicate a most probable position differing from the dead reckoning position, for the DR plot provides an indication of current and leeway. A series of estimated positions may not be consistent because of the continual revision of the estimate as additional information is received. However, it is good practice to plot all MPP's, and sometimes to maintain a separate EP plot based upon the best estimate of course and speed being made good over the ground, for this should furnish valuable information to indicate whether the present course is a safe one.

Aids to Navigation

914. Kinds of aids.—When piloting, a navigator is concerned primarily with the position of his vessel relative to nearby land, shoals, and other dangers. It is natural, therefore, that he make extensive use of **landmarks,** which are conspicuous objects, structures, or lights serving as indicators for guidance or warning of a craft. Such an object visible from a distance to seaward is called a **seamark.** Either type of mark may be called a **daymark** if useful only during daylight, or a **nightmark** if useful primarily during darkness. A natural or artificial mark used to assist a vessel in avoiding a particular hazard may be called a **clearing mark.** If an uncharted landmark is discovered, its position might be established from available information or by triangulation (art. 4110) from known positions, and plotted on the chart for future use. A permanent feature might well be reported to the appropriate government charting agency.

A mark established by man, to serve as a landmark, is called an **aid to navigation.** This should not be confused with the expression **navigational aid,** which includes, in addition to aids to navigation, such items as instruments, charts, tables, etc. The principal aids to navigation are:

Lighthouse, a structure exhibiting a major light designed to serve as an aid to navigation. Lighthouses vary in appearance because of location, relative importance, the type of soil upon which they are constructed, prevalence of violent storms, backgrounds against which they are seen, distances the lights are to be seen, etc. Some are located on land, and some in the water. Figure 914 illustrates several typical light structures. The type of structure and its coloring assist in daylight identification. There are about 400 lighthouses in United States waters, being located along all coasts, the Great Lakes, and many of the inland waterways.

Beacon. In a general sense, a beacon is anything serving as a signal or indication, either for guidance or warning. However, as a distinctive type of aid to navigation, a beacon is either a *fixed* aid (not a floating one) or an unlighted aid (sometimes called a **daybeacon**). As thus defined, a lighthouse is a beacon. However, the term "beacon" is generally applied particularly to secondary fixed structures, whether lighted or not. There are about 15,000 beacons of this type in United States waters.

Lightship, a distinctively marked vessel anchored or moored at a charted point, to serve as an aid to navigation. By night it displays a characteristic masthead light and a less brilliant light on the forestay. The forestay indicates the direction in which the vessel is headed, and hence the direction of the current (or wind), since lightships head into the wind or current. By day a lightship displays the International Code signal of the station when requested, or if an approaching vessel does not seem to recognize it. The name of the station is painted in large letters on the side of the

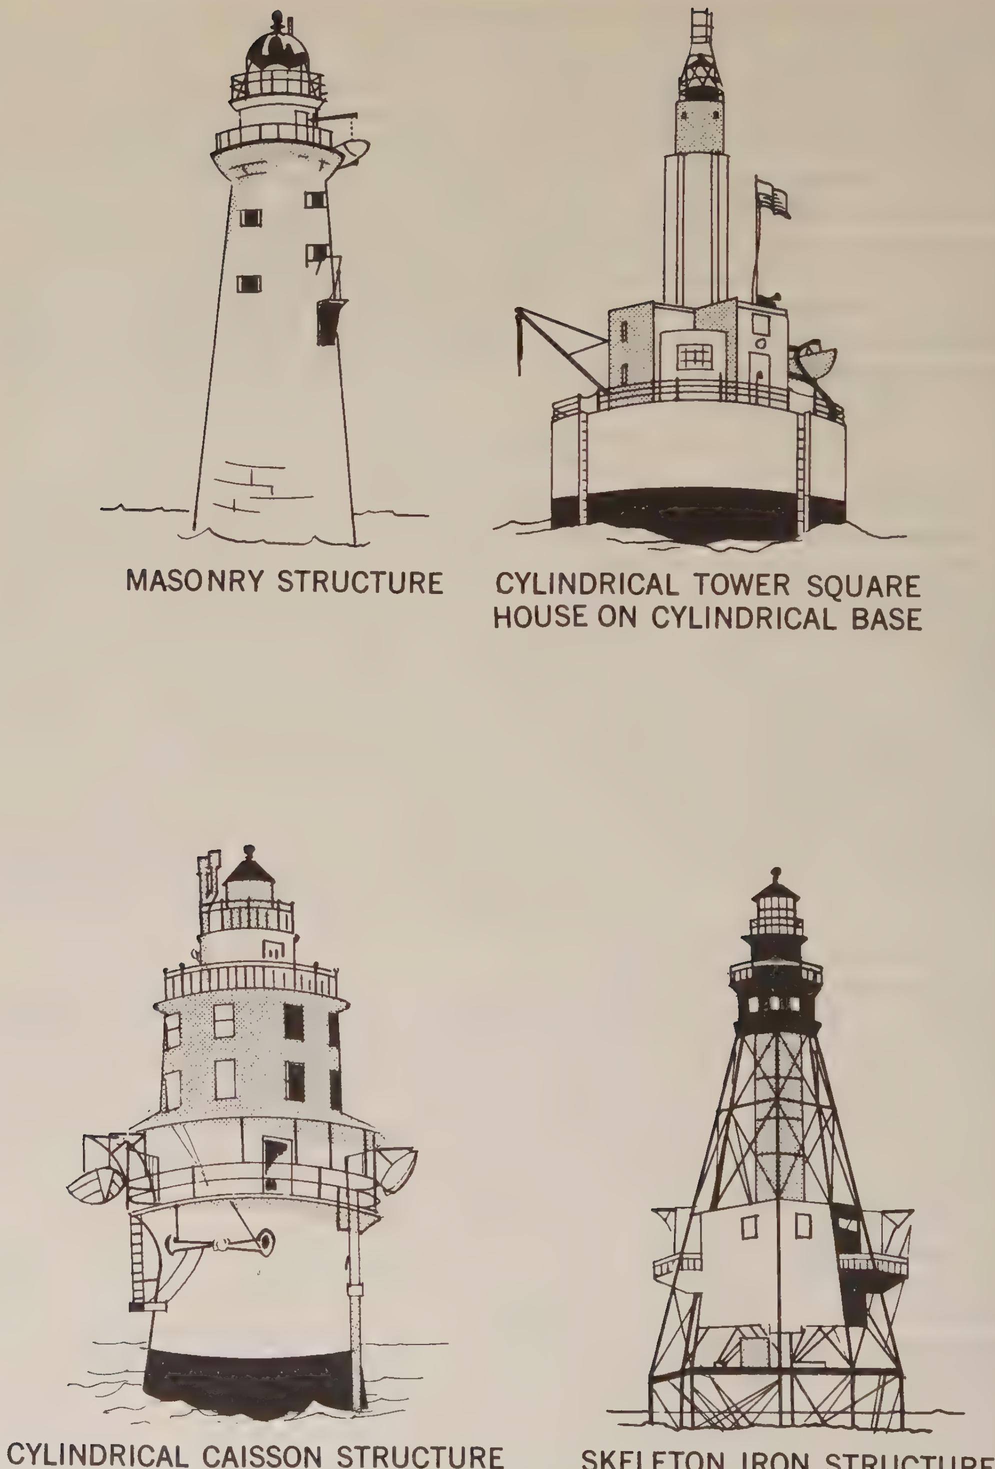

FIGURE 914.—Typical light structures.

vessel. All lightships except Lake Huron Lightship have red hulls; white lettering and superstructure; and buff masts, lantern galleries, ventilators, and stacks. Relief lightships have the same coloring, but carry the name "Relief." Lake Huron Lightship has a black hull. A lightship may be equipped with certain auxiliary devices such as a fog signal, submarine sound signal, and radiobeacon. When under way or off station a lightship displays the lights and sounds the signals prescribed by the rules of the road, and flies the International Code signal flags "PC," signifying that it is not then serving as an aid to navigation. It does not then show or sound any of the signals of a lightship. A lightship is the floating equivalent of a lighthouse. Most U. S. lightships eventually will be replaced by structures similar to Texas towers.

Buoy, a floating object, other than a lightship, moored to the bottom as an aid to navigation. There are many different types of buoys to serve different purposes. Buoys are the most numerous aid to navigation, about 20,000 unlighted and 3,000 lighted buoys being maintained by the United States Coast Guard alone.

Any lighted aid to navigation may be called a **light.**

Along the coasts of the United States, and in the Great Lakes (United States side) most aids to navigation are installed and maintained by the United States Coast Guard. Along certain rivers they are under the control of other government agencies, notably the Corps of Engineers of the United States Army. A number of privately maintained aids are in use. An example of such aids are lights at the ends of privately owned piers.

915. Lights.—A light extends the use of various aids to navigation to periods of darkness. If such a light is to serve its purpose, the user must be able to distinguish it from the general background of shore lights, and to determine *which* navigational light it is. That is, one must be able to *identify* the light. For this purpose each light is given a distinctive sequence of light and dark periods, and in some cases a distinctive color, or color sequence. These features are called the **characteristics** of the light (fig. 915). No two lights are given the same characteristics if they are so located that one might be mistaken for the other.

The U.S. Coast Guard publishes a *Light List* in five volumes: two volumes for the Atlantic coast and Gulf of Mexico, and one volume each for the Pacific coast and islands, Great Lakes, and Mississippi River system. The U.S. Navy Hydrographic Office publishes seven *Lists of Lights* giving characteristics of lights of foreign waters and the principal lights along the coasts of the United States. Characteristics are also indicated on charts. The letter *W* indicates a white light, *R* a red light, and *G* a green light. Other colors are not used by the United States Coast Guard. If no color indication is given, a light is white. Colors are produced by glass shades or screens. The **period** of a light is the time required for one complete sequence of characteristics.

Some lights provide bearing indication by a system of **light sectors,** different colors being exhibited in the various sectors. As an observer crosses the boundary between sectors, he can note the change of color. The boundaries are indicated in the light lists and by broken lines on charts. The bearings given in these indications are those *of* the light as observed at a distance, not the direction outward *from* the light. In general, red sectors are used to indicate obstruction areas. In using light sectors to determine bearing, one should remember that the line of demarcation is not always sharply defined, and that when haze or smoke is present, a white light might have a reddish hue.

916. Visibility of lights.—Usually a navigator wants to know not only the identity of a light, but also the area in which he might reasonably expect to observe it. His track is planned to take him within range of lights which can prove useful during

Illustration	Symbols and meaning		Phase description
	Lights which do not change color	Lights which show color variations	
	F. = Fixed	Alt. = Alternating.	A continuous steady light.
	F. Fl. = Fixed and flashing.	Alt. F. Fl. = Alternating fixed and flashing.	A fixed light varied at regular intervals by a flash of greater brilliance.
	F. Gp. Fl. = Fixed and group flashing.	Alt. F. Gp. Fl. = Alternating fixed and group flashing	A fixed light varied at regular intervals by groups of 2 or more flashes of greater brilliance.
	Fl. = Flashing	Alt. Fl. Alternating flashing.	Shows a single flash at regular intervals, the duration of light always being less than the duration of darkness. Shows not more than 30 flashes per minute.
	Gp. Fl. = Group flashing.	Alt. Gp. Fl. = Alternating group flashing.	Shows at regular intervals groups of 2 or more flashes.
	Qk. Fl. = Quick flashing.	----------------	Shows not less than 60 flashes per minute.
	I. Qk. Fl. = Interrupted quick flashing.	----------------	Shows quick flashes for about 4 seconds, followed by a dark period of about 4 seconds.
	S-L. Fl. = Short-long flashing.	----------------	Shows a short flash of about 0.4 second, followed by a long flash of 4 times that duration.
	Occ. = Occulting	Alt. Occ. = Alternating occulting.	A light totally eclipsed at regular intervals, the duration of light always equal to or greater than the duration of darkness.
	Gp. Occ. = Group occulting.	----------------	A light with a group of 2 or more eclipses at regular intervals.

Light colors used and abbreviations: W = white, R = red, G = green.

FIGURE 915.—Light characteristics.

periods of darkness. If lights are not sighted within a reasonable time after prediction, a dangerous situation may exist, requiring resolution or action to insure safety of the vessel.

The area in which a light can be observed is normally a circle with the light as the center, and the range of visibility as the radius. However, on some bearings the range may be reduced by obstructions. In this case the obstructed arc might differ with height of eye and distance. Also, lights of different colors may be seen at different distances. This fact should be considered not only in predicting the distance at which a light can be seen, but also in identifying it. The condition of the atmosphere has a considerable effect upon the distance at which lights can be seen. Sometimes lights are obscured by fog, haze, dust, smoke, or precipitation which may be present at the light, or between it and the observer, but not at the observer, and possibly unknown

to him. There is always the possibility of a light being extinguished. In the case of unwatched lights, this condition might not be detected and corrected at once. During periods of armed conflict, certain lights might be deliberately extinguished if they are considered of greater value to the enemy than to one's own vessels.

On a dark, clear night the range of visibility is limited primarily in two ways: (1) luminosity and (2) curvature of the earth. A weak light cannot normally be expected to be seen beyond a certain range, regardless of the height of eye. This distance is called **luminous range.** Light travels in almost straight lines, so that an observer below the visible horizon of the light should not expect to see the light, although the loom extending upward from the light can sometimes be seen at greater distances. Table 8 gives the distance to the horizon at various heights. The tabulated distances assume normal refraction. Abnormal conditions might extend this range somewhat (or in some cases reduce it). Hence, the **geographic range,** as the luminous range, is not subject to exact prediction at any given time.

The geographic range depends upon the height of both the light and the observer, as shown in figure 916. In this illustration a light 150 feet above the water is shown. At this height, the distance to the horizon, by table 8, is 14.0 miles. Within this range the light, if powerful enough and atmospheric conditions permit, is visible regardless of the height of eye of the observer (if there is no obstruction). Beyond this range, the visibility depends upon the height of eye. Thus, by table 8 an observer with height of eye of five feet can see the light on his horizon if he is 2.6 miles beyond the horizon of the light, or a total of 16.6 miles. For a height of 30 feet the distance is $14.0+6.3 = 20.3$ miles. If the height of eye is 70 feet, the geographic range is $14.0+9.6 = 23.6$ miles.

The range of important lights is given in the light lists, and also on the charts. *The tabulated or charted range is for mean high water and a height of eye of 15 feet,* and because of various uncertainties is given only to the nearest whole mile. Where the luminous range is less than the charted range, the shorter distance is given. This fact is not indicated. Therefore, in predicting the range at which a light can be seen, one should first determine the geographic range and compare this with the charted range.

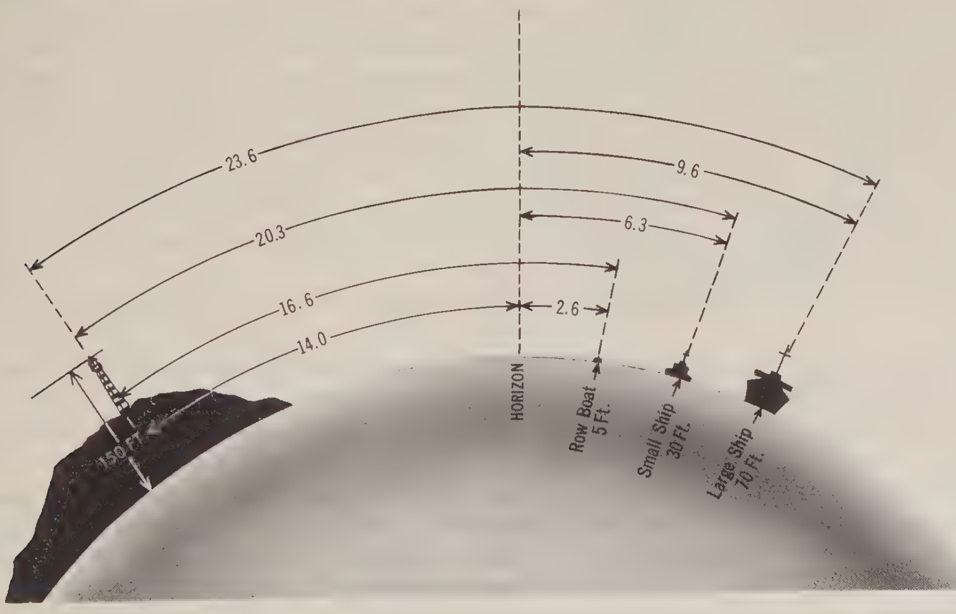

FIGURE 916.—Geographic range of visibility of a light.

This is done by *adding* 4.4 miles (the distance to the horizon at a height of 15 feet) to the value from table 8 for the height of the light. If this value approximates the charted range, one is generally safe in assuming that the charted range is the geographic range. The predicted range is then found by adding the distance to the horizon for both the light and the observer, as indicated above, or, approximately, by taking the *difference* between 4.4 and the distance for the height of eye of the observer (a constant for any given height) and *adding* this value to the charted range (subtracting if the height of eye is less than 15 feet). In making a prediction, one should keep in mind the possibility of the luminous range being *between* the charted range and the predicted range. The *power* of the light should be of some assistance in identifying this condition.

If one is approaching a light, and wishes to predict the *time* at which it should be sighted, he first predicts the range. It is then good practice to draw a circle indicating the limit of visibility. The point at which the course line crosses the circle of visibility is the predicted position of the vessel at the time of sighting the light. The predicted time of arrival at this point is the predicted time of sighting the light. The direction of the light from this point is the predicted bearing at which the light should be sighted. Conversion of the true bearing to a relative bearing is usually helpful in sighting the light. The accuracy of the predictions depends upon the accuracy of the predicted range, and the accuracy of the predicted time and place of crossing the circle of visibility. If the course line crosses the circle of visibility at a small angle, a small lateral error in track may result in a large error of prediction, both of bearing and time. This is particularly apparent if the vessel is *farther* from the light than predicted, in which case the light might be passed without being sighted. Thus, if a light is not sighted at the predicted time, the error *may* be on the side of safety. However, such an interpretation should not be given unless confirmed by other information, for there is always the possibility of reduced range of visibility, or of the light being extinguished.

When a light is first sighted, one might determine whether it is on the horizon by immediately reducing the height of eye by several feet, as by squatting or changing position to a lower height. If the light disappears, and reappears when the original height is resumed, it is on the horizon. This process is called **bobbing a light.** If a vessel has considerable vertical motion due to the condition of the sea, a light sighted on the horizon may alternately appear and disappear. This may lead the unwary to assign faulty characteristics and hence to err in its identification. The true characteristics should be observed after the distance has decreased, or by increasing the height of eye of the observer.

917. Buoys.—The primary functions of buoys are to delineate channels, indicate shoals, mark obstructions, and warn the mariner of danger.

The principal types of buoys used by the United States are illustrated in figure 917, and described as follows:

Can, a buoy built up of steel plates, in the shape of an ordinary cylindrical "tin" can.

Nun, a buoy built up of steel plates, the above-water portion being in the shape of a truncated cone.

Spar, a large log, trimmed, shaped, and appropriately painted. Some spar buoys of the same shape are constructed of steel.

Bell, a steel float surmounted by a short skeleton tower in which the bell is located. Older bell buoys are sounded by the motion of the buoys in the sea. In newer types the bells are struck by compressed gas or electrically operated hammers. A **gong buoy** is similar to a bell buoy, but instead of a bell it has a set of gongs, each of which has a distinctive tone.

Whistle, a steel float surmounted by a small tower in which a whistle is located. Older whistle buoys are sounded by the motion of the sea. In some newer buoys a trumpet is sounded electrically.

Lighted, a steel float surmounted by a skeleton tower with the light at the top. Energy for the light is provided by electric batteries or a tank of acetylene gas, located in the metal float.

Combination, a buoy having more than one means of conveying intelligence, as a **lighted bell buoy** or **lighted whistle buoy.**

Some unlighted buoys are fitted with reflectors to assist in their location and identification by searchlight at night. The colors of the reflectors have the same significance as those of lights. Radar reflectors are fitted to some buoys to increase the strength of the returned signal. A buoy may be equipped with a marker radiobeacon.

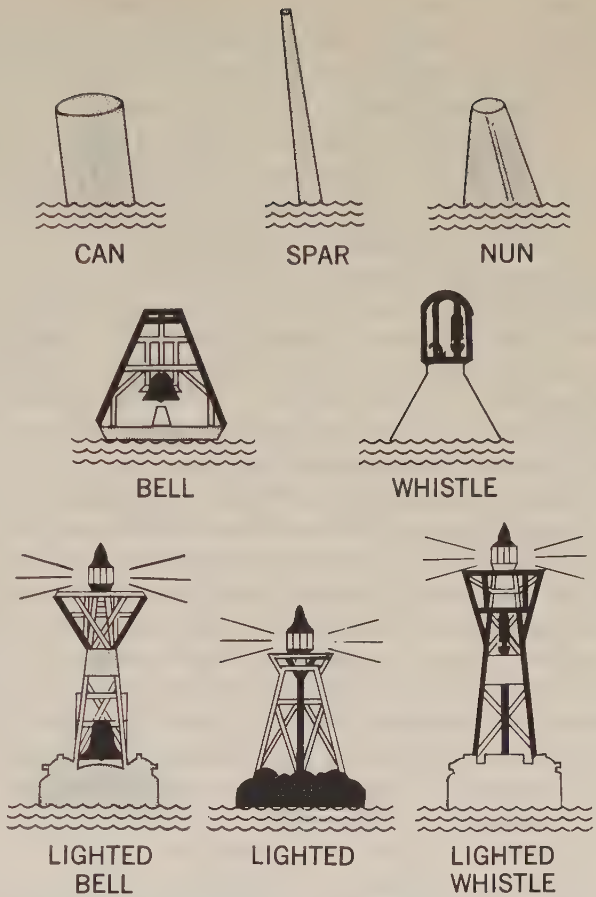

FIGURE 917.—Principal buoy types used by United States.

Most maritime countries use either the **lateral system** of buoyage or the **cardinal system,** or both. In the lateral system, used on all navigable waters of the United States, the coloring, shape, numbering, and lighting of buoys indicate the direction to a danger relative to the course which should be followed. In the cardinal system the coloring, shape, and lighting of buoys indicate the direction to a danger relative to the buoy itself. The color, shape, lights, and numbers of buoys in the lateral system as used by the United States are determined relative to a direction *from* seaward. Along the *coasts* of the United States, the *clockwise* direction around the country is arbitrarily considered to be the direction "from seaward." Some countries using the lateral system have methods of coloring their buoys and lights opposite to that of the United States. Appendix J treats this subject in greater detail.

In United States waters the following distinctive system of identification is used:

Red nun buoys mark the *right* side of channels for an inbound vessel, and obstructions which should be kept to starboard. They have *even* numbers which increase from seaward.

Black can buoys mark the *left* side of channels for an inbound vessel, and obstructions which should be kept to port. They have *odd* numbers which increase from seaward.

Red and black horizontally banded buoys mark junctions or bifurcations of channels, or an obstruction that can be passed on either side. The color (red or black) of the

top band and the shape (nun or can) indicate the side on which the buoy should be passed by a vessel proceeding along the principal channel.

Black and white vertically striped buoys mark the center of a channel and should be passed close aboard. These "mid-channel buoys" may be either nuns or cans.

In fairways and channels solid red or solid black buoys have numbers. Others may have letter designations. Along channels certain numbers may be omitted to maintain the approximate sequence on both sides of the channels.

Lights. Red lights are used only on red buoys and buoys with a red band at the top, green lights are used only on black buoys and buoys with a black band at the top. White lights are used without any color significance. Lights on red and black buoys, if not fixed, are always regularly flashing or regularly occulting. Quick flashing lights are used when a light of distinct cautionary significance is desired, as at a sharp turn or constriction in the channel. Interrupted quick flashing lights are used on red and black horizontally banded buoys. White short-long flashing lights are used on black and white vertically striped buoys.

Special purpose buoys. White buoys mark anchorages. Yellow buoys mark quarantine anchorages. White buoys with green tops are used in dredging and survey operations. Black and white horizontally banded buoys mark fish net areas. Yellow and black vertically striped buoys mark seadromes. White and orange banded, either horizontally or vertically, are used for special purposes.

Wreck buoys are generally placed on the seaward or channel side, as near the wreck as conditions permit. The possibility of the wreck having shifted position due to sea action since the buoy was placed should not be overlooked.

Station buoys, are placed close to some lightships and important buoys to mark the position if the regular aid is not at the assigned position. Such buoys are colored and numbered the same as the regular aid, lightship station buoys having the letters "LS" above the initials of the station.

Buoys are secured by anchor, and swing in a circle of small radius as the current changes. In this respect, they are inferior to fixed aids for position fixing. They may be shifted, carried away, capsized, or sunk. Lighted buoys may be extinguished and sound buoys may not function.

Dates shown in light lists for seasonal buoys are approximations which vary with local conditions.

918. Fog signals.—Any sound-producing device may serve as a fog signal to warn the mariner of danger or to assist him in establishing the position of his vessel. If a fog signal is to be fully effective for the second of these functions, the mariner must be able to recognize it as a fog signal and to know from what point it is sounded. Bells, whistles, etc., which are sounded by action of the sea are erratic in operation, and positive identification is not always possible. At most lighthouses and lightships fog signals are operated by mechanical means, providing a definite sequence of sounds and silent periods resembling the characteristics of lights. The sequence, stated in the light list, is an aid to identification. The distinctive sound of each type of signal apparatus is helpful in this respect. About 600 fog signals are maintained by the United States Coast Guard. These are of the following types:

Bell, sounded by means of a hammer actuated by hand, descending weight, compressed gas, or electricity.

Diaphone, a device producing sound by means of a slotted reciprocating piston actuated by compressed air. "Two-tone" diaphones produce a blast with a high pitch followed by a lower pitch.

Diaphragm horn, a device producing sound by means of a disk diaphragm vibrated by compressed air, steam, or electricity. Duplex or triplex units produce simultaneous sounds of different pitch, resulting in a chime signal.

Reed horn, a device producing sound by means of a steel reed vibrated by compressed air.

Siren, a device producing sound by means of either a disk or a cup-shaped rotor actuated by compressed air, steam, or electricity.

Whistle, producing sound by compressed air or steam emitted through a circular slot into a cylindrical bell chamber.

Radiobeacons, radar, and other electronic aids to navigation can be of considerable assistance to a vessel equipped to use them.

Tides and Currents

919. Tidal effects.—The daily rise and fall of the **tide,** with its attendant flood and ebb of **tidal current,** is familiar to every mariner. He is aware, also, that at **high water** and **low water** the depth of water is momentarily constant, a condition called **stand.** Similarly, there is a moment of **slack water** as a tidal current reverses direction. As a general rule, the *change* in height or the current *speed* is at first very slow, increasing to a maximum about midway between the two extremes, and then decreasing again. If plotted against time, the height of tide or speed of a tidal current takes the general form of a sine curve. Sample curves, and more complete information about causes, types, and features of tides and tidal currents, are given in chapter XXXI. Ocean (nontidal) currents are discussed in chapter XXXII. The present chapter is concerned primarily with the application of tides and currents to piloting, and predicting the tidal conditions that might be encountered at any given time.

Although tides and tidal currents are caused by the same phenomena, the time relationship between them varies considerably from place to place. For instance, if an estuary has a wide entrance and does not extend far inland, the time of maximum speed of current occurs at about the mid time between high water and low water. However, if an extensive tidal basin is connected to the sea by a small opening, the maximum current may occur at about the time of high water or low water outside the basin, when the difference in height is maximum.

The *height of tide* should not be confused with *depth of water.* For reckoning tides a reference level is selected. Soundings shown on the largest scale charts are the vertical distances from this level to the bottom. At any time the actual depth is this charted depth *plus* the height of tide. In most places the reference level is some form of low water. But all low waters at a place are not the same height, and the selected reference level is seldom the *lowest* tide that occurs at the place. When lower tides occur, these are indicated by a negative sign. Thus, at a spot where the charted depth is 15 feet, the actual depth is 15 feet plus height of tide. When the tide is three feet, the depth is $15+3=18$ feet. When it is $(-)$ 1 foot, the depth is $15-1=14$ feet. It is well to remember that *the actual depth can be less than the charted depth.* In an area where there is a considerable **range of tide** (the difference between high water and low water), the height of tide might be an important consideration in using soundings to assist in determining position, or whether the vessel is in safe water.

One should remember that heights given in the tide tables are *predictions*, and that when conditions vary considerably from those used in making the predictions, the heights shown may be considerably in error. Heights lower than predicted are particularly to be anticipated when the atmospheric pressure is higher than normal, or when there is a persistent strong offshore wind. Along coasts where there is a large

inequality between the two high or two low tides during a tidal day the height predictions are less reliable than elsewhere.

The current encountered in pilot waters is due primarily to tidal action, but other causes are sometimes present. The tidal current tables give the best prediction of total current, regardless of cause. The predictions for a river may be considerably in error following heavy rains or a drought. The effect of current is to alter the course and speed made good over the bottom (art. 807). Due to the configuration of land (or shoal areas) and water, the set and drift may vary considerably over different parts of a harbor. Since this is generally an area in which small errors in position of a vessel are of considerable importance to its safety, a knowledge of predicted currents can be critical, particularly if the visibility is reduced by fog, snow, etc. If the vessel is proceeding at reduced speed, the effect of current with respect to distance traveled is greater than normal. Strong currents are particularly to be anticipated in narrow passages connecting larger bodies of water. Currents of more than five knots are encountered from time to time in the Golden Gate at San Francisco. Currents of more than 13 knots sometimes occur at Seymour Narrows, British Columbia.

In straight portions of rivers and channels the strongest currents usually occur in the middle, but in curved portions the swiftest currents (and deepest water) usually occur near the outer edge of the curve. Countercurrents and eddies may occur on either side of the main current of a river or narrow passage, especially near obstructions and in bights.

In general, the range of tide and the speed of tidal current are at a minimum upon the open ocean or along straight coasts. The greatest tidal effects are usually encountered in rivers, bays, harbors, inlets, bights, etc. A vessel proceeding along a coast can be expected to encounter stronger sets toward or away from the shore while passing an indentation than when the coast is straight.

920. Predictions of tides and currents to be expected at various places are published annually by the U. S. Coast and Geodetic Survey. These are supplemented by nine sets of **Tidal Current Charts,** each set consisting of 12 charts, one for each hour of the tidal cycle. On these charts the set of the current at various places in the area is shown by arrows, and the drift by numbers. Since these are *average* conditions, they indicate in a general way the tidal conditions on any day and during any year. They are designed to be used with the tidal current tables (except those for New York Harbor, which are used with the tide tables). These charts are available for Boston Harbor, Narragansett Bay to Nantucket Sound, Long Island Sound and Block Island Sound, New York Harbor, Delaware Bay and River, Tampa Bay, San Francisco Bay, Puget Sound (northern part), and Puget Sound (southern part). Current arrows are sometimes shown on nautical charts. These represent average conditions and should not be considered reliable predictions of the conditions to be encountered at any given time. When a strong current sets over an irregular bottom, or meets an opposing current, ripples may occur on the surface. These are called **tide rips.** Areas where they occur frequently are shown on charts.

Usually, the mariner obtains tidal information from tide and tidal current tables. However, if these are not available, or if they do not include information at a desired place, the mariner may be able to obtain locally the **mean high water lunitidal interval** or the **high water full and change.** The approximate *time* of high water can be found by adding either interval to the time of transit (either upper or lower) of the moon (art. 2104). Low water occurs approximately ¼ tidal day (about 6^h12^m) before and after the time of high water. The actual interval varies somewhat from day to day, but approximate results can be obtained in this manner. Similar information for tidal currents (**lunicurrent interval**) is seldom available.

921. Tide tables for various parts of the world are published in four volumes by the U. S. Coast and Geodetic Survey. Each volume is arranged as follows:

Table 1 contains a complete list of the predicted times and heights of the tide for each day of the year at a number of places designated as **reference stations.**

Table 2 gives differences and ratios which can be used to modify the tidal information for the reference stations to make it applicable to a relatively large number of **subordinate stations.**

Table 3 provides information for use in finding the approximate height of the tide at any time between high water and low water.

Table 4 is a sunrise-sunset table at five-day intervals for various latitudes from 76°N to 60°S (40°S in one volume).

Table 5 provides an adjustment to convert the local mean time of table 4 to zone or standard time.

Table 6 (two volumes only) gives the zone time of moonrise and moonset for each day of the year at certain selected places.

Table 7 gives certain astronomical data. In the two volumes not having moonrise-moonset tables, this is table 6.

Extracts from tables 1, 2, and 3 for the East Coast of North and South America are given in appendix T. Before the edition having predictions for 1958, the arrangement of tables 1 and 2 were somewhat different than shown.

922. Tide predictions for reference stations.—The first page of appendix T is the table 1 daily predictions for New York (The Battery) for the first quarter of 1958. As indicated at the bottom of the page, times are for Eastern Standard Time (+5 zone, time meridian 75° W). Daylight saving time is not used. Times are given on the 24-hour basis. The tidal reference level for this station is mean low water.

For each day, the date and day of week are given, and the time and height of each high and low water are given in chronological order. Although high and low waters are not labeled as such, they can be distinguished by the relative heights given immediately to the right of the times. Since *two* high tides and *two* low tides occur each tidal day, the type of tide at this place is *semidiurnal* (art. 3105). The *tidal* day being longer than the *civil* day (because of the revolution of the moon eastward around the earth), any given tide occurs *later* from day to day. Thus, on Saturday, March 22, 1958, the first tide that occurs is the lower low water (−0.3 foot at 0333). The following high water (lower high water) is 4.1 feet above the reference level (a 4.4 foot rise from the preceding low water), and occurs at 0929. This is followed by the higher low water (−0.2 feet) at 1540, and then the higher high water of 4.4 feet at 2143. The cycle is repeated on the following day with variations in height, and later times.

Because of later times of corresponding tides from day to day, certain days have only one high water or only one low water. Thus, on January 9 high tides occur at 1051 and 2329. The next following high tides are at 1146 on January 10 and 0024 on January 11. Thus, only one high tide occurs on January 10, the previous one being shortly before midnight on the ninth, and the next one occurring early in the morning of the eleventh, as shown.

923. Tide predictions for subordinate stations.—The second page of appendix T is a page of table 2 of the tide tables. For each subordinate station listed, the following information is given:

Number. The stations are listed in geographical order and given consecutive numbers. At the end of each volume an alphabetical listing is given, and for each entry the consecutive number is shown, to assist in finding the entry in table 2.

Place. The list of places includes both subordinate and reference stations, the latter being given in bold type.

Position. The approximate latitude and longitude are given to assist in locating the station. The latitude is north or south, and the longitude east or west, depending upon the letters (N, S, E, W) next *above* the entry. These may not be the same as those at the *top* of the column.

Differences. The differences are to be applied to the predictions for the reference station shown in bold capitals next *above* the entry on the page. Time and height differences are given separately for high and low waters. Where differences are omitted, they are either unreliable or unknown.

The time difference is the number of hours and minutes to be applied to the time at the reference station to find the time of the corresponding tide at the subordinate station. This interval is added if preceded by a plus sign (+), and subtracted if preceded by a minus sign (−). Special conditions occurring at a few stations are indicated by footnotes on the applicable pages. In some instances, the corresponding tide falls on a different date at reference and subordinate stations.

Height differences are shown in a variety of ways. For most entries separate height differences in feet are given for high water and low water. These are applied to the height given for the reference station. In many cases a *ratio* is given for either high water or low water, or both. The height at the reference station is multiplied by this ratio to find the height at the subordinate station. For a few stations, *both* a ratio and difference are given. In this case the height at the reference station is first multiplied by the ratio, and the difference is then applied. An example is given in each volume of tide tables. Special conditions are indicated in the table or by footnote. Thus, a footnote on the second page of appendix T indicates that "Values for the Hudson River above George Washington Bridge are based upon averages for the six months May to October, when the fresh-water discharge is a minimum."

Ranges. Various ranges are given, as indicated in the tables. In each case this is the difference in height between high water and low water for the tides indicated.

Example.—List chronologically the times and heights of all tides at Yonkers, (No. 1581) on January 10, 1958.

Solution.—

Date	January 10, 1958
Subordinate station	Yonkers
Reference station	New York
High water time difference	(+) 1^h09^m
Low water time difference	(+) 1^h10^m
High water height difference	(−) 0.7 ft.
Low water height difference	0.0 ft.

	New York		*Yonkers*	
HW	2329 (9th)	4.4 ft.	0038	3.7 ft.
LW	0525	(−) 0.6 ft.	0635	(−) 0.6 ft.
HW	1146	4.6 ft.	1255	3.9 ft.
LW	1758	(−) 0.8 ft.	1908	(−) 0.8 ft.

924. Finding height of tide at any time.—Table 3 of the tide tables provides means for determining the approximate height of tide at any time. It is based upon the assumption that a plot of height versus time is a sine curve (art. O40). Instructions for use of the table are given in a footnote below the table, which is reproduced in appendix T.

Example 1.—Find the height of tide at Yonkers (No. 1581) at 1000 on January 10, 1958.

Solution.—The given time is between the low water at 0635 and the high water at 1255 (example of art. 923). Therefore, the tide is rising. The duration of rise is $1255-0635=6^h20^m$. The range of tide is $3.9-(-0.6)=4.5$ feet. The given time is 2^h55^m *before* high water, the nearest tide. Enter the upper part of the table with duration of rise 6^h20^m, and follow the line horizontally to 2^h57^m (the nearest tabulated value to 2^h55^m). Follow this column vertically downward to the entry 2.0 feet in the line for a range of tide of 4.5 feet. This is the correction to be applied to the nearest tide. Since the nearest tide is high water, subtract 2.0 from 3.9 feet. The answer, 1.9 feet, is the height of tide at the given time.

Answer.—Ht. of tide at 1000, 1.9 ft.

Interpolation in this table is not considered justified.

It may be desired to know at what time a given depth of water will occur. In this case, the problem is solved in reverse.

Example 2.—The captain of a vessel drawing 22 feet wishes to pass over a temporary obstruction near Days Point, Weehawken (No. 1571), having a charted depth of 21 feet, passage to be made during the morning of January 10, 1958.

Required.—The earliest time after 0800 that this passage can be made, allowing a safety margin of two feet.

Solution.—The least acceptable depth of water is 24 feet, which is three feet more than the charted depth. Therefore, the height of tide must be three feet or more. At the New York reference station a low tide of (—) 0.6 foot occurs at 0525, followed by a high tide of 4.6 feet at 1146. At Days Point the corresponding low tide is (—) 0.6 foot at 0548, and the high tide is 4.4 feet at 1210. The duration of rise is 6^h22^m, and the range of tide is 5.0 feet. The least acceptable tide is 3.0 feet, or 1.4 feet less than high tide. Enter the *lower* part of table 3 with range 5.0 feet and follow the horizontal line until 1.5 feet is reached (the nearest tabulated value to 1.4 feet). Follow this column vertically *upward* until the value of 2^h19^m is reached on the line for a duration of 6^h20^m (the nearest tabulated value to 6^h22^m). The minimum depth will occur about 2^h19^m *before* high water, or at about 0951.

Answer.—A depth of 24 feet occurs at 0951.

If the range of tide is more than 20 feet, *half* the range (*one third* if the range is greater than 40 feet) is used to enter table 3, and the correction to height is *doubled* (*trebled* if one third is used).

A diagram for a graphical solution is given in figure 924. Eye interpolation can be used if desired. The steps in this solution are as follows:

1. Enter the upper graph with the duration of rise or fall. This is represented by a horizontal line.
2. Find the intersection of this line and the curve representing the interval from the nearest *low* water (point *A*).
3. From *A*, follow a vertical line to the sine curve of the lower diagram (point *B*).
4. From *B*, follow horizontally to the vertical line representing the range of tide (point *C*).
5. Using *C*, read the correction from the series of curves.
6. Add (algebraically) the correction of step 5 to the *low* water height, to find the height at the given time.

The problem illustrated in figure 924 is similar to that of example 1 given above. The duration of rise is 6^h25^m, and the interval from *low* water is 5^h23^m. The range of tide is 6.1 feet. The correction (by interpolation) is 5.7 feet. If the height of the preceding low tide is (—)0.2 foot, the height of tide at the given time is $(-)0.2+5.7=5.5$ feet. To solve example 2 by the graph, enter the lower graph and find the intersection of the vertical line representing 5.0 feet and the curve representing 3.6 feet (the mini-

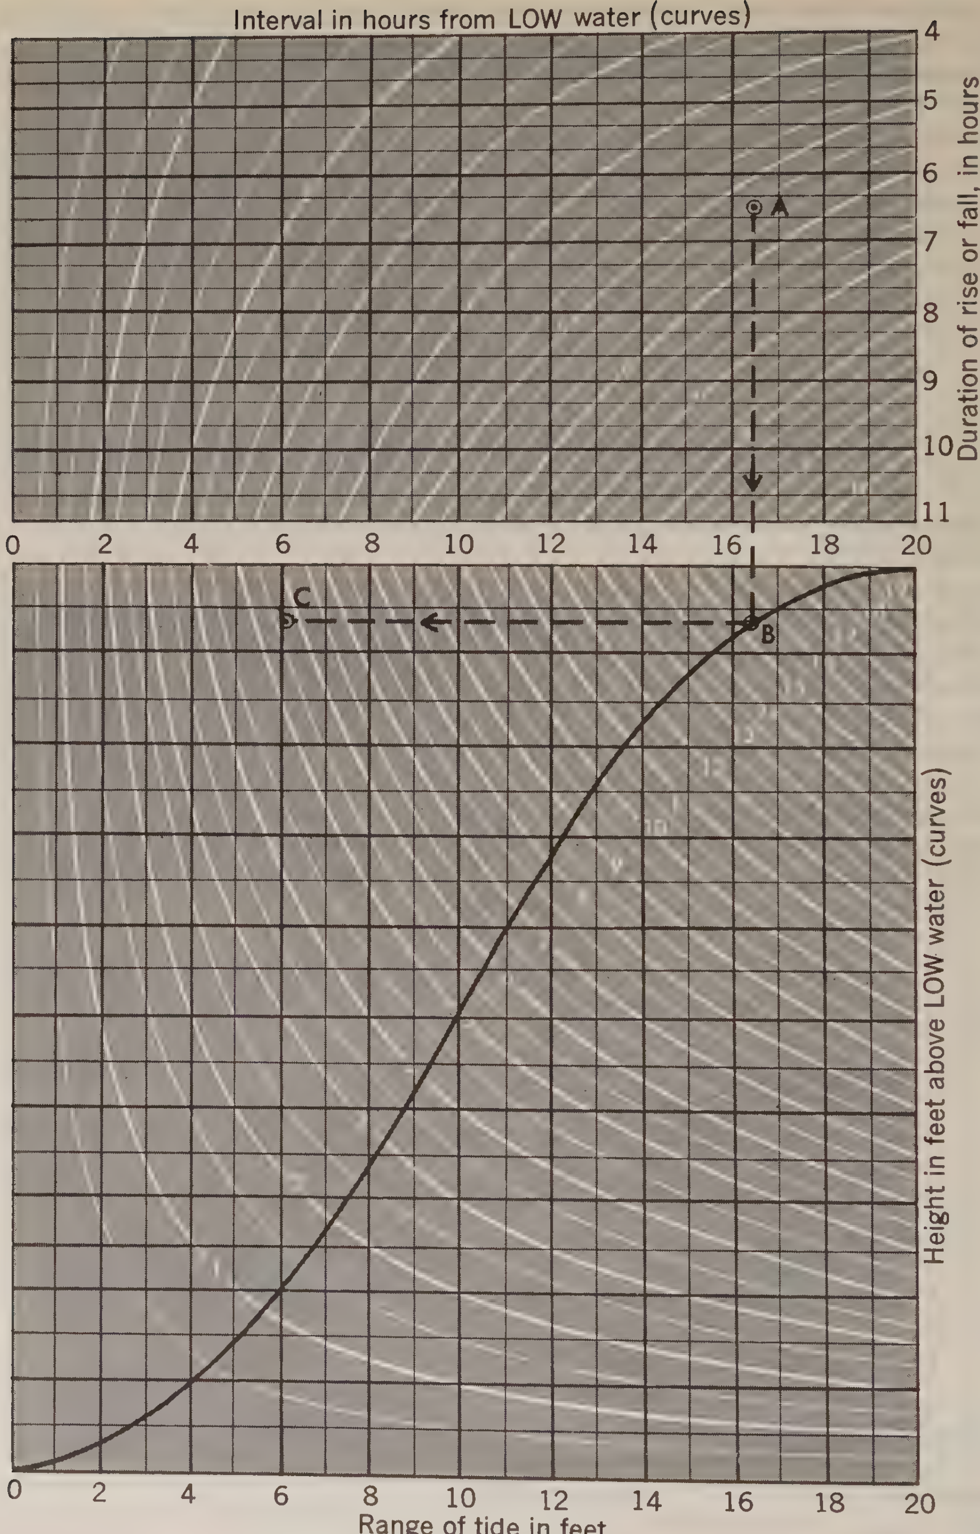

FIGURE 924.—Graphical solution for height of tide at any time.

mum acceptable height above low water). From this point follow horizontally to the sine curve, and then vertically to the horizontal line in the upper figure representing the duration of rise of 6^h22^m. From the curve, determine the interval 4^h10^m. The earliest time is about 4^h10^m *after* low water, or at about 0958.

925. Tidal current tables are somewhat similar to tide tables, but the coverage is less extensive, being given in two volumes. Each volume is arranged as follows:

Table 1 contains a complete list of predicted times of maximum currents and slack, with the velocity (speed) of the maximum currents, for a number of reference stations.

Table 2 gives differences, ratios, and other information related to a relatively large number of subordinate stations.

Table 3 provides information for use in finding the speed of the current at any time between tabulated entries in tables 1 and 2.

Table 4 gives the number of minutes the current does not exceed stated amounts, for various maximum speeds.

Table 5 (Atlantic Coast of North America only) gives information on rotary tidal currents.

Each volume contains additional useful information related to currents. Extracts from the tables for the Atlantic Coast of North America are given in appendix U. Before the edition having predictions for 1958, the arrangement of tables 1 and 2 were somewhat different than shown.

926. Tidal current predictions for reference stations.—The extracts of appendix U are for The Narrows, New York Harbor. Times are given on the 24-hour basis, for meridian 75° W.

For each day, the date and day of week are given, with complete current information. Since the cycle is repeated twice each tidal day, currents at this place are semidiurnal. On most days there are four slack waters and four maximum currents, two of them floods (f) and two of them ebbs (e). However, since the tidal day is longer than the civil day, the corresponding condition occurs later from day to day, and on certain days there are only three slack waters or three maximum currents. At some places, the current on some days runs maximum flood twice, but ebb only once, a minimum flood occurring in place of the second ebb. The tables show this information.

As indicated by appendix U, the sequence of currents at The Narrows on Wednesday, February 26, 1958, is as follows:

0000 Flood current, 8^m after maximum velocity (speed).
0300 Slack, ebb begins.
0625 Maximum ebb of 1.6 knots, setting 160°.
1019 Slack, flood begins.
1217 Maximum flood of 1.1 knots, setting 340°.
1512 Slack, ebb begins.
1840 Maximum ebb of 1.5 knots, setting 160°.
2216 Slack, flood begins.
2400 Flood current, 42^m before maximum velocity (speed).

Only one maximum flood occurs on this day, the previous one having occurred 8 minutes before the day began, and the following one predicted for 42 minutes after the day ends.

927. Tidal current predictions for subordinate stations.—For each subordinate station listed in table 2 of the tidal current tables, the following information is given:

Number. The stations are listed in geographical order and given consecutive numbers, as in the tide tables (art. 923). At the end of each volume an alphabetical listing is given, and for each entry the consecutive number is shown, to assist in finding the entry in table 2.

Place. The list of places includes both subordinate and reference stations, the latter being given in **bold type**.

Position. The approximate latitude and longitude are given to assist in locating the station. The latitude is north or south and the longitude east or west as indicated by the letters (N, S, E, W) next *above* the entry. The current given is for the center of the channel unless another location is indicated by the station name.

Time difference. Two time differences are tabulated. One is the number of hours and minutes to be applied to the tabulated times of slack water at the reference station to find the times of slack waters at the subordinate station. The other time difference is applied to the times of maximum current at the reference station to find the times of the corresponding maximum current at the subordinate station. The intervals, which are added or subtracted in accordance with their signs, include any difference in time between the two stations, so that the answer is correct for the standard time of the subordinate station. Limited application and special conditions are indicated by footnotes.

Velocity (speed) ratios. Speed of the current at the subordinate station is found by multiplying the speed at the reference station by the tabulated ratio. Separate ratios may be given for flood and ebb currents. Special conditions are indicated by footnotes.

As indicated in appendix U, the currents at Chelsea Docks (No. 1005) can be found by *adding* 1^h30^m for slack water and 1^h40^m for maximum current to the times for The Narrows, and multiplying flood currents by 0.9 and ebb currents by 1.2. Applying these to the values for Wednesday, February 26, 1958, the sequence is as follows:

0000 Flood current, 1^h32^m before maximum velocity (speed).
0132 Maximum flood of 1.4 knots, setting 010°.
0430 Slack, ebb begins.
0805 Maximum ebb of 1.9 knots.
1149 Slack, flood begins.
1357 Maximum flood of 1.0 knots, setting 010°.
1642 Slack, ebb begins.
2020 Maximum ebb of 1.8 knots.
2346 Slack, flood begins.
2400 Flood current, 14^m after slack.

928. Finding speed of tidal current at any time.—Table 3 of the tidal current tables provides means for determining the approximate velocity (speed) at any time. Instructions for its use are given below the table, which is reproduced in appendix U.

Example 1.—Find the speed of the current at Chelsea Docks at 1500 on February 26, 1958.

Solution.—The given time is between the maximum flood of 1.0 knots at 1357 and the slack at 1642 (art. 927). The interval between slack and maximum current (1642 —1357) is 2^h45^m. The interval between slack and the desired time (1642—1500) is 1^h42^m. Enter the table (A) with 2^h40^m at the top, and 1^h40^m at the left side (the nearest tabulated values to 2^h45^m and 1^h42^m, respectively), and find the factor 0.8 in the body of the table. The approximate speed at 1500 is $0.8 \times 1.0 = 0.8$ knot, and it is flooding.

Answer.—Speed 0.8 kn.

It may be desired to determine the period during which the current is less (or greater) than a given amount. Table 4 of the tidal current tables can be used to determine the period during which the speed does not exceed 0.5 knot. For greater speeds, and for more accurate results under some conditions, table 3 of the tidal current tables can be used, solving by reversing the process used in example 1.

Example 2.—During what period on the evening of February 26, 1958, does the ebb current equal or exceed 1.0 knot at Chelsea Docks?

Solution.—The maximum ebb of 1.8 knots occurs at 2020. This is preceded by a slack at 1642, and followed by the next slack at 2346. The interval between the earlier slack and the maximum ebb is 3^h38^m, and the interval between the ebb and following slack is 3^h26^m. The desired factor is $\frac{1.0}{1.8}=0.6$. Enter table A with 3^h40^m (the nearest tabulated value to 3^h38^m) at the top, and follow down the column to 0.6 (midway between 0.5 and 0.7). At the left margin the interval between slack and the desired time is found to be 1^h30^m (midway between 1^h20^m and 1^h40^m). Therefore, the current becomes 1.0 knot at $1642+1^h30^m=1812$. Next, enter table A with 3^h20^m (the nearest tabulated value to 3^h26^m) at the top, and follow down the column to 0.6. Follow this line to the left margin, where the interval between slack and desired time is found to be 1^h20^m. Therefore, the current is 1.0 knot or greater until $2346-1^h20^m=2226$. If the two intervals between maximum current and slack were nearest the same 20^m interval, table A would have to be entered only once.

Answer.—The speed equals or exceeds 1.0 knot between 1812 and 2226.

929. Current diagrams.—A current diagram is a graph showing the speed of the current along a channel at different stages of the tidal current cycle. The current tables include such diagrams for Boston Harbor; Vineyard and Nantucket Sounds (one diagram); East River, New York; New York Harbor; Delaware Bay and River (one diagram); Chesapeake Bay; South San Francisco Bay; and North San Francisco Bay. The diagram for New York Harbor is reproduced in appendix U.

On this diagram each vertical line represents a given instant identified in terms of the number of hours before or after slack *at The Narrows.* Each horizontal line represents a distance from Ambrose Channel Entrance, measured along the usually-traveled route. The names along the left margin are placed at the correct distances from Ambrose Channel Entrance. The current is for the center of the channel opposite these points. The intersection of any vertical line with any horizontal line represents a given moment in the current cycle at a given place in the channel. If this intersection is in a shaded area, the current is flooding; if in an unshaded area, it is ebbing. The speed in knots can be found by interpolation (if necessary) between the numbers given in the body of the diagram. The given values are *averages.* To find the value at any given time, multiply the speed found from the diagram by the ratio of *maximum speed of the current involved* to the *maximum shown on the diagram,* both values being taken for The Narrows. If the diurnal inequality is large, the accuracy can be improved by altering the width of the shaded area to fit conditions. The diagram covers 1½ current cycles, so that the right-hand third is a duplication of the left-hand third.

If the current for a single station is desired, table 1 or 2 should be used. The current diagrams are intended for use in either of two ways: First, to determine a favorable time for passage through the channel. Second, to find the average current to be expected during any passage through the channel. For both of these uses a number of "speed lines" are provided. When the appropriate line is transferred to the correct part of the diagram, the current to be encountered during passage is indicated along the line.

Example.—During the morning of January 10, 1958, a ship is to leave Pier 83 at W. 42nd St., and proceed down the bay at ten knots.

Required.—(1) Time to get underway to take maximum advantage of a favorable current, allowing 15 minutes to reach mid channel.

(2) Average speed over the bottom during passage down the bay.

Solution.—(1) Transfer the line (slope) for ten knots southbound to the diagram, locating it so that it is centered on the unshaded ebb current section between W. 42nd

St. and Ambrose Channel Entrance. This line crosses a horizontal line through W. 42nd St. about one-third of the distance between the vertical lines representing three and two hours, respectively, after ebb begins at The Narrows. The setting is not critical. Any time within about half an hour of the correct time will result in about the same current. Between the points involved, the entire speed line is in the ebb current area.

(2) Table 1 indicates that on the morning of January 10 ebb begins at The Narrows at 0050. Two hours forty minutes after ebb begins, the time is 0330. Therefore, the ship should reach mid channel at 0330. It should get underway 15 minutes earlier, at 0315.

(3) To find the average current, determine the current at intervals (as every two miles), add, and divide by the number of entries.

Distance	*Current*
18	1.2
16	1.4
14	1.9
12	1.5
10	2.0
8	1.9
6	1.3
4	1.2
2	1.4
0	1.2
sum	14.8

The sum of 14.8 is for ten entries. The average is therefore $14.8 \div 10 = 1.5$ knots.

(4) This value of current is correct only if the ebb current is an average one. From table 1 the maximum ebb involved is 2.2 knots. From the diagram the maximum value at The Narrows is 2.0 knots. Therefore, the average current found in step (3) should be increased by the ratio $2.2 \div 2.0 = 1.1$. The average for the run is therefore $1.5 \times 1.1 = 1.6$ knots. Speed over the bottom is $10 + 1.6 = 11.6$ knots.

Answers.—(1) T 0315, (2) S 11.6 kn.

In the example, an ebb current is carried throughout the run. If the transferred speed line had been partly in a flood current area, all ebb currents (those increasing the ship's speed) should be given a positive sign (+), and all flood currents a negative sign (−). A separate ratio should be determined for each current (flood or ebb), and applied to the entries for that current. In Chesapeake Bay it is not unusual for an outbound vessel to encounter three or even four separate currents during passage down the bay. Under the latter condition, it is good practice to multiply *each* current taken from the diagram by the ratio for the current involved.

If the time of starting the passage is fixed, and the current during passage is desired, the starting time is identified in terms of the reference tidal cycle. The speed line is then drawn through the intersection of this vertical time line and the horizontal line through the place. The average current is then determined in the same manner as when the speed line is located as described above.

Miscellaneous

930. Allowing for turning characteristics of vessel.—When precise piloting is necessary (as in an area where maneuvering space is limited, when a specified anchorage is approached, or when steaming in formation with other ships), the turning char-

acteristics of the vessel should be considered. That is, a ship does not complete a turn instantaneously, but follows a curve the characteristics of which depend upon the vessel's length, beam, underwater contour, draft, etc. From the moment the rudder is put over until the new course is reached, the vessel moves a certain distance in the direction of the original course. This distance is called **advance.** The distance the vessel moves perpendicular to the original course line during the turn is called **transfer.** These terms are illustrated in figure 930a. The amount of advance and transfer for a given vessel depends primarily upon the amount of rudder used and the angle through which the ship is to be turned. The speed of the vessel has little effect. Allowance for advance and transfer is illustrated in the following example.

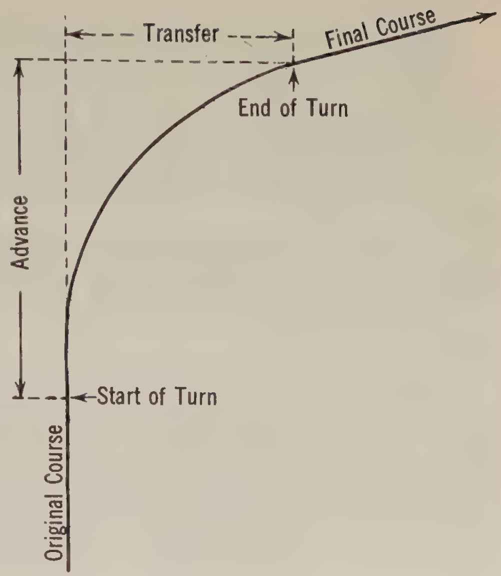

FIGURE 930a.—Advance and transfer.

Example (fig. 930b).—A ship proceeding on course 100° is to turn 60° to the left to come on a range which will guide it up a channel. For a 60° turn and the amount of rudder used, the advance is 920 yards and the transfer is 350 yards.

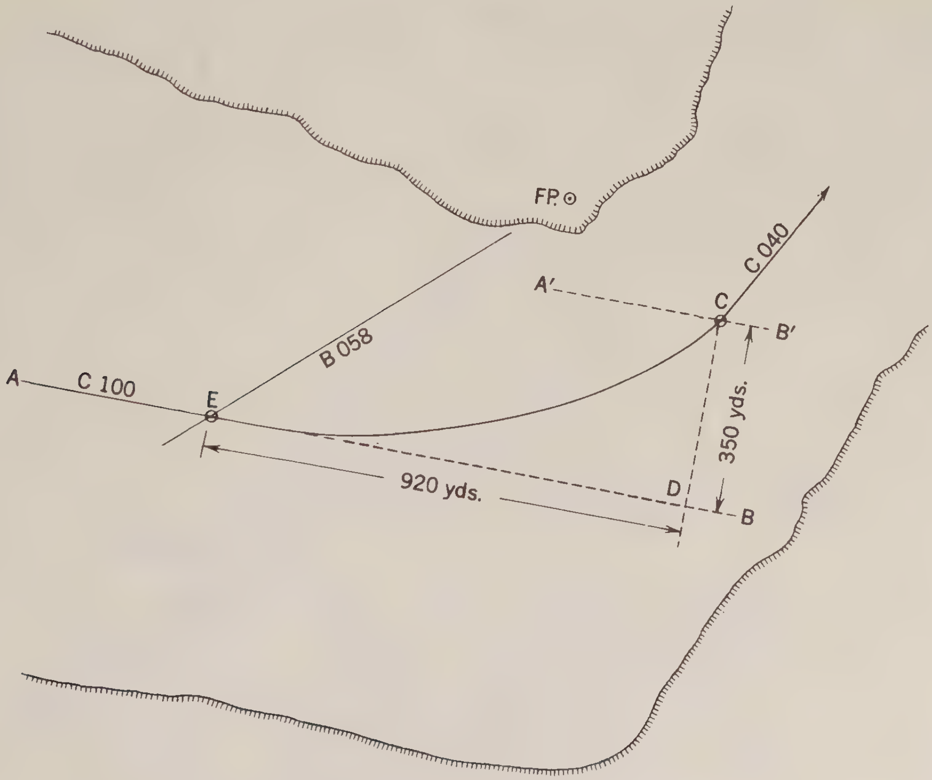

FIGURE 930b.—Allowing for advance and transfer.

Required.—The bearing of flagpole "FP." when the rudder is put over.

Solution.—(1) Extend the original course line, *AB*.

(2) At a perpendicular distance of 350 yards, the transfer, draw a line *A′B′* parallel to the original course line *AB*. The point of intersection, *C*, of *A′B′* with the new course line (located by the range) is the place at which the turn is to be completed.

(3) From *C* draw a perpendicular, *CD*, to the original course line, intersecting it at *D*.

(4) From *D* measure the advance, 920 yards, *back* along the original course line. This locates *E*, the point at which the turn should be started.

(5) The direction of "FP." from *E*, 058°, is the bearing when the turn should be started.

Answer.—B 058°.

931. Anchoring.—If a vessel is to anchor at a predetermined point, as in an assigned berth, an established procedure should be followed to insure accuracy of placing the anchor. In the case of naval vessels, it is desired that the error not exceed ten yards. This requires a high order of navigational accuracy. Several procedures have been devised. The following is representative (fig. 931).

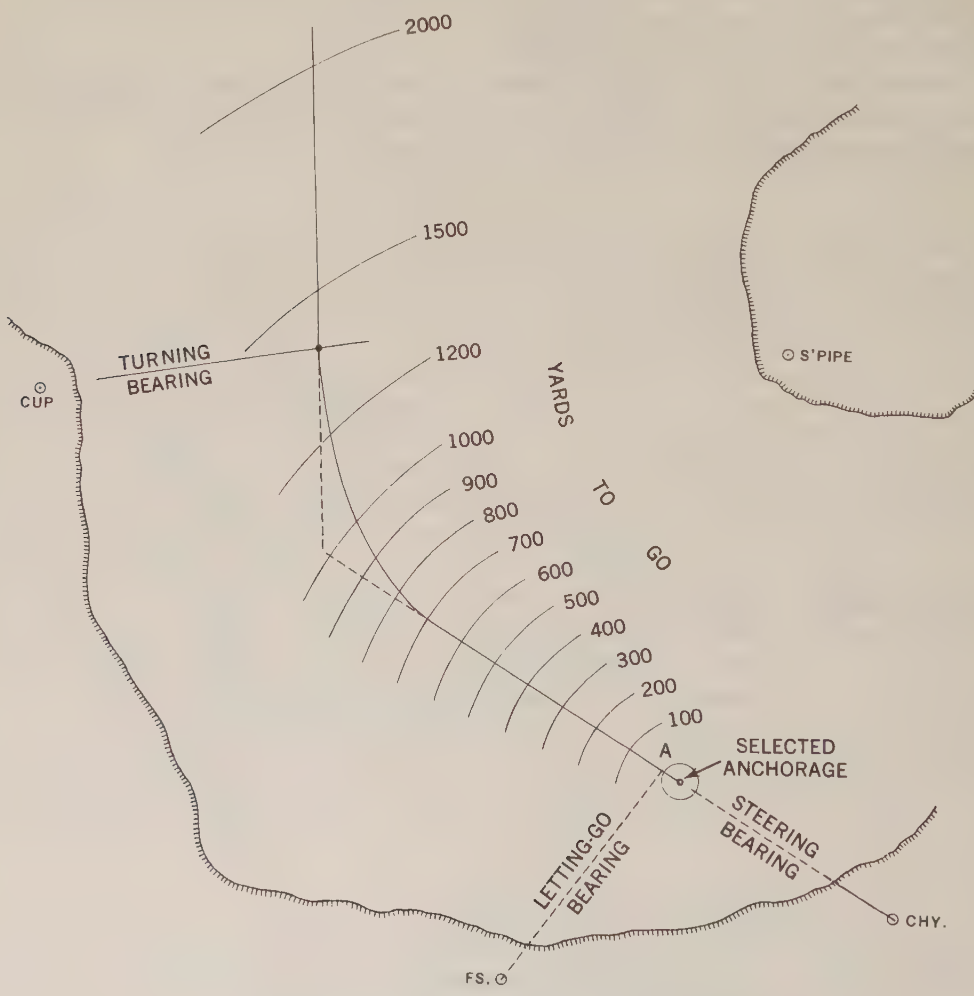

Figure 931.—Anchoring.

The position selected for anchoring is located on the chart. The direction of approach is then determined, considering limitations of land, shoals, other vessels, etc. Where conditions permit, the approach should be made heading into the current or, if the wind has a greater effect upon the vessel, into the wind. It is desirable to approach from such direction that a prominent object, or preferably a range, is available dead ahead to serve as a steering guide. It is also desirable to have a range or prominent object near the beam at the point of letting go the anchor. If practicable a straight approach of at least 500 yards should be provided to permit the vessel to steady on the required course. The track is then drawn in, allowing for advance and transfer during any turns.

Next, a circle is drawn with the selected position of the anchor as the center, and with a radius equal to the distance between the hawsepipe and pelorus, alidade, etc., used for measuring bearings. The intersection of this circle and the approach track, point *A*, is the position of the vessel (bearing-measuring instrument) at the moment of letting go. A number of arcs of circles are then drawn and labeled as shown in figure 931. The desired position of the anchor is the common center of these arcs. The selected radii may be chosen at will. Those shown in figure 931 have been found to be generally suitable. In each case the distance indicated is from the small circle. Turning bearings may also be indicated.

During the approach to the anchorage, fixes are plotted at frequent intervals, the measurement and plotting of bearings going on continuously, usually to the nearest half or quarter degree. The navigator advises the captain of any tendency of the vessel to drift from the desired track, so that adjustments can be made. The navigator also keeps the captain informed of the distance to go, to permit adjustment of the speed so that the vessel will be nearly dead in the water when the anchor is let go.

At the moment of letting go, the position of the vessel should be determined as accurately as possible, preferably by two simultaneous horizontal sextant angles, or by simultaneous or nearly simultaneous bearings of a number of prominent landmarks.

A number of variations may suggest themselves. One occasionally mentioned is as follows: An inverted compass rose (0° at south) is placed around each landmark used. A thumb tack with an attached thread is inserted at the symbol of two landmarks. One observer continually notes the bearing of each object. Alternately they call out the bearings. The navigator takes one thread in each hand and maintains a slight strain. As each bearing is called out, he adjusts the appropriate thread by means of the reverse compass rose. The point of intersection of the two threads is the position of the vessel. By this means the ship can be "walked in" to the anchorage. This method is particularly to be recommended when one landmark is on each bow.

The exact procedure to use depends upon local conditions, number and training of available personnel, equipment, and personal preference of individuals concerned. Whatever the procedure, it should be carefully planned, and any needed advance preparations should be made early enough to avoid haste and the attendant danger of making a mistake. Teamwork is important. Each person involved should understand precisely what is expected of him.

932. Piloting and electronics.—Many of the familiar electronic aids to navigation are used primarily in piloting. The radio direction finder provides bearings through fog and at greater distance from the aids. Distance finding stations provide distances which might not otherwise be available. The sonic depth finder provides frequent or continuous soundings. Radar provides bearings, distances, and information on the location and identity of various targets. Some of the longer range systems such as loran, consol, and Decca extend piloting techniques far to sea, where nearness of shoals and similar dangers is not a problem. Electronic aids, whether applicable primarily to piloting or to other forms of navigation, are discussed in part three (chs. X–XIII).

933. Practical piloting.—In pilot waters, navigation is primarily an art. It is essential that the principles explained in this chapter be mastered and applied intelligently. From every experience the wise navigator acquires additional knowledge and improves his judgment. The mechanical following of a set procedure should not be expected to produce satisfactory results always.

While piloting, the successful navigator is somewhat of an opportunist, fitting his technique to the situation at hand. If a vessel is steaming in a large area having relatively weak currents and moderate traffic, like Chesapeake Bay, fixes may be obtained at relatively long intervals, with a dead reckoning plot between. In a narrow channel with swift currents and heavy traffic, like the East River between Manhattan and Long Island, New York City, an almost continuous fix is needed. In such an area the navigator may draw the desired track on the chart and obtain fixes every few minutes, or even seconds, directing the vessel back on the track as it begins to drift to one side.

If the navigator is to traverse unfamiliar waters, he studies the chart, sailing directions or coast pilot, tide and tidal current tables, and light lists to familiarize himself with local conditions. The experienced navigator learns to interpret the signs around him. The ripple of water around buoys and other obstructions, the direction and angle of tilt of buoys, the direction at which vessels ride at anchor, provide meaningful information regarding currents. The wise navigator learns to interpret such signs when the position of his vessel is not in doubt. When visibility is poor, or available information is inconsistent, the ability developed at favorable times can be of great value.

With experience, a navigator learns when a danger angle or danger bearing is useful, and what ranges are reliable and how they should be used. However familiar one is with an area, he should not permit himself to become careless in the matter of timing lights for identification, plotting his progress on a chart, or keeping a good recent position. Fog sometimes creeps in unnoticed, obscuring landmarks before one realizes its presence. A series of frequent fixes obtained while various aids are visible provides valuable information on position and current.

Practical piloting requires a thorough familiarity with principles involved and local conditions, constant alertness, and judgment. A study of avoidable groundings reveals that in most cases the problem is not lack of knowledge, but failure to use or interpret available information. Among the more common errors are:

1. Failure to obtain or evaluate soundings.
2. Failure to identify aids to navigation.
3. Failure to use all available navigational aids.
4. Failure to correct charts.
5. Failure to adjust a magnetic compass or maintain an accurate table of corrections.
6. Failure to apply deviation, or error in its application.
7. Failure to apply variation, or to allow for change in variation.
8. Failure to check gyro and magnetic compass readings at frequent and regular intervals.
9. Failure to keep a dead reckoning plot.
10. Failure to plot information received.
11. Failure to properly evaluate information received.
12. Poor judgment.
13. Failure to do own navigating (following another vessel).
14. Failure to obtain and use information available on charts and in various publications.

15. Poor ship organization.
16. Failure to "keep ahead of the vessel."

Further discussion on practical piloting is given in chapter XXIII.

Problems

904. The navigator of a vessel on gyro course 214° obtains a relative bearing on a lighthouse of 86° left. The gyro error is 1° W, deviation of the standard compass is 3° W, and variation is 13° E.

Required.—The (1) gyro, (2) true, (3) standard-compass, and (4) magnetic bearings of the lighthouse.

Answers.—(1) Bpgc 128°, (2) TB 127°, (3) CB 117°, (4) MB 114°.

Problems 906a–909g, 911a–911c, and 916b are based upon the following fictitious aids to navigation, which can be plotted on a large-scale plotting sheet (art. 324) or a clear part of a coast chart for the appropriate latitude. The latitude range of these problems is from 40°20′ N to 40°40′ N. Approach charts to New York include this range. The longitude range is from 164°20′ W to 164°40′ W. In these problems the gyro compass is the reference for all courses and bearings, and it is considered to be without error.

	Latitude	*Longitude*
Jones Point Light	40°20′.6 N	164°20′.5 W
Parker Point Light	40°23′.7 N	164°21′.2 W
Point Carlson Light	40°22′.0 N	164°28′.3 W
North Baker Range Light	40°33′.9 N	164°38′.2 W
South Baker Range Light	40°31′.5 N	164°34′.7 W
Hanford Mid-channel Buoy	40°22′.9 N	164°34′.1 W
Water tower	40°36′.2 N	164°27′.9 W
West Bank Lightship	40°39′.5 N	164°20′.3 W
Cupola	40°25′.4 N	164°21′.3 W

906a. A navigator of a vessel on course 075° observes Jones Point Light to bear 56° right at the same time an assistant observes Parker Point Light to bear 46° left.

Required.—The fix at the time of the bearings.

Answer.—Fix: L 40°21′.9 N, λ 164°22′.5 W.

906b. A vessel under way in fog obtains simultaneous radar ranges (distances) on Point Carlson Light bearing southerly (3.0 miles) and Parker Point Light (5.5 miles).

Required.—The fix at the time of the distance measurements.

Answer.—Fix: L 40°25′.0 N, λ 164°28′.2 W.

906c. A vessel under way with the Baker Range dead ahead observes Point Carlson Light broad on the port beam.

Required.—The fix at the time Point Carlson Light is abeam.

Answer.—Fix: L 40°24′.9 N, λ 164°25′.0 W.

906d. The navigator of a vessel on course 110° measures the vertical sextant angle between the top of Point Carlson Light and the horizon at the same time the light bears dead ahead. The top of the light is 230 feet above the water and the sextant angle is 0°18′.3. The height of eye of the observer is 30 feet. There is no IC.

Required.—The fix at the time the angle is measured.

Answer.—Fix: L 40°24′.4 N, λ 164°37′.0 W.

906e. A vessel is under way with the Baker Range dead ahead. The South Baker Range Light is 5.0 miles off by radar.

Required.—The fix at the time of measurement.

Answer.—Fix: L 40°28′.2 N, λ 164°29′.8 W.

906f. A southbound vessel passes Hanford Mid-channel Buoy close aboard at 0327.

Required.—The fix at this time.

Answer.—Fix: L 40°22′.9 N, λ 164°34′.1 W.

907a. Using horizontal sextant angles, a navigator measures the angle between South Baker Range Light and Point Carlson Light to be 54°14′. At the same time an assistant measures the angle between Parker Point Light and Point Carlson Light to be 25°04′.

Required.—The fix at the time of observation.

Answer.—Indeterminable because the three lights and the vessel are all located on the circumference of the same circle.

907b. Using horizontal sextant angles, a navigator measures the angle between South Baker Range Light and Point Carlson Light to be 85°45′. At the same time an assistant measures the angle between Parker Point Light and Point Carlson Light to be 35°10′.

Required.—The fix at the time of observation.

Answer.—Fix: L 40°31′.6 N, λ 164°27′.6 W.

908. About 0229 the navigator of a vessel observes the following bearings:

Jones Point Light	150°
Point Carlson Light	263°
Parker Point Light	020°
Point Carlson Light	266°
Jones Point Light	154°

The time intervals between bearings are approximately equal. The bearing on Parker Point Light is obtained at 0229.

Required.—(1) The bearings to plot for an 0229 fix.

(2) The 0229 fix.

Answers.—(1) Jones Point Light, B 152°; Point Carlson Light, B 264½°; Parker Point Light, B 020°. (2) 0229 fix: L 40°22′.5 N, λ 164°21′.8 W.

909a. A vessel is underway on course 071°, speed 15.0 knots. At 1150 the water tower bears 051°. At 1200 the tower bears 009°.

Required.—The 1200 running fix.

Answer.—1200 R fix: L 40°34′.9 N, λ 164°28′.2 W.

909b. At 1205 the vessel of problem 909a changes course to 047°, and at 1210 the water tower bears 270°.

Required.—The 1210 running fix, by advancing the 1200 bearing line and crossing it with the 1210 bearing line.

Answer.—1210 R fix: L 40°36′.2 N, λ 164°25′.4 W.

909c. Under way in fog, a vessel on course 188°, speed 5.0 knots, passes west of the West Bank Lightship and at 0613 it is 1.2 miles off by distance finding signals. At 0622 the distance is 1.8 miles.

Required.—The 0622 running fix.

Answer.—0622 R fix: L 40°38′.1 N, λ 164°21′.8 W.

909d. The navigator of a vessel on course 052°, speed 13.5 knots, observes Point Carlson Light bearing 079° at 2117.

Required.—The distance off when abeam if Point Carlson Light is abeam at (1) 2126, (2) 2129, (3) 2132.

Answers.—(1) D 1.1 mi., (2) D 1.4 mi., (3) D 1.7 mi.

909e. The navigator of a vessel on course 000° observes South Baker Range Light bearing 324° at 0551 and 270° at 0600.

Required.—The distance off when abeam if the vessel is making good (1) 15.0 kn., (2) 16.0 kn., (3) 17.0 kn.

Answers.—(1) D 1.6 mi., (2) D 1.8 mi., (3) D 1.9 mi.

909f. The navigator of a vessel obtains bearings on West Bank Lightship, as follows: 033° at 1423, 021° at 1435, 010° at 1443.

Required.—The course being made good over the ground.

Answer.—COG 073°.

909g. A vessel on course 214°, speed 14.0 knots, fixes its position at latitude 40°33!0 N, longitude 164°21!5 W at 1200. At 1254 a second fix places the vessel at latitude 40°22!0 N, longitude 164°32!5 W.

Required.—The set and drift of the current during the run.

Answers.—Set 249°, drift 1.6 kn.

910a. The navigator of a vessel steaming at 17 knots observes the following pairs of relative bearings on different landmarks and seamarks as indicated:

	Time	*Object*	*Relative bearing*		*Time*	*Object*	*Relative bearing*
(1)	1237	*A*	318°	(3)	1325	*C*	335°
	1258	*A*	292°		1350	*C*	303°
(2)	1306	*B*	040°	(4)	1401	*D*	281°
	1321	*B*	059°		1452	*D*	257°

Required.—In each case, the distance off at the time of the second bearing, and the distance when abeam, using table 7.

Answers.—

	Object	*Dist. at 2nd bearing*	*Dist. abeam*
(1)	*A*	9. 2	8. 5
(2)	*B*	8. 3	7. 1
(3)	*C*	5. 7	4. 8
(4)	*D*	34. 8	34. 0

910b. A vessel is steaming on course 193° at 20 knots. The following true bearings are observed on the objects indicated:

	Time	*Object*	*True Bearing*		*Time*	*Object*	*True Bearing*
(1)	0800	*A*	229°	(4)	0912	*D*	215°5
	0836	*A*	265°		0927	*D*	238°
(2)	0840	*B*	238°	(5)	0929	*E*	223°
	0855	*B*	283°		0954	*E*	253°
(3)	0855	*C*	256°5	(6)	0959	*F*	233°
	0906	*C*	283°		1031	*F*	272°

Required.—Without plotting, and without the use of table 7, determine the distances off *A*, *B*, *D*, and *E* at the time of the second bearing, and the distances off *B*, *C*, *D*, *E*, and *F* when abeam.

Answers.—

	Object	*Dist. at 2nd bearing*	*Dist. abeam*
(1)	*A*	12. 0	—
(2)	*B*	5. 0	5. 0
(3)	*C*	—	7. 3
(4)	*D*	5. 0	3. 5
(5)	*E*	8. 3	7. 3
(6)	*F*	—	10. 7

911a. Two shoals to the south of South Baker Range Light are marked by buoys. The positions of the buoys are reported to be unreliable because of the recent passage of a storm. At the narrowest point in the channel the position of the danger sounding on each side is lat. 40°25′.5 N, long. 164°37′.2 W; and lat. 40°25′.7 N, long. 164°35′.6 W.

Required.—The maximum and minimum danger bearings on South Baker Range Light to clear the shoals.

Answers.—B 018° and B 007°.

911b. A vessel is to pass along the coast north of Parker Point and inside a submerged rock a short distance offshore. In this area the five-fathom curve (the danger sounding) is farthest offshore at lat. 40°24′.5 N, long. 164°22′.3 W. The closest safe approach to the rock is at lat. 40°24′.4 N, long. 164°22′.9 W.

Required.—The maximum and minimum horizontal sextant angles between Parker Point Light and the prominent cupola to the north of it which will permit safe passage between the five-fathom curve and the rock.

Answers.—Danger angles: 92° and 68°.

911c. A vessel steaming at 13.0 knots has West Bank Lightship abeam at 0311, and immediately begins a course change to keep the lightship broad on the beam. At 0316 the change in heading is noted.

Required.—(1) Distance off if the heading change is 19°.

(2) Distance off if the heading change is 16°.

Answers.—(1) D 3.2 mi., (2) D 3.9 mi.

916a. A lookout at a height of eye of 55 feet observes a flashing light on the horizon. The light is timed and identified as a navigational light 117 feet above sea level.

Required.—The distance of the vessel from the light when it is first observed.

Answer.—D 20.9 mi.

916b. The light of Hanford Mid-channel Buoy is located 11 feet above sea level and has a charted range of 6 miles. At 0207 a vessel on course 221°, speed 15 knots, passes West Bank Lightship abeam, 0.9 mile to starboard. The height of eye on the bridge is 48 feet.

Required.—(1) The distance at which the navigator, on the bridge, can expect to see the buoy light in clear weather with good visibility.

(2) The time and bearing at which the light should be sighted.

Answers.—(1) D 6.0 mi., (2) T 0302, B 202°.

916c. A navigational light 120 feet above sea level has a charted range of 17 miles.

Required.—The distance at which an observer at a height of eye of 60 feet can expect to see the light.

Answer.—D 17 to 21.4 mi., depending upon the luminous range of the light.

920. The mean high water lunitidal interval at a certain port is 2^h17^m.

Required.—The approximate times of each high and low water on a day when the moon transits the local meridian at 1146.

Answers.—HW at 0139 and 1403, LW at 0751 and 2015.

922. List chronologically the times and heights of all tides at New York (The Battery) on February 11, 1958.

Answer.—

Time	*Tide*	*Height*
0157	HW	4.5 ft.
0831	LW	(−) 0.1 ft.
1423	HW	3.8 ft.
2049	LW	(−) 0.1 ft.

923. List chronologically the times and heights of all tides at Castle Point, Hoboken, N. J. (No. 1569) on March 18, 1958.

Answer.—

Time	*Tide*	*Height*
0113	LW	(−) 0.3 ft.
0723	HW	4.4 ft.
1336	LW	(−) 0.4 ft.
1945	HW	4.3 ft.

924a. Find the height of tide at Union Stock Yards, New York (No. 1573) at 0600 on February 6, 1958.

Answer.—Ht. of tide at 0600, 0.3 ft.

924b. The captain of a vessel drawing 24 feet wishes to pass over a temporary obstruction near Bayonne, N. J. (No. 1555) having a charted depth of 22 feet, passage to be made during the evening of March 5, 1958.

Required.—The earliest and latest times that the passage can be made, allowing a safety margin of two feet.

Answers.—Earliest time 1806, latest time 2148.

926. Determine the sequence of currents at The Narrows on January 8, 1958.

Answer.—

0000 Ebb current, 56^m after slack.
0222 Maximum ebb of 2.3 knots.
0543 Slack, flood begins.
0821 Maximum flood of 2.2 knots.
1135 Slack, ebb begins.
1454 Maximum ebb of 2.5 knots.
1828 Slack, flood begins.
2051 Maximum flood of 1.9 knots.
2357 Slack, ebb begins.
2400 Ebb current, 3^m after slack.

927. Determine the sequence of currents at Highlands Bridge, Shrewsbury River (No. 1083) on January 5, 1958.

Answer.—

0000 Ebb current, 22^m before maximum velocity (speed).
0022 Maximum ebb of 2.7 knots.
0351 Slack, flood begins.
0628 Maximum flood of 3.3 knots, setting 170°.
0940 Slack, ebb begins.
1302 Maximum ebb of 3.0 knots.
1644 Slack, flood begins.
1855 Maximum flood of 2.6 knots, setting 170°.
2150 Slack, ebb begins.
2400 Ebb current, 1^h11^m before maximum velocity (speed).

928a. Find the speed of the current at Bear Mountain Bridge (No. 1029) at 0900 on February 19, 1958.

Answer.—Speed 0.5 kn.

928b. At about what time during the morning of February 3, 1958, does the flood current northwest of The Battery (No. 1001) reach a speed of 1.0 knot?

Answer.—T 0525.

929. A vessel arrives at Ambrose Channel Entrance two hours after flood begins at The Narrows on the morning of February 16, 1958.

Required.—(1) The speed through the water required to take fullest advantage of the flood tide in steaming to Chelsea Docks.

(2) The average current to be expected.

(3) Estimated time of arrival off Chelsea Docks.

Answers.—(1) S 9 kn., (2) S 1.4 kn., (3) ETA 0608.

930. A vessel on course 337° begins a 90° turn at half right rudder when a buoy is close aboard. When the heading is 067°, the buoy bears 192°, distant 1225 yards by radar.

Required.—Advance and transfer.

Answers.—Advance 1,000 yards, transfer 712 yards.

931. In the solution of this problem, a plotting sheet covering the area between latitudes 40°29′35″ N and 40°30′25″ N, and longitudes 164°19′35″ W and 164°20′50″ W will be needed. The plotting sheet or chart used for other problems of this chapter will be suitable if the scale is adjusted so that one graduation equals 50 feet (two graduations equal one second of arc).

A vessel in convoy receives orders to anchor in lat. 40°29′50″ N, long. 164°20′25″ W. After studying the chart, the navigator and captain select two landmarks to use as reference points in making the approach. Landmark *A* is located at lat. 40°29′40″ N, long. 164°20′50″ W; landmark *B* at lat. 40°30′20″ N, long. 164°20′30″ W. It is decided that the approach will be made with landmark *A* dead ahead. The gyro repeater to be used in taking bearings is located 200 feet abaft the hawsepipes.

Required.—(1) The course during approach. The bearings of landmark *B* when there are (2) 1,000 yards, (3) 600 yards, (4) 400 yards, (5) 200 yards, (6) 100 yards, (7) 0 yards (the let-go point) to go, assuming the vessel keeps landmark *A* dead ahead.

Answers.—(1) C 242°.5, (2) B 295°.5, (3) B 314°.0, (4) B 325°.5, (5) B 337°.5, (6) B 343°.5, (7) B 349°.5.

CHAPTER X

RADIO WAVES

1001. Source of radio waves.—All matter is made up of tiny particles called **atoms.** Each atom has a central **nucleus** composed principally of subatomic particles called **protons** and **neutrons.** One or more **electrons** revolve around the nucleus in orbits resembling those of planets around the sun (art. 1407). The number and arrangement of the particles constituting an atom of each element of matter determine the properties of that element. Electrons, each having a mass of only about 1/1,840 that of a proton or neutron, are kept in their orbits principally by means of an attractive electrical force, each electron carrying one negative "charge" and each proton one positive "charge." Like charges repel and unlike charges attract. This electrical attraction is additional to the gravitational attraction existing between all particles in the universe. The neutron is electrically neutral.

Under suitable conditions, some electrons become detached from their atoms. An excess or deficiency of electrons in a nonconductor is called **static electricity.** A substance which provides a path for electron movement with relatively little resistance is called a **conductor.** A *flow* of electrons along such a conductor constitutes an **electric current,** although the current direction is conventionally considered to be opposite to the direction of flow of the electrons. A **direct current** flows continuously in the same direction. If the strength of the current varies rhythmically but does not change direction, the current is said to be **pulsating.** If the direction of flow periodically reverses, an **alternating current** results.

In addition to its electrical and gravitational forces, a moving electron is accompanied by a **magnetic force.** As long as the flow is steady, the magnetic force is constant. If a conductor is in the region of influence or **field** of magnetism, there is no noticeable effect unless the strength of the field is changing, or relative motion exists between the conductor and the field, when an **induced current** flows in the conductor. The extent to which a substance has electrons free to move under suitable influence determines its value as a conductor. One which offers great resistance to such flow is called an **insulator.**

In a suitable electrical system, an electric charge creates a magnetic field which builds up to a maximum. If the electric current is then discontinued, the magnetic field collapses. This change in the strength of the magnetic field induces an electric current in the conductor, but in the opposite direction to the original current. This current creates a new magnetic field, and the cycle repeats. Thus, an alternating current is produced, the strength increasing to a maximum in one direction, decreasing to zero, increasing to a maximum in the opposite direction, and again decreasing to zero to start a new cycle. This cycle is repeated many times each second, the number depending upon the characteristics of the system. Such a system is called an **oscillating circuit.**

A relatively small amount of energy is dissipated as heat in overcoming the resistance of the circuit. The remainder continues to oscillate between electric and magnetic fields. The build-up and collapse of each field occurs at about the speed of light, which is approximately 186,000 statute miles (300,000,000 meters) per second. If a relatively long period of time is available for the cycle to occur, the energy is fully transferred before the next step occurs. However, if the cycle is speeded until the time needed

for each field to build up or collapse is more than about one-half cycle, some of the energy becomes detached and is radiated into space, through which it travels at about the speed of light. This **electromagnetic radiation,** having both electrical and magnetic properties, is known as **radio waves,** if of a frequency suitable for radio communication.

1002. Radio wave terminology.—The build-up and collapse of the electric and magnetic fields are proportional to the *sine* of the portion of the cycle completed, as shown in figure 1002. This representation has led to the use of the term "wave" when referring to electromagnetic propagation. The highest point on the curve (in the direction considered positive) is the **crest,** and the lowest point the **trough.** Either point may be called the **peak,** considered positive or negative if a distinction is desired. The displacement of a peak from zero is called the **amplitude.** The forward side of any wave is called the **wave front.** For a nondirectional antenna each wave proceeds outward as an expanding sphere (or hemisphere).

One **cycle** is a complete sequence of values, as from crest to crest. The distance traveled by the energy during one cycle is the **wave length,** usually expressed in metric units (meters, centimeters, etc.). The number of cycles repeated during unit time (usually one second) is the **frequency.** This is given in **cycles per second (cps), kilocycles per second (kc), megacycles per second (mc),** or occasionally **kilomegacycles per second (kmc).** A kilocycle is 1,000 cycles, a megacycle is 1,000,000 cycles, and a kilomegacycle is 1,000,000,000 cycles. Wave length and frequency are inversely proportional. The approximate value of either may be found by dividing 300,000,000 by the other quantity, if wave length is expressed in meters and frequency in cycles per second. Thus, if the frequency is 1,500 kilocycles per second (1,500,000 cps), the wave length is $\frac{300,000,000}{1,500,000}=200$ meters. If the wave length is ten centimeters (0.1 meter), the frequency is about $\frac{300,000,000}{0.1}=3,000,000,000$ cycles per second or three kilomegacycles (usually expressed as 3,000 megacycles). A more precise value for the speed of propagation in air is 299,708,000 meters per second. This is equivalent to 186,230 statute miles, or 161,829 nautical miles, per second. The exact value varies slightly with density of the medium through which the wave travels, and frequency. The speed in a vacuum is a little more than that in air.

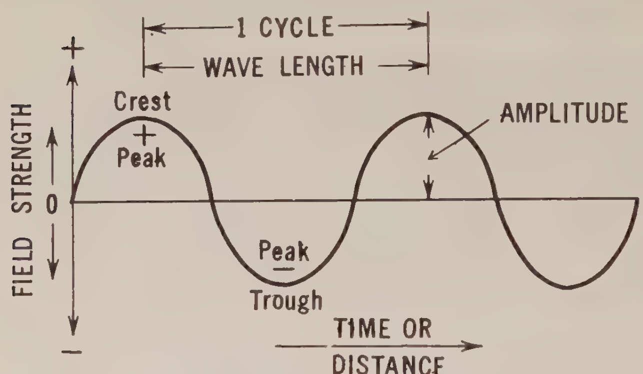

FIGURE 1002.—Radio wave terminology.

The **phase** of a wave is the amount by which the cycle has progressed from a specified origin. For most purposes it is stated in circular measure, a complete cycle being considered 360°. Generally, the origin is not important, principal interest being the phase relative to that of some other wave. Thus, two waves having crests one-fourth cycle apart are said to be 90° "out of phase." If the crest of one wave occurs at the trough of another, the two are 180° out of phase.

1003. Electromagnetic spectrum.—The entire range of electromagnetic radiation frequencies is called the **electromagnetic spectrum.** The range of frequencies suitable for radio transmission, called the **radio spectrum,** extends from ten kilocycles per second

to 300,000 megacycles per second, approximately. For convenience, it is divided into a number of **bands,** as shown in table 1003. Below the radio spectrum, but overlapping it, is the **audio frequency** band, extending from 20 to 20,000 cycles per second, approximately. This is the range of frequencies that can be heard by the human ear. Above the radio spectrum are heat and infrared, the visible spectrum (light in its various colors), ultraviolet, X-rays, gamma rays, and cosmic rays. These are included in table 1003. Waves shorter than one meter are sometimes called **microwaves.**

Band	Abbreviation	Range of frequency	Range of wave length
Audio frequency	AF	20 to 20,000 cps	15,000,000 to 15,000 m
Radio frequency	RF	10 kc to 300,000 mc	30,000 m to 0.1 cm
Very low frequency	VLF	10 to 30 kc	30,000 to 10,000 m
Low frequency	LF	30 to 300 kc	10,000 to 1,000 m
Medium frequency	MF	300 to 3,000 kc	1,000 to 100 m
High frequency	HF	3 to 30 mc	100 to 10 m
Very high frequency	VHF	30 to 300 mc	10 to 1 m
Ultra high frequency	UHF	300 to 3,000 mc	100 to 10 cm
Super high frequency	SHF	3,000 to 30,000 mc	10 to 1 cm
Extremely high frequency	EHF	30,000 to 300,000 mc	1 to 0.1 cm
Heat and infrared *		10^6 to 3.9×10^8 mc	0.03 to 7.6×10^{-5} cm
Visible spectrum *		3.9×10^8 to 7.9×10^8 mc	7.6×10^{-5} to 3.8×10^{-5} cm
Ultraviolet *		7.9×10^8 to 2.3×10^{10} mc	3.8×10^{-5} to 1.3×10^{-6} cm
X-rays *		2.0×10^9 to 3.0×10^{13} mc	1.5×10^{-5} to 1.0×10^{-9} cm
Gamma rays *		2.3×10^{12} to 3.0×10^{14} mc	1.3×10^{-8} to 1.0×10^{-10} cm
Cosmic rays *		$>4.8\times10^{15}$ mc	$<6.2\times10^{-12}$ cm

* Values approximate.

Table 1003.—Electromagnetic spectrum.

1004. Polarization.—As indicated in article 1001, radio waves have both electrical and magnetic properties. The two fields are conceived as having direction associated with the orientation of the vibrations. The direction of the electric component of the field is called the **polarization** of the electromagnetic field. Thus, if the electric component is vertical, the wave is said to be "vertically polarized," and if horizontal, "horizontally polarized." A wave traveling through space may be polarized in any direction. One traveling along the surface of the earth is always vertically polarized because the earth, a conductor, short-circuits any horizontal component. The magnetic field and the electrical field are always mutually perpendicular.

1005. Reflection.—When radio waves strike a surface, they are reflected in the same manner as light waves, if conditions are favorable. Radio waves of all frequencies are reflected by the surface of the earth. The strength of the **reflected wave** depends upon **grazing angle** (the angle between the incident ray and the horizontal), type of polarization, frequency, reflecting properties of the surface, and divergence of the reflected ray. Lower frequency results in greater penetration. At very low frequencies usable radio signals can be received some distance below the surface of the sea.

A change of phase takes place when a wave is reflected from the surface of the earth. The amount of the change varies with the conductivity of the earth and the polarization of the wave, reaching a maximum of 180° for a horizontally polarized wave reflected from sea water (considered to have infinite conductivity). When **direct waves** (those traveling from transmitter to receiver in a relatively straight line, without reflection) and reflected waves arrive at a receiver, the total signal is the vector sum of the two. If the signals are in phase, they reinforce each other, producing a stronger signal. If there is a phase difference, the signals tend to cancel each other, the cancellation being complete if the phase difference is 180° and the two signals have the same amplitude. This interaction of waves is called **wave interference.** A

phase difference may occur because of the change of phase of a reflected wave, or because of the longer path followed by it. The second effect decreases with greater distance between transmitter and receiver, for under these conditions the difference in path lengths is smaller. At lower frequencies there is no practical solution to interference caused in this way. For VHF and higher frequencies the condition can be improved by elevating the antenna, if the wave is vertically polarized. Also, interference at higher frequencies can be more nearly eliminated because of the greater ease of beaming the signal to avoid reflection.

Reflections may also occur from mountains, trees, and other obstacles. Such reflection is negligible for lower frequencies, but becomes more prevalent as frequency increases. In radio communication it can be reduced by using directional antennas, but this solution is not always available for navigational systems.

Various reflecting surfaces occur in the atmosphere. At high frequencies, reflections take place from rain. At still higher frequencies, reflections are possible from clouds, particularly rain clouds. Reflections may even occur at a sharply defined boundary surface between air masses, as when warm, moist air flows over cold, dry air. When such a surface is roughly parallel to the surface of the earth, radio waves may travel for greater distances than normal. A somewhat similar condition is described in article 1006. The principal source of reflection in the atmosphere is the ionosphere (arts. 1007, 1008).

1006. Refraction of radio waves is similar to that of light waves (art. 1613). Thus, as a signal passes from air of one density to that of a different density, the direction of travel is altered. The principal cause of refraction in the atmosphere is the difference in temperature and pressure occurring at various heights and in different air masses.

Refraction occurs at all frequencies, but at those below 30 mc the effect is small as compared with ionospheric effects (art. 1008), diffraction (art. 1009), and absorption (art. 1010). At higher frequencies, refraction in the lower layer of the atmosphere extends the **radio horizon** to a distance about 15 percent greater than the visible horizon. The effect is the same as if the radius of the earth were about one-third greater than it is, and there were no refraction.

Sometimes the lower portion of the atmosphere becomes stratified with horizontal layers of air having certain characteristics, resulting in nonstandard temperature and moisture changes with height. If there is a marked temperature inversion (art. 3815) or a sharp decrease in water vapor content with increased height, a horizontal radio **duct** may be formed. High frequency radio waves traveling horizontally within the duct are refracted to such an extent that they remain within the duct, following the curvature of the earth for phenomenal distances. This is called **super-refraction.** Maximum results are obtained when both transmitting and receiving antennas are within the duct. There is a lower limit to the frequency affected by ducts. It varies from about 200 mc to more than 1,000 mc.

At night, surface ducts may occur over land due to cooling of the surface. At sea, surface ducts about 50 feet thick may occur at any time in the trade wind belt. Surface ducts 100 feet or more in thickness may extend from land out to sea when warm air from the land flows over the cooler ocean surface. Elevated ducts from a few feet to more than 1,000 feet in thickness may occur at elevations of 1,000 to 5,000 feet, due to the settling of a large air mass. This is a frequent occurrence in Southern California and certain areas of the Pacific Ocean.

Refraction effects associated with the ionosphere are discussed in article 1008.

A bending in the horizontal plane occurs when a ground wave (art. 1008) crosses a coast at an oblique angle. This is due to a marked difference in the conducting and

reflecting properties of the land and water over which the wave travels. The effect is known as **coastal refraction** or **land effect.**

1007. The ionosphere.—Since an atom normally has an equal number of negatively charged electrons and positively charged protons, it is electrically neutral. An **ion** is an atom or group of atoms which has become electrically charged, either positively or negatively, by the loss or gain of one or more electrons.

Loss of electrons may occur in a variety of ways. In the atmosphere, ions are usually formed by collision of atoms with rapidly moving particles, or by the action of cosmic rays or ultraviolet light. In the lower portion of the atmosphere, recombination soon occurs, leaving a small percentage of ions. In thin atmosphere far above the surface of the earth, however, atoms are widely separated and a large number of ions may be present. The region of numerous positive and negative ions and unattached electrons is called the **ionosphere.** The extent of ionization depends upon the kinds of atoms present in the atmosphere, the density of the atmosphere, and the position relative to the sun (time of day and season). After sunset, ions and electrons recombine faster than they are separated, decreasing the ionization of the atmosphere.

An electron can be separated from its atom only by the application of greater energy than that holding the electron. Since the energy of the electron depends primarily upon the kind of an atom of which it is a part, and its position relative to the nucleus of that atom, different kinds of radiation may cause ionization of different substances.

In the outermost regions of the atmosphere the density is so low that oxygen exists largely as separate atoms, rather than combining as molecules as it does nearer the surface of the earth. At great heights the energy level is low and ionization from solar radiation is intense. This is known as the **F layer.** Above this level the ionization decreases because of the lack of atoms to be ionized. Below this level it decreases because the ionizing agent of appropriate energy has already been absorbed. During daylight, two levels of maximum F ionization can be detected, the F_2 layer at about 125 statute miles above the surface of the earth, and the F_1 layer at about 90 statute miles. At night, these combine to form a single F layer.

At a height of about 60 statute miles the solar radiation not absorbed by the F layer encounters, for the first time, large numbers of oxygen *molecules.* A new maximum ionization occurs, known as the **E layer.** The height of this layer is quite constant, in contrast with the fluctuating F layer. At night the E layer becomes weaker, sometimes completely disappearing.

Below the E layer a weak **D layer** forms at a height of about 45 statute miles, where the incoming radiation encounters ozone (O_3) for the first time. The D layer is the principal source of absorption of HF waves, and of reflection of LF and VLF waves during daylight.

1008. The ionosphere and radio waves.—When a radio wave encounters a particle having an electric charge, it causes that particle to vibrate. The vibrating particle absorbs electromagnetic energy from the radio wave and reradiates it. The net effect is a change of polarization and an alteration of the path of the wave. That portion of the wave in a more highly ionized region travels faster, causing the wave front to tilt and the wave to be directed toward a region of less intense ionization.

Refer to figure 1008a, in which a single layer of the ionosphere is considered. Ray 1 enters the ionosphere at such an angle that its path is altered, but it passes on through and proceeds outward into space. As the angle with the horizontal decreases, a critical value is reached where the ray (2) is bent or reflected back toward the earth. As the angle is still further decreased, as at 3, the return to earth occurs at a greater distance from the transmitter.

A wave reaching a receiver by way of the ionosphere is called a **sky wave.** This expression is also appropriately applied to a wave reflected from an air mass boundary. In common usage, however, it is generally associated with the ionosphere. The wave which travels along the surface of the earth is called a **ground wave.** At angles greater than the critical angle, no sky-wave signal is received. Therefore, there is a minimum distance from the transmitter at which sky waves can be received. This is called the **skip distance,** shown in figure 1008a. If the ground wave extends out for less distance than the skip distance, a **skip zone** occurs, in which no signal is received.

The critical radiation angle depends upon the intensity of ionization, and the frequency of the radio wave. As the frequency increases, the angle becomes smaller. At frequencies greater than about 30 mc virtually all of the energy penetrates through or is absorbed by the ionosphere. Therefore, at any given receiver there is a maximum usable frequency if sky waves are to be utilized. The strongest signals are received at or slightly below this frequency. There is also a lower practical frequency beyond which signals are too weak to be of value. Within this band the optimum frequency

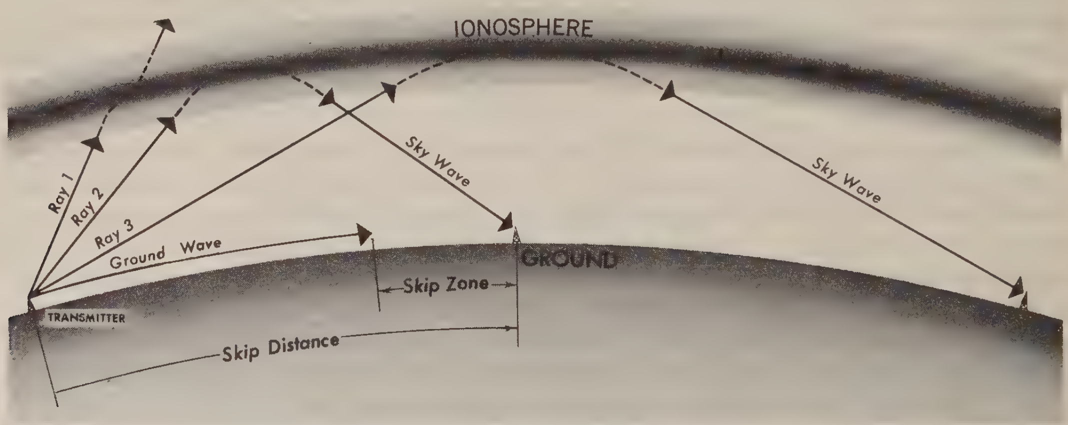

FIGURE 1008a.—The effect of the ionosphere on radio waves.

can be selected to give best results. It cannot be too near the maximum usable frequency because this frequency fluctuates with changes of intensity within the ionosphere. During magnetic storms the ionospheric density decreases. The maximum usable frequency decreases, and the lower usable frequency increases. The band of usable frequencies is thus narrowed. Under extreme conditions it may be completely eliminated, isolating the receiver and causing a radio **blackout.**

Sky-wave signals reaching a given receiver may arrive by any of several paths, as shown in figure 1008b. A signal which undergoes a single reflection is called a "one-hop" signal, one which undergoes two reflections with a ground reflection between is called a "two-hop" signal, etc. A "multihop" signal undergoes several reflections. The layer at which the reflection occurs is usually indicated, also, as "one hop E," "two hop F," etc.

Because of the different paths and phase changes occurring at each reflection, the various signals arriving at a receiver have different phase relationships. Since the density of the ionosphere is continually fluctuating, the strength and phase relationships of the various signals may undergo an almost continuous change. Thus, the various signals may reinforce each other at one moment and cancel each other at the next, resulting in fluctuations of the strength of the total signal received. This is

called **fading.** This phenomenon may also be caused by interaction of components within a single reflected wave, or changes in its strength due to changes in the reflecting surface. Ionospheric changes are associated with fluctuations in the radiation received from the sun, since this is the principal cause of ionization. Signals from the F layer are particularly erratic because of the rapidly fluctuating conditions within the layer itself.

The maximum distance at which a one-hop-E signal can be received is about 1,400 miles. At this distance the signal leaves the transmitter in approximately a horizontal direction. A one-hop-F signal can be received out to about 2,500 miles. At low frequencies ground waves extend out for great distances.

A sky wave may undergo a change of polarization during reflection from the ionosphere, accompanied by an alteration in the direction of travel of the wave. This is

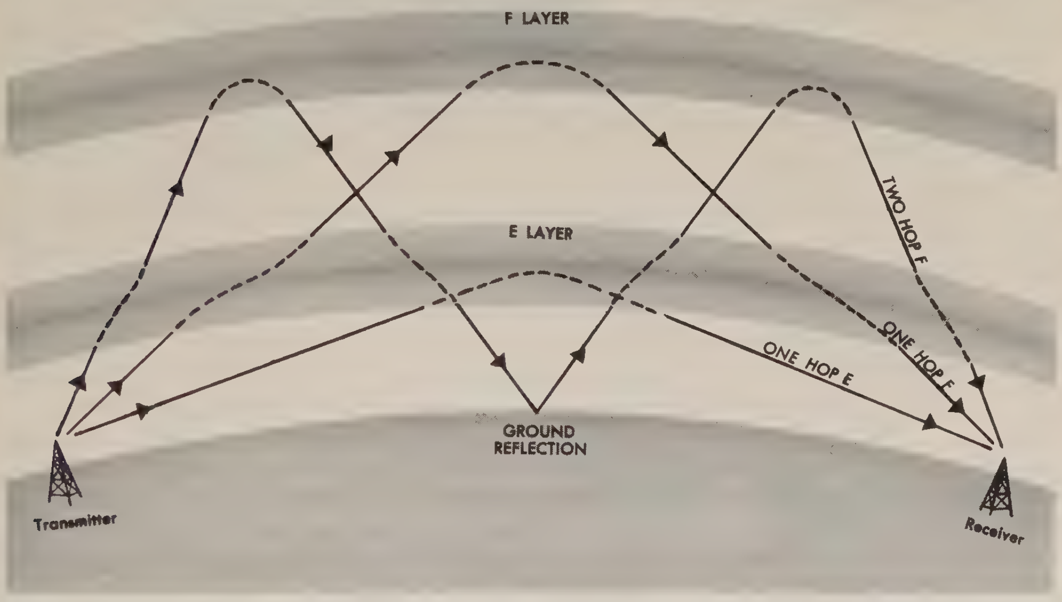

FIGURE 1008b.—Various paths by which a sky wave signal might be received.

called **polarization error.** Near sunrise and sunset, when rapid changes are occurring in the ionosphere, reception may become erratic and polarization error a maximum. This is called **night effect.**

1009. Diffraction.—When a radio wave encounters an obstacle, its energy is reflected or absorbed, causing a **shadow** beyond the obstacle. However, some energy does enter the shadow area because of **diffraction.** This is explained by **Huygens' principle,** which states that *every point on the surface of a wave front is a source of radiation, transmitting energy in all directions ahead of the wave.* No noticeable effect of this principle is observed until the wave front encounters an obstacle, which intercepts a portion of the wave. From the edge of the obstacle, energy is radiated into the shadow area, and also outside of the area. The latter interacts with energy from other parts of the wave front, producing alternate bands in which the secondary radiation reinforces or tends to cancel the energy of the primary radiation. Thus, the practical effect of an obstacle is a greatly reduced signal strength in the shadow area,

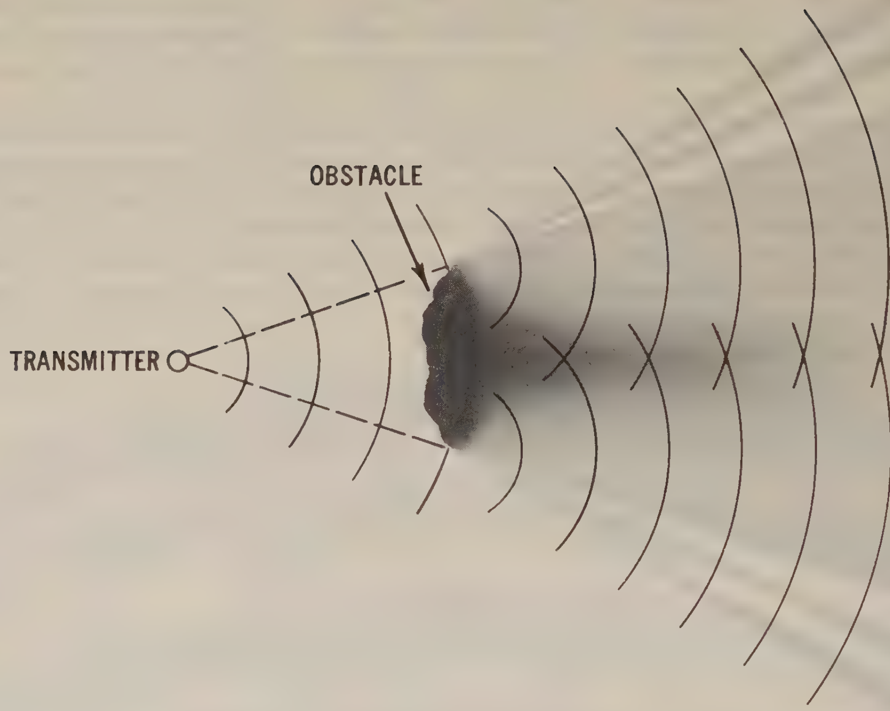

FIGURE 1009.—Diffraction.

and a disturbed pattern for a short distance outside the shadow area. This is illustrated in figure 1009.

The amount of diffraction is inversely proportional to the frequency, being greatest at very low frequencies.

1010. Absorption and scattering.—The amplitude of a radio wave expanding outward through space varies inversely with distance. That is, it gets weaker with increased distance. The decrease of strength with distance is called **attenuation.** Under certain conditions the attenuation is greater than in free space.

A wave traveling along the surface of the earth loses a certain amount of energy to the earth. The wave is diffracted downward and absorbed by the earth. As a result of this absorption, the remainder of the wave front tilts downward, resulting in further absorption by the earth. Attenuation is greater over a surface that is a poor conductor. Relatively little absorption occurs over sea water, which is an excellent conductor at low frequencies, and low frequency ground waves travel great distances over water.

A sky wave suffers an attenuation loss in its encounter with the ionosphere. The amount depends upon the height and composition of the ionosphere, as well as the frequency of the radio wave. Maximum ionospheric absorption occurs at about 1,400 kc.

In general, atmospheric absorption increases with frequency, being a problem only at SHF and EHF. At these frequencies, attenuation is further increased by **scattering** due to reflection by oxygen, water vapor, water droplets, and rain in the atmosphere.

1011. Noise.—Unwanted signals in a receiver are called **interference.** The intentional production of such interference to obstruct communication is called **jamming.** Unintentional interference is called **noise.**

Noise may originate within the receiver. **Hum** is usually the result of induction from neighboring circuits carrying alternating current. **Microphonic noise** is the result of vibration of elements in an electron tube. Irregular crackling or sizzling sounds may be caused by poor contacts or faulty components within the receiver. Electron movement in normal components causes some noise. This source sets the ultimate limit of sensitivity (art. 1018) that can be achieved in a receiver. It is the same at any frequency.

Noise originating outside the receiver may be either man-made or natural. Man-made noises originate in electrical appliances, motor and generator brushes, ignition systems, and other sources of sparks which transmit electromagnetic signals that are picked up by the receiving antenna.

Natural noise is caused principally by discharge of static electricity in the atmosphere. This is called **atmospheric noise, atmospherics,** or **static.** An extreme example is a thunderstorm. An exposed surface may acquire a considerable charge of static electricity. This may be caused by friction of water or solid particles blown against or along such a surface. It may also be caused by splitting of a water droplet which strikes the surface, one part of the droplet acquiring a positive charge and the other a negative charge. These charges may be transferred to the surface. The charge tends to gather at points and ridges of the conducting surface, and when it accumulates to a sufficient extent to overcome the insulating properties of the atmosphere, it discharges into the atmosphere. Under suitable conditions this becomes visible and is known as **St. Elmo's fire,** which is sometimes seen at mastheads, the ends of yardarms, etc.

Atmospheric noise occurs to some extent at all frequencies, but decreases with higher frequencies. Above about 30 mc it is not generally a problem.

Since most of the noise occurs at low frequencies, it travels great distances and the accumulation may reach troublesome proportions at these frequencies, particularly during the summer in mountainous regions.

1012. Antenna characteristics.—Antenna design and orientation have a marked effect upon radio wave propagation. For a single-wire antenna, strongest signals are transmitted along the perpendicular to the wire, and virtually no signal in the direction of the wire. For a vertical antenna, the signal strength is the same in all horizontal directions. Unless the polarization undergoes a change during transit, the strongest signal *received* from a vertical transmitting antenna occurs when the receiving antenna is also vertical.

For lower frequencies the radiation of a radio signal takes place by interaction between the antenna and the ground. For a vertical antenna, efficiency increases with greater length of the antenna. For a horizontal antenna, efficiency increases with greater distance between antenna and ground. Near-maximum efficiency is attained when this distance is one-half wave length. This is the reason for elevating low frequency antennas to great heights. However, at the lowest frequencies, the required height becomes prohibitively great. At 10 kc it would be about eight nautical miles for a half-wave-length antenna. Therefore, lower frequency antennas are inherently inefficient. This is partly offset by the greater range of a low frequency signal of the same transmitted power as one of higher frequency.

At higher frequencies, the ground is not used, both conducting portions being included in a **dipole** antenna. Not only can such an antenna be made efficient, but it can also be made sharply directive, thus greatly increasing the strength of the signal transmitted in a desired direction.

The power received is inversely proportional to the square of the distance from the transmitter, assuming there is no attenuation due to absorption or scattering.

1013. Range.—The range at which a usable signal is received depends upon the power transmitted, the sensitivity of the receiver, frequency, route of travel, noise level, and perhaps other factors. For the same *transmitted* power, both the ground-wave and sky-wave ranges are greatest at the lowest frequencies, but this is somewhat offset by the lesser efficiency of antennas for these frequencies. At higher frequencies, only direct waves are useful, and the effective range is greatly reduced. Attenuation, skip distance, ground reflection, wave interference, condition of the ionosphere, atmospheric noise level, and antenna design all affect the distance at which useful signals can be received.

1014. Frequency and radio wave propagation.—Frequency is an important consideration in radio wave propagation, as indicated previously. The following summary indicates the principal effects associated with the various frequency bands, starting with the lowest and progressing to the highest usable radio frequency.

Very low frequency (VLF, 10 to 30 kc). For a given transmitted power, sky-wave signals travel tremendous distances, the ionosphere being most effective in reflecting waves of the lowest frequency. Diffraction is also maximum. However, because of the long wave length, large antennas are needed, and even these are inefficient, permitting radiation of relatively small amounts of power. Relatively little energy is reflected by the ground or other obstacles. Magnetic storms have little effect upon transmission because of the efficiency of the ionosphere in reflecting VLF waves. During such storms, VLF signals may constitute the only source of radio communication over great distances. However, interference from atmospheric noise may be troublesome. Signals may be received below the surface of the sea.

Low frequency (LF, 30 to 300 kc). As frequency is increased to the LF band, the ionosphere becomes less efficient as a reflector, diffraction decreases, ground losses increase, and range for a given power output falls off rapidly. However, this is partly offset by more efficient transmitting antennas, which can be made of a size practical for use aboard ship. The LF band is useful for radio direction finding (art. 1202) and ground-wave transmission over medium distances.

Medium frequency (MF, 300 to 3,000 kc). Ground waves provide dependable service, but the range for a given power is reduced greatly, varying from about 400 miles at the lower portion of the band to about 15 miles at the upper end for a transmitted signal of one kilowatt. These values are influenced, however, by the power of the transmitter, the directivity and efficiency of the antenna, and the nature of the terrain over which signals travel. Elevating the antenna to obtain direct waves may improve the transmission. At the lower frequencies of the band, sky waves are available both day and night. As the frequency is increased, ionospheric absorption increases to a maximum at about 1,400 kc. At higher frequencies the absorption decreases, permitting increased use of sky waves. Since the ionosphere changes with the hour, season, and sunspot cycle, the reliability of sky-wave signals is variable. By careful selection of frequency, one can obtain ranges of as much as 8,000 miles with one kilowatt of transmitted power, using multihop signals. However, the frequency selection is critical. If it is too high, the signals penetrate the ionosphere and are lost in space. If it is too low, signals are too weak. In general, sky-wave reception is equally good by day or night, but lower frequencies are needed at night. The standard broadcast band for commercial stations (535 to 1,605 kc) and the authorized frequencies for loran (art. 1302) are in the MF band.

High frequency (HF, 3 to 30 mc). As with higher medium frequencies, the ground-wave range of HF signals is limited to a few miles, but the elevation of the antenna may increase the direct-wave distance of transmission. Also, the height of the antenna

does have an important effect upon sky-wave transmission because the antenna has an "image" within the conducting earth. The distance between antenna and image is related to the height of the antenna, and this distance is as critical as the distance between elements of an antenna system. Maximum usable frequencies (art. 1008) fall generally within the HF band. By day this may be 10 to 30 mc, but during the night it may drop to eight to ten mc. The HF band is widely used for ship-to-ship and ship-to-shore communication.

Very high frequency (VHF, 30 to 300 mc). Communication is limited primarily to the direct wave, or the direct wave plus a ground-reflected wave. Elevating the antenna to increase the distance at which direct waves can be used results in increased distance of reception, even though some wave interference between direct and ground-reflected waves is present. Diffraction is much less than with lower frequencies, but is most evident when signals cross sharp mountain peaks or ridges. Under suitable conditions, reflections from the ionosphere are sufficiently strong to be useful, but generally they are unavailable. There is relatively little interference from atmospheric noise in this band. Reasonably efficient directional antennas are possible with VHF. The VHF band is much used for communication with aircraft and for radio aids to air navigation. The first television and FM channels were within this band.

Ultra high frequency (UHF, 300 to 3,000 mc). Sky waves are not used in the UHF band because the ionosphere is not sufficiently dense to reflect the waves, which pass through it into space. Ground waves and ground-reflected waves are used, although there is some wave interference. Diffraction is negligible, but the radio horizon extends about 15 percent beyond the visible horizon, due principally to refraction. Reception of UHF signals is virtually free from fading and interference by atmospheric noise. Sharply directive antennas can be produced for transmission in this band, which is coming into wider use for television and other line-of-sight transmission.

Super high frequency (SHF, 3,000 to 30,000 mc). There are no sky waves in the SHF band, transmission being entirely by direct and ground-reflected waves. Diffraction and interference by atmospheric noise are virtually nonexistent. Highly efficient, sharply directive antennas can be produced. Thus, transmission in this band is similar to that of UHF, but with the effects of shorter waves being greater. Reflection by clouds, water droplets, dust particles, etc., increases, causing greater scattering, increased wave interference, and fading. At the upper end of the band, absorption in the atmosphere increases as the frequency approaches that of molecular motion. Use of this band is largely experimental.

Extremely high frequency (EHF, 30,000 to 300,000 mc). The effects of shorter waves are more pronounced in the EHF band, transmission being free from wave interference, diffraction, fading, and interference by atmospheric noise. Only direct and ground-reflected waves are available. Scattering and absorption in the atmosphere are pronounced and may produce an upper limit to the frequency useful in radio communication. The EHF band is a region of experimentation.

1015. Regulation of frequency use.—While the characteristics of various frequencies are important to the selection of the most suitable one for any given purpose, these are not the only considerations. Confusion and extensive interference would result if every user had complete freedom of selection. Some form of regulation is needed. The allocation of various frequency bands to particular uses is a matter of international agreement. Within the United States the Federal Communications Commission has responsibility for authorizing use of particular frequencies. In some cases a given frequency is allocated to several widely separated transmitters, but only under conditions which minimize interference, as during daylight hours. Interference between stations is further reduced by the use of **channels,** each of a narrow band of

frequencies. That is, assigned frequencies are separated by an arbitrary band of frequencies that are not authorized for use. In the case of radio aids to navigation, ship communications, etc., bands of several channels are allocated, permitting selection of band and channel by the user.

1016. Kinds of radio transmission.—A series of waves transmitted at constant frequency and amplitude is called a **continuous wave (CW).** This cannot be heard except at the very lowest radio frequencies, when it may produce, in a receiver, an audible hum of high pitch.

Although a continuous wave may be used directly, as in radio direction finding (art. 1202) or Decca (art. 1309), it is more commonly modified in some manner. This

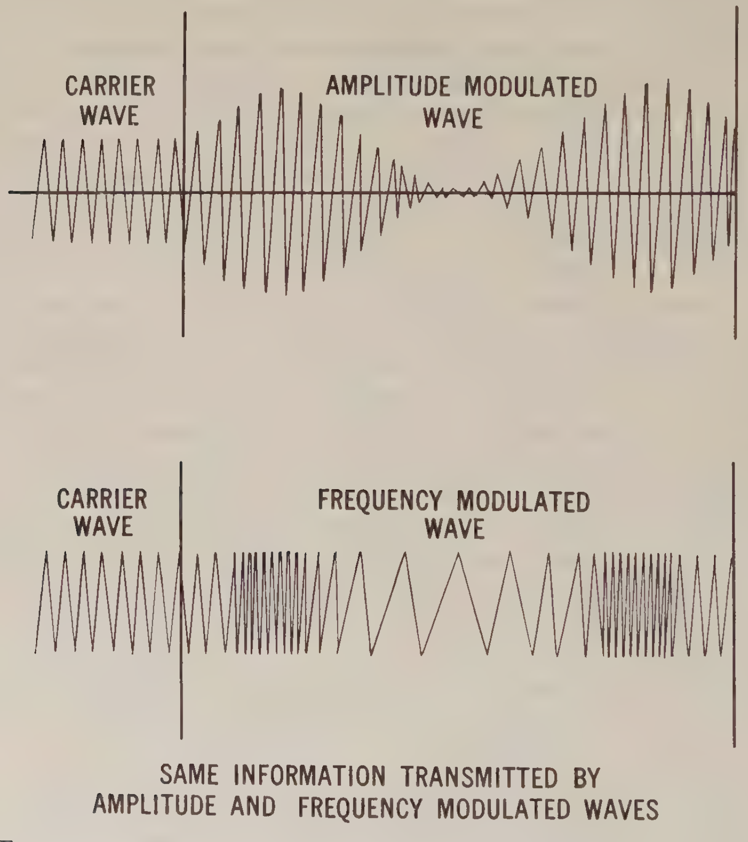

FIGURE 1016a.—Amplitude modulation (upper figure) and frequency modulation (lower figure) by the same modulating wave.

is called **modulation.** When this occurs, the continuous wave serves as a **carrier wave** for information. Any of several types of modulation may be used.

In **amplitude modulation (AM)** the amplitude of the carrier wave is altered in accordance with the amplitude of a **modulating wave,** usually of audio frequency, as shown in figure 1016a. In the receiver the signal is **demodulated** by removing the modulating wave and converting it back to its original form. This form of modulation is widely used in voice radio, as in the standard broadcast band of commercial broadcasting.

If the *frequency* instead of the *amplitude* is altered in accordance with the amplitude of the impressed signal, as shown in figure 1016a, **frequency modulation (FM)** occurs. This is used for FM broadcasts and the sound portion of television broadcasts.

Pulse modulation (PM) is somewhat different, there being no impressed modulating wave. In this form of transmission, very short bursts of carrier wave are transmitted, separated by relatively long periods of "silence," during which there is no transmission. This type of transmission, illustrated in figure 1016b, is used in some common radio navigational aids, including radar (art. 1208) and loran (art. 1302).

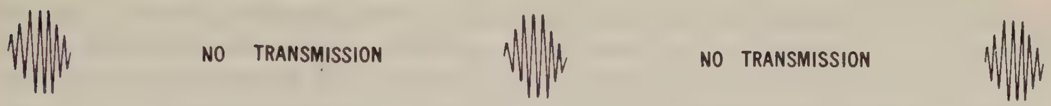

FIGURE 1016b.—Pulse modulation.

1017. Transmitters.—A radio **transmitter** consists essentially of (1) a **power supply** to furnish direct current, (2) an **oscillator** to convert direct current into radio-frequency oscillations (the carrier wave), (3) a device to control the generated signal, (4) an **amplifier** to increase the output of the oscillator. For some transmitters a **microphone** is needed with a **modulator** and final amplifier to modulate the carrier wave. In addition, an **antenna** and **ground** (for lower frequencies) are needed to produce electromagnetic radiation. These components are illustrated diagrammatically in figure 1017.

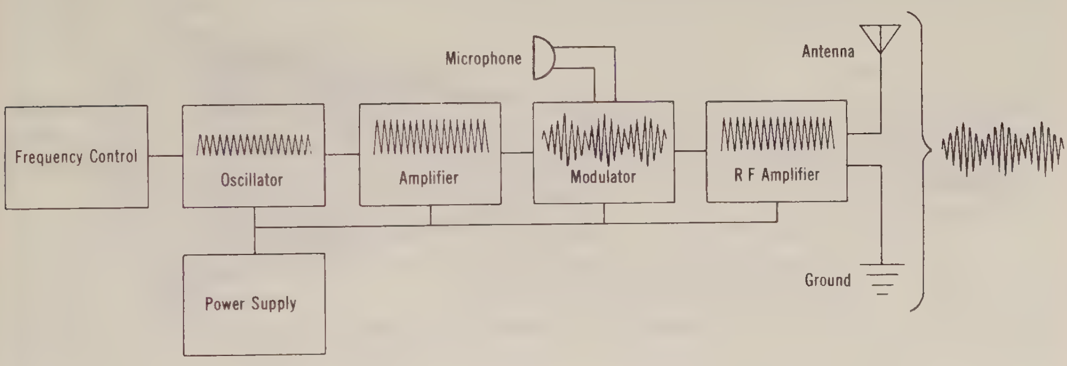

FIGURE 1017.—Components of a radio transmitter.

1018. Receivers.—When a radio wave passes a conductor, a current is induced in that conductor. A radio **receiver** is a device which accepts the power thus generated in an antenna, and transforms it into usable form. It should be able to select signals of a single frequency (actually a narrow band of frequencies) from among the many which may reach the receiving antenna. If necessary, the receiver should be able to demodulate the signal, and always it should provide adequate amplification. The output of a receiver may be presented audibly by earphones or loud speaker; or visually on a dial, cathode ray tube (art. 1019), counter, or other display. Thus, the useful reception of radio signals requires three components: (1) an antenna, (2) a receiver, and (3) a display unit.

Radio receivers differ mainly in (1) **frequency range,** the range of frequencies to which they can be tuned; (2) **selectivity,** the ability to confine reception to signals of the desired frequency and avoid others of nearly the same frequency; (3) **sensitivity,** the ability to amplify a weak signal to usable strength against a background of noise; (4) **stability,** the ability to resist drift from conditions or values to which set; and (5) **fidelity,** the completeness with which the essential characteristics of the original signal are reproduced. Receivers may have additional features such as an automatic frequency control, automatic noise limiter, etc.

Some of these characteristics are interrelated. For instance, if a receiver lacks selectivity, signals of a frequency differing slightly from those to which the receiver is tuned may be received. This condition is called **spillover,** and the resulting interference is called **cross talk.** If the selectivity is increased sufficiently to prevent spillover, it may not permit receipt of a great enough band of frequencies to obtain the full range of those of the desired signal. Thus, the fidelity may be reduced.

1019. The cathode ray tube is a useful device for presenting certain types of information. This tube, with its associated controls, is often called an **oscilloscope,** or **scope** for short. In television receivers it is usually called the **picture tube.**

The essential components of a cathode ray tube are shown in figure 1019. At the left is a **cathode** which serves as a source of electrons. In this usage it is called an **electron gun.** The electrons are collected and focused into a beam by a **focusing anode,** and then speeded up by an **accelerating anode.** If there were no other controls, the beam of electrons would travel the remainder of the length of the tube and strike the enlarged, curved surface of the tube **face** at its center, approximately. The inside of the face is coated with a material known as a **phosphor** (such as zinc sul-

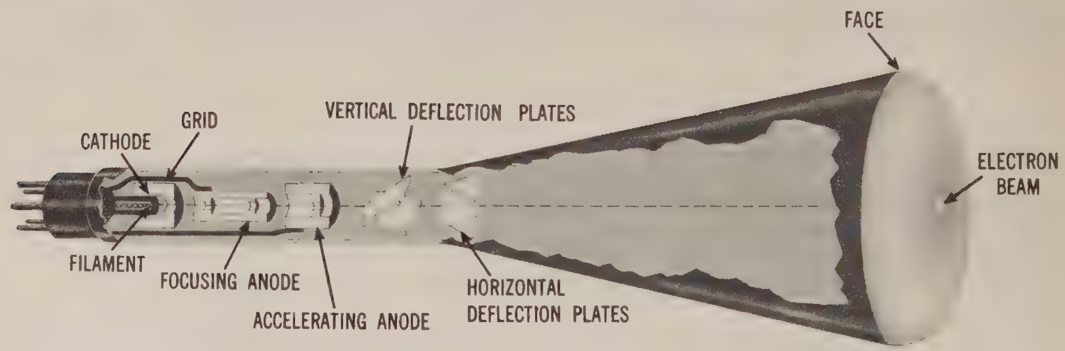

Figure 1019.—A cathode ray tube.

phide or calcium sulphide) which becomes luminous (**phosphorescent**) where a beam of electrons impinges upon it. If the beam is sharply focused, a dot of light appears at the point of impact.

By means of the **vertical deflection plates,** the beam is bent upward or downward. This is accomplished by impressing electric charges on these plates. The beam, being negatively charged, is repelled by the negative plate and attracted by the positive plate. If an alternating current is used, the strength and polarity of the electric charge on each plate changes continually, causing the beam to be deflected alternately up and down. This results in vertical motion of the spot of light on the face of the tube. If the motion is sufficiently rapid, a vertical *line* appears on the face of the tube. This is true not only because of the persistency of vision within the eye, but also because the tube face does not immediately fade when the stream of electrons is moved to another point. This visible line is called a **trace,** and the motion of the dot in producing it, a **sweep.** A horizontal trace can be made by means of the **horizontal deflection plates** which operate in a manner similar to that of the vertical deflection plates.

If both sets of plates are energized at the same time, the spot of light can be moved to various places on the face of the tube. If two alternating currents are properly synchronized, the spot can be made to trace repeatedly some pattern, such as a sine

wave. It is generally desirable to have one trace repeated in accordance with a prearranged plan, having the deflection such that motion in one direction across the face of the tube is relatively slow, and that in the opposite direction is very fast, so that the return of the spot to a starting point is almost instantaneous. Such a return is called **flyback,** and the faint trace that may be visible is called a **retrace.** The position of the spot along the trace can be used as a measurement of elapsed time since the spot was at some reference point. This is usually accomplished by having a received signal impress a momentary charge on the *other* set of deflecting plates, causing a deflection of the trace as the spot is momentarily moved to one side of the line; or by causing the received signal to intensify the spot, causing it to glow brighter.

By suitable controls, the trace can be divided into two or more parts, made to rotate, or take any of a great variety of motions and shapes.

In a **dark trace tube** the spot appears dark on a lighter background.

The cathode ray tube has many applications in electronic navigational equipment.

CHAPTER XI

ELECTRONICS AND NAVIGATION

1101. Electronics is the science and technology relating to the emission, flow, and effects of electrons in a vacuum or through a semiconductor such as a gas, and to systems using devices in which this action takes place. The widest use of electronics is in radio in its various forms. However, by the definition given above, electronics may be used in a secondary sense in a great many devices which are otherwise unrelated to radio.

1102. Use of electronics in navigation.—The expression "electronic navigation" may imply a distinct type of navigation comparable to celestial navigation, piloting, and dead reckoning. However, the use of electronics by the navigator is nearly always in one of these fields, although it is true that piloting techniques have been extended far from shore.

In celestial navigation, electronics is used for transmission of radio time signals to ships at sea, permitting the frequent checking of chronometers. A more direct application is the **radio sextant.** If the body is above the horizon, this instrument can measure altitudes of the sun and moon through an overcast or in clear weather, day or night. With further development, it may be possible to use this instrument for measurement of altitudes of other celestial bodies.

In piloting, electronics has its widest application. In addition to the various radio aids commonly associated with navigation, electronics is used in the echo sounder (art. 619), sonar (art. 1108), and sofar (art. 1313).

In dead reckoning, electronics is used in some devices for automatically determining dead reckoning position. These may be essentially *recording* or *indicating* devices, or instruments for *measuring* speed and direction, as well as indicating the results of the measurements (art. 809).

In addition to these applications of electronics to navigation, radio communication is helpful to the mariner. Weather maps and other information may be sent by facsimile (art. 3828). Various navigational warnings are broadcast, as well as weather and ice reports and predictions, distress information, and even medical advice. Information concerning the various services available is given in H.O. Pubs. Nos. 117–A and 117–B, *Radio Navigational Aids*, and in 118–A and 118–B, *Radio Weather Aids*.

The use of electronics for direct determination of positional information is related primarily to measurement of direction and measurement of distance or difference in distance.

1103. Direction measurement at the receiving site is accomplished by means of a directional antenna. Nearly all antennas have some directional properties, but in the usual antenna used for radio communication, these properties are not sufficiently critical for navigational use.

A widely used directional antenna is in the form of a **loop.** Suppose a transmitted radio signal encounters such a loop oriented in the direction of travel of the radio signal, as shown in figure 1103a. If the diameter of the loop is half the wave length, the crest of one wave arrives at one side of the loop at the same time that the trough arrives at the opposite side, as shown. Thus, the currents induced in the two sides reinforce each other, causing maximum output from the antenna. A short time later, as the wave continues to move past the antenna, the crest reaches the other side of the

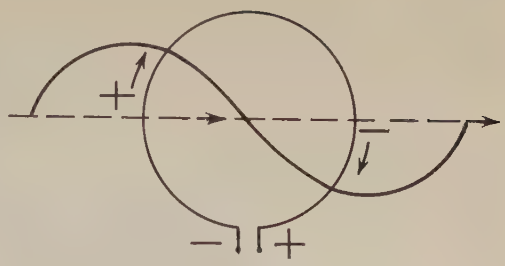

FIGURE 1103a.—Principle of the loop antenna.

loop, and a new trough reaches the approach side. A maximum current now flows in the opposite direction. Therefore, with the antenna in this orientation, an alternating current flows in the loop. If the loop diameter is less than half a wave length, the current is less than maximum.

If the antenna is rotated 90°, the alternate crests and troughs arrive at both sides at the same time, tending to cause currents to flow in opposite directions around the loop. Under these conditions the two parts cancel each other, resulting in zero antenna output. This condition is called a **null.**

As the antenna is rotated, its output varies with the angle relative to the direction of motion of the radio signal. This condition is illustrated in figure 1103b. The length of a line from the center to the outer edge of the shaded area represents the strength of the antenna output at that bearing, relative to the direction of motion of the radio wave. Thus, when it is in line, *with either side of the loop toward the approaching signal,* the output is maximum, and at 90° it is minimum. Since the change with bearing is most rapid near the region of minimum signal, this is the portion used for determination of direction.

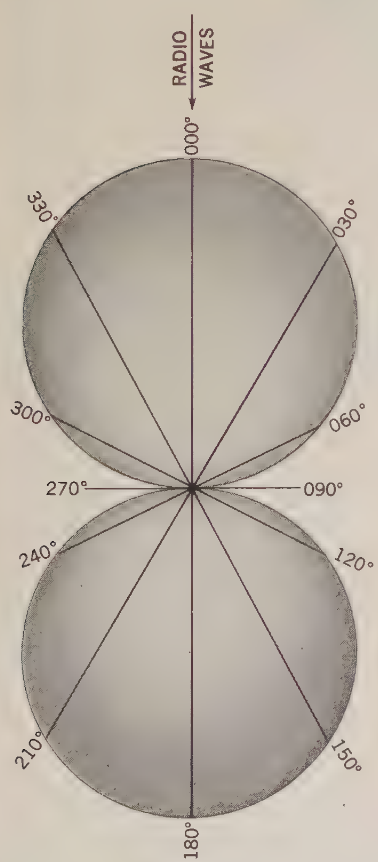

FIGURE 1103b.—Polar diagram of output of loop antenna.

Because of the characteristics of the simple loop antenna, a 180° **ambiguity** exists. That is, a signal approaching from either of two directions 180° apart would cause the same antenna output. This ambiguity can be resolved by using a vertical **sense antenna** in connection with a loop. The output from this wire, if the direction of motion of the signal is horizontal, is the same in all directions. Therefore, the polar diagram of its output is a circle, with the same polarity in all directions. If this output is exactly equal to the maximum of the loop, it will cancel the output from one side and double that from the other, since the polarity in the two sides is opposite. The resulting diagram of antenna output is shown in figure 1103c. With this arrangement, a single minimum exists, permitting the determination of which of the two reciprocal bearings is correct, thereby removing the ambiguity. The loop antenna is then used for making the reading. This is the type of equipment commonly used with a radio direction finder (art. 1202).

Two variations of the loop antenna are also used in radio direction finders. In one of these, the **crossed loop** type, two loops are rigidly mounted in such manner that one is rotated 90° with respect to the other. The *relative* output of the two antennas is related to the orientation of each with

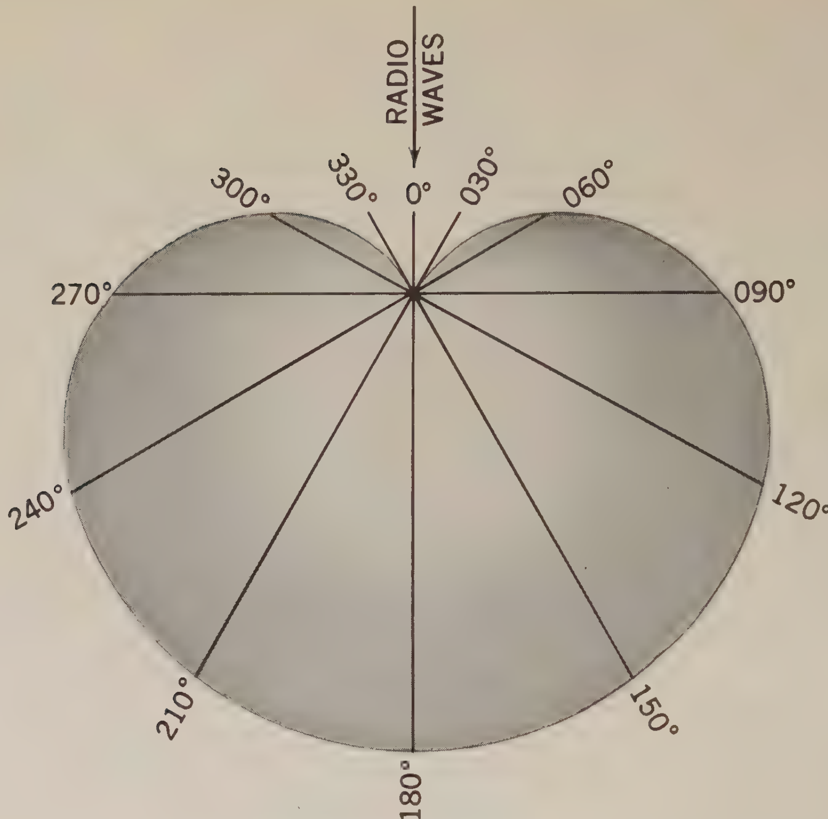

FIGURE 1103c.—Polar diagram of output of loop antenna with vertical sense antenna.

respect to the direction of travel of the radio wave, and is measured by a device called a **goniometer.** This is the type antenna used in an automatic direction finder. In the other variation, the **rotating loop** type, a single loop is kept in rapid rotation by means of a motor. The antenna output is shown on a cathode ray tube, and the resulting display shows the direction of the signal.

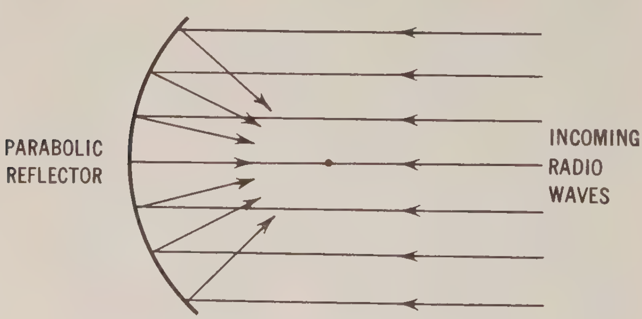

FIGURE 1103d.—Principle of the parabolic reflector.

With higher frequencies, for which a dipole antenna is used, a different method of achieving directional properties is employed. The antenna is placed at the focus of a reflecting parabola (art. O34). Incoming parallel beams are all reflected to the antenna, which receives a concentration of energy, as shown in figure 1103d. When the parabola is turned away from the approaching signal, little or no signal is received. The effectiveness of such an arrangement increases with higher frequency, for which an efficient antenna decreases in size, approaching a single point. This type antenna is used for radar (art. 1208), and the ramark beacon (art. 1210) depends upon it.

1104. Directional transmission.—The simple loop antenna, with or without a vertical sensing antenna, can be used for transmitting signals. The polar diagram of the strength of the transmitted signal is similar to that of the output of a receiving antenna, as shown in figure 1103b or figure 1103c.

Where it is desired to maintain the same direction or directions of transmission, permanent large installations can be made and properly designed for maximum efficiency at the frequency used. This is called an **Adcock antenna,** which is similar in principle to the loop except that it is not connected across the top.

For higher frequencies, the parabolic reflector is used to produce a beam of radio energy. The effect is similar to that of a searchlight.

Various combinations of antennas and phase relationships are used to produce patterns of signals serving as a navigational system. Some of these are discussed in articles 1105 and 1106.

1105. Radio tracks.—A track defined by radio may be called a "radio track." One of the simplest methods is to use two Adcock antennas placed 90° with respect to each other. As shown in figure 1105, one antenna can be used to produce a "figure 8" pattern with its axis in a north-south direction, and a second one to produce a similar pattern in an east-west direction. If each antenna transmits a characteristic signal, the lines along which these two signals are received with equal intensity represent radio tracks. This system, used in the **radio ranges** (art. 1207) which for many years constituted the primary guidance along the federal airways of the United States, has a 90° ambiguity. The directions of the tracks can be altered by changing the orientation of the antennas, or by changing the phases of the signals from the two antennas.

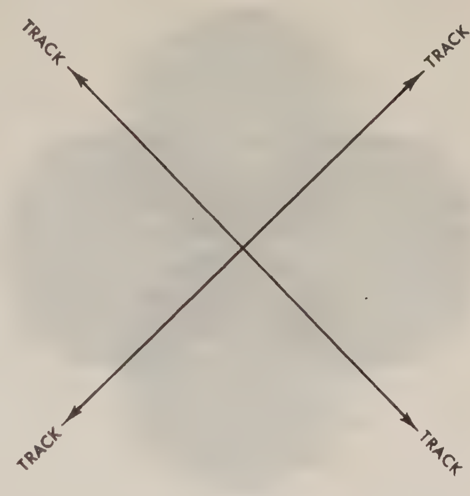

FIGURE 1105.—Radiation pattern of two Adcock antennas rotated 90° with respect to each other.

A variation of this system is the use of three or more antennas equally spaced along a straight line, the distance between consecutive antennas being three wave lengths. By a combination of amplitudes and phase shifts, a series of equisignal tracks are produced. This system, known as **elektra,** was used by the Germans during the early part of World War II. It was the predecessor of the German **sonne** and British **consol** systems (art. 1206).

At higher frequencies, radio tracks can be provided by parabolic reflectors. The disadvantage of such a system is that virtually no signal is received unless one is almost directly in line with the beam.

Although ships have occasionally used radio tracks, particularly the four-course radio ranges, such systems have been designed primarily for use by aircraft. Simple track guidance, as here described, has been largely replaced by rotating beacons providing multiple track guidance.

1106. Rotating beacons may be used to provide an indication of direction without actual direction measurement at the receiver. In the earliest installations, a directional antenna was mounted on a vertical axis and rotated slowly at uniform speed. When a distinctive phase of the pattern, such as a null, passed through a reference direction (usually true or magnetic north), a nondirectional signal was transmitted. When this

signal was received, a stopwatch was started. The elapsed time from this moment until the distinctive phase was received was an indication of the direction of the receiver from the transmitter.

In later installations the antenna remains stationary and the radiation pattern is caused to rotate. In the **vortac** ranges (art. 1207) used for air navigation with respect to the federal airways, two signal patterns are transmitted by VHF antennas similar in principle to the Adcock antenna. The pattern of one remains fixed, and that of the other rotates. The result is a change of *phase* with direction. Along the reference direction (magnetic north) from the transmitter the signals are in phase. The phase difference along any other radial is constant. The receiver measures the phase difference and indicates the direction on a dial. The receiver is also provided with a knob for selecting a desired phase difference (direction) and a pointer to indicate whether the craft should go right or left to reach the desired radial.

With three antennas in line, as in the elektra system, rotation is accomplished by slowly shifting the phase of the current in the two outer antennas. This, in combination with periodic reversal of the direction of the current, produces alternate sectors of dot and dash signals. During the cycle of operation, the patterns rotate so that a portion of each pattern sweeps past the receiver. The relative number and order of dots and dashes is an indication of direction when referred to a table or special chart for interpretation. However, identical readings can be obtained in a number of sectors. A radio direction finder bearing, dead reckoning position, or other positional information can be used to resolve the ambiguity. As developed by the Germans, this system was known as **sonne**. The British further developed the system under the name **consol** (art. 1206). The American development is known as **consolan.**

1107. Speed measurement can be accomplished electronically by utilizing the Doppler principle. A beam of electromagnetic energy can be transmitted from a moving craft. If this energy strikes an obstacle and some of the energy returns as an echo, it will have a slightly different apparent frequency because of the motion of the transmitter. The difference is proportional to the speed *in the direction of the beam.* If the beam is directed ahead or astern, the speed of the craft is indicated. If two beams are used with a fixed angle between them, and the two rotated about a vertical axis until both readings are the same, direction of motion can also be measured. In this case the measured speed is a fixed proportion of the actual speed. Thus, **Doppler navigation** (art. 809) is a dead reckoning system, since it provides measurement of both speed and direction of motion. This method is particularly applicable to aircraft.

Another method of measuring speed and direction of motion is by **inertial navigation** (art. 809). By this principle, fore-and-aft and athwartship accelerations are measured and automatically integrated once to provide a measurement of speed in each direction, and a second time to provide an indication of distance.

Since both Doppler and inertial systems provide dead reckoning information, their errors are cumulative, tending to increase with time.

1108. Distance measurement.—Since the speed of travel of radio waves is nearly constant, the time of travel between two points is directly proportional to the distance between the points. Therefore, it provides a possible method of determining distance if a means is available for measuring very small intervals of time. Considering the speed of radio waves as 186,230 statute miles per second, or 983,294,400 feet per second, a wave travels approximately 983 feet in one-*millionth* of a second. This small unit is called a **microsecond** (μs). About 6.18 μs are needed for a wave to travel one nautical mile.

If signals are transmitted from a known point at established times, as every second

of GMT, and the time of reception at a second point is measured, the difference between the two times is an indication of distance. Such a system requires clocks that can be kept synchronized to a very small unit of time, perhaps one microsecond.

Another method is to measure a time *interval* by means of a cathode ray tube (art. 1019). The reference or starting time needed for measurement of the interval is commonly provided by originating the signal at or near the receiving antenna. The signal travels to the "target" and back, the time required for the round trip being measured. This is the principle of radar (art. 1208). In **primary radar,** a reflected signal or **echo** is returned. In **secondary radar,** the transmitted signal serves as an interrogator to **trigger** a **transponder,** which immediately (or after a known delay) transmits a return signal. This is the principle of shoran (art. 1213), hiran (art. 1213), electronic position indicator (art. 1213), distance measuring equipment used with vortac (art. 1207), and racons (art. 1210).

In order to utilize this principle, it is necessary to be able to transmit very short bursts or "pulses" of energy. Otherwise, the return signal would be lost in the stronger outgoing signal. This is accomplished by means of pulse modulation (art. 1016), which permits transmission of signals during a period as short as a fraction of a microsecond, if needed.

Distance through the water is measured in a similar manner, using sound waves. The short bursts of energy, usually in the ultrasonic range above audible frequencies, are produced electronically. Because of the much slower speed of sound waves, as compared with radio signals, the lengths of the individual pulses are correspondingly greater, and simpler means are generally used for measuring the time interval. This principle is used in **sonar** (from **so**und **n**avigation **a**nd **r**anging) to measure horizontal distances, and in **echo sounders** (art. 619) to measure vertical distances. The term "sonar" is sometimes used in a general sense to include echo sounders.

Another method of measuring distance electronically is by comparison of the phase difference between signals derived from two continuous wave transmissions of different frequency. A transmitter and a receiver are located at each of the points between which distance is to be measured. At each station the interaction between the transmitted and received signals produces signals of two additional frequencies, called **beat frequencies,** equal to the sum and difference, respectively, of the two signals. If one of these additional signals is transmitted from one station to the other and compared with the corresponding signal there, the phase difference is an indication of distance. If the distance between the stations is changing, a Doppler effect occurs, permitting measurement of speed. This is the operating principle of pure-range **Raydist** (art. 1214).

Distance can also be measured by a combination of radio and sound signals. Simultaneous signals are transmitted by radio and by sound, either through the air or through the water. The difference in speed is so great that the travel time of the radio signal can be considered zero. Thus, the time interval between reception of the radio and sound signals is an indication of distance. This method is used only over relatively short distances, where the distance in nautical miles can be considered equal to the elapsed time in seconds divided by 1¼ if the sound travels through water, and by 5½ if it travels through air. This was the first electronic method of determining distance and is still utilized in a number of **distance finding stations** (art. 1205). The method is sometimes used by surveyors, who have a special beacon for this purpose. The finding of distance by this beacon is called **radio acoustic ranging (RAR),** further discussed in article 1205.

1109. Distance-difference measurement.—If synchronized signals from two stations are transmitted, the *difference* in distance from the stations can be measured, either by means of the elapsed time interval between the arrival of the two signals, or

by measurement of the phase difference between the signals. If beat frequencies are used, synchronization may not be needed.

Refer to figure 1109. Let *M* and *S* be two stations. Synchronization is achieved by letting the signals of *M*, the **master,** control those of *S*, the **slave.** Circles *M*1, *M*2, *M*3, etc., are units of distance from *M*; and circles *S*1, *S*2, *S*3, etc., are units of distance from *S*. If both signals are transmitted at the same instant, they will arrive together at any point along a line equidistant from the two stations. This **center line** is the perpendicular bisector of the **base line** joining the two stations. On a sphere, both center line and base line are great circles.

The center line is the zero time difference line. If the *M* signal arrives at some point before the *S* signal, the time difference can be found by subtracting the *M* signal travel time (or distance) from the *S* signal travel time (or distance). If a line is drawn through all intersections at which units of distance from *S* are greater by *one* than those from *M* (*S*8, *M*7; *S*7, *M*6; *S*6, *M*5; etc.), a curve is formed, as shown at "+1" in figure 1109. A similar curve labeled "−1" is formed if all points at which units of distance from *S* are *less* by *one* than those from *M* (*M*8, *S*7; *M*7, *S*6; etc.) are connected. The minus sign indicates that the *M* signal arrives (−)1 time unit *before* the *S* signal, or $S-M=(-)1$. On a plane surface, such curves are **hyperbolas** (art. O34) because they connect points of equal *difference* of distance between two fixed points. On a sphere, such curves are called **spherical hyperbolas.** On the spheroidal earth they are not plane hyperbolas, and differ somewhat from spherical hyperbolas.

Other, more sharply curving hyperbolas are formed by connecting lines of greater time (distance) difference, as at (+)2, (−)2, (+)3, (−)3, etc. The maximum difference occurs along the **base line extensions** beyond the transmitters. This difference depends upon the distance between stations. A pattern of all positive readings can be obtained by delaying the start of the *S* signal until the *M* signal is received at *S*, or longer. Suppose the *S* signal is transmitted ten units *after* the *M* signal. The *M* signal for a base line six units long will already have traveled four units beyond *S* when the *S* signal leaves the transmitter. Therefore, the reading along the base line extension from *S* is (+)4, or ten *more* than shown in figure 1109. By the time the *S* signal arrives at the master transmitter, the *M* signal will be at ten (the delay) plus six (the number of units between *M* and *S*) units, or 16 units away. Therefore, the reading along the base line extension beyond *M* is $10+6=(+)16$. Similarly it can be shown that all other readings are also increased by (+)10.

Each hyperbola becomes more nearly a straight line (great circle) as distance from the base line increases. At a distance from the center of the base line of five times the length of the base line, the departure of the hyperbola from a great circle becomes very small. For a "long" base line of several hundred miles, as in loran (art. 1302), the lines are considered curves over their entire length. This is also true of a "medium" base line as used in gee (art. 1308), Decca (art. 1309), Lorac (art. 1310), and hyperbolic Raydist (art. 1311), which are not used over such an extensive area. If the base line is very short, as in sonne and consol (art. 1312), the system is considered directional rather than hyperbolic, beyond a distance of a few miles from the station.

Each hyperbola is a line of position. Accuracy of such a system is greatest along the base line, where the hyperbolas are most closely spaced. As the distance between consecutive lines increases, the accuracy decreases, being so low along the base line extensions that use of this part of the pattern is normally avoided.

A hyperbolic system has the disadvantage of requiring two stations for a single family of lines of position. This can be partly overcome by using a series or **chain** of stations, so that each station except the end ones operates with the station on either side to form an intersecting **lattice** of position lines. This method is used with loran

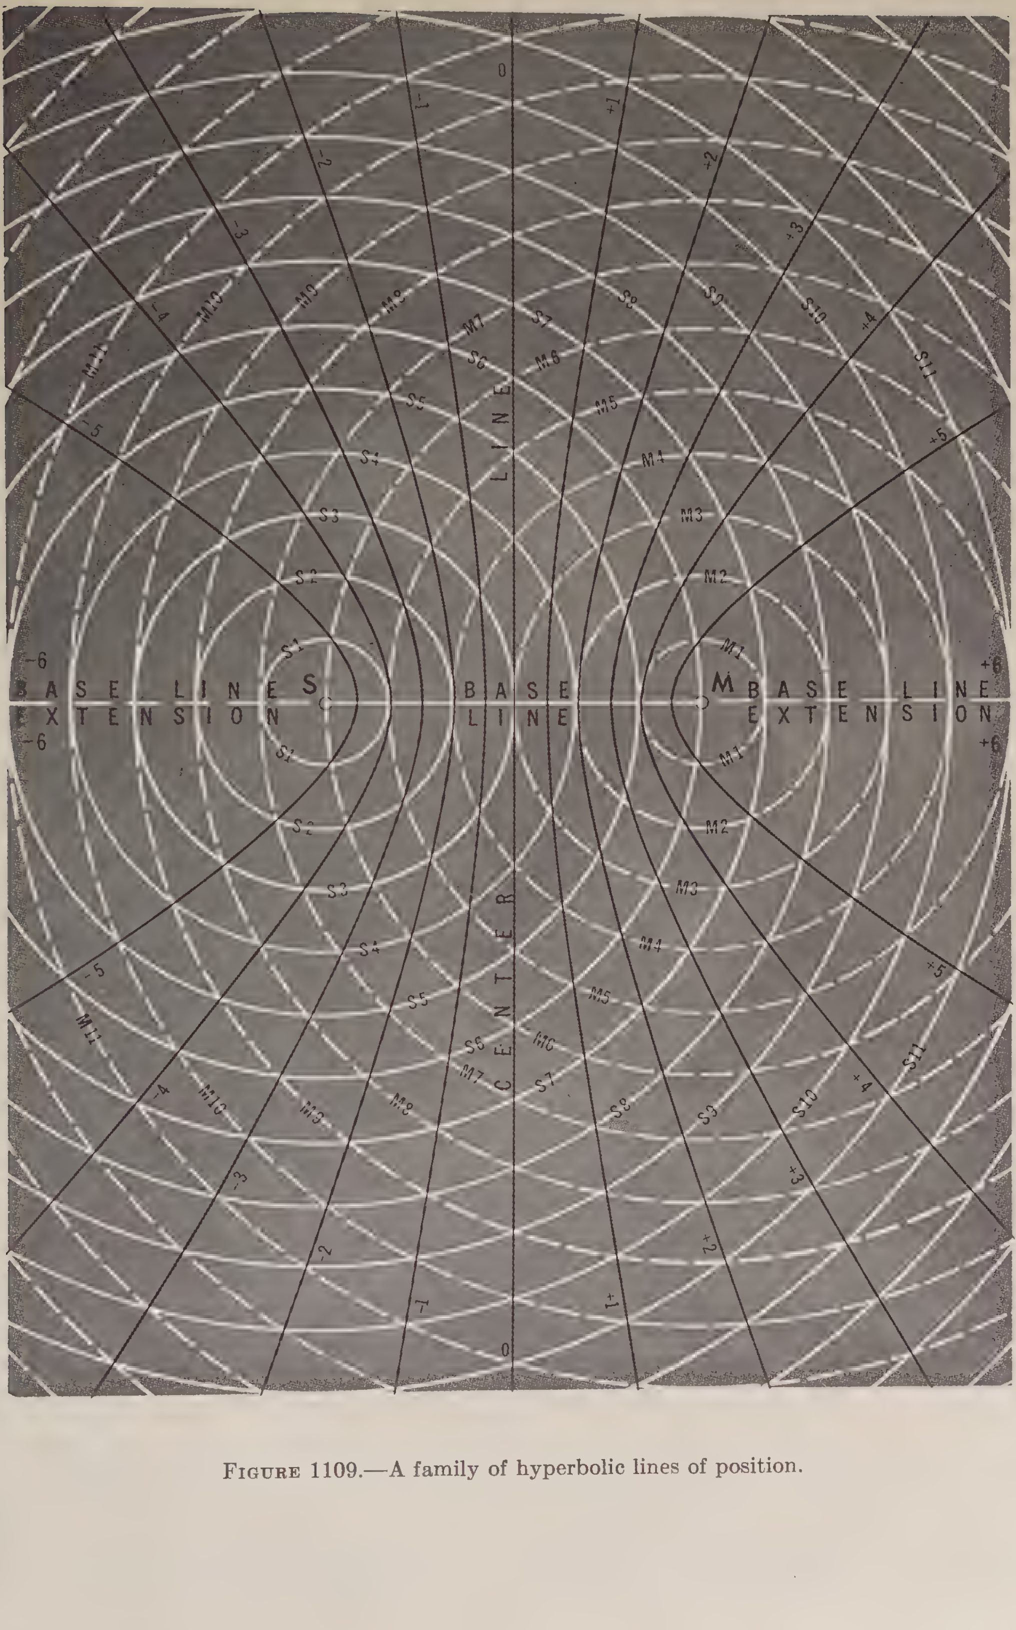

FIGURE 1109.—A family of hyperbolic lines of position.

(art. 1302). With Decca (art. 1309), a central master operates with three slaves surrounding it. Another disadvantage of a hyperbolic system is the need for computation of points along the hyperbolas. These points are computed in advance and tabulated, or plotted and connected by curves on special charts. This task is not normally performed by the user, but it does add to the cost of the system.

An advantage of a hyperbolic system is that it may not require transmission from the craft, an important consideration in time of war.

Hyperbolic lines of position may also be established by means of sound signals. Such a system, called **sofar,** is described in article 1313.

CHAPTER XII

DIRECTION AND DISTANCE BY ELECTRONICS

1201. Introduction.—Many systems have been proposed to utilize the various techniques described in chapter XI. Only the more prominent ones put to practical use are discussed in this chapter and the following one.

1202. Radio direction finder (**RDF**).—The type radio direction finder commonly used aboard ship consists essentially of a loop antenna (art. 1103) that can be turned in any direction around a vertical axis, and some kind of indicator. In its usual form, the indicator consists of a compass rose with a pointer pivoted at its center. The pointer is so oriented to the antenna that it points toward the direction from which the signal is coming when the null is received. If the compass rose is oriented with 0° in line with the ship's head, the usual orientation in a permanent installation, measured directions are *relative* bearings. In many permanent installations, there is a course input from the gyro compass so that approximately true bearings are measured.

Radio bearings may be taken on any received radio signal within frequency range of the receiver. At many locations **radiobeacons** are provided for this purpose. Their locations and identifying signals are shown on the chart by appropriate symbol (app. K) and the abbreviation "R. Bn.", and are tabulated in H.O. Pub. No. 117, *Radio Navigational Aids*. When bearings are taken on other stations, one should be careful to determine the location of the *transmitting* antenna from which the signal is coming. This may not always be the same as a receiving antenna associated with the same station, and the signal may possibly be rebroadcast from another station.

Along some foreign coasts **direction finder stations** are provided to obtain bearings, upon request, and transmit the information to the vessel requesting it. These stations are indicated on the chart by the letters "R.D.F.", and listed in H.O. Pub. No. 117.

1203. Errors of radio bearings.—Bearings obtained by radio direction finder are subject to certain errors, as follows:

Quadrantal error. When radio waves arrive at a receiver, they are influenced somewhat by the environment, resulting in an erroneous indication of direction. Aboard ship this is a function of the *relative* bearing, normally being maximum for bearings broad on the bow and broad on the quarter. Its value for various bearings can be determined, and a **calibration table** made. The usual method of calibration is to obtain a series of simultaneous radio and visual bearings on a transmitter. This may be done while a ship swings at anchor, or more quickly by steaming in a circle within sight of a transmitter. Another method, when two ships are available, is for the second ship to transmit while circling the first. Naval vessels sometimes use this method while both ships are underway, proceeding between ports. A vector diagram solution, usually on a maneuvering board (art. 1212), can be used to determine the courses and speeds of the maneuvering vessel. Metal booms, cranes, etc., should be in their normal positions during calibration. If their positions are changed when the radio direction finder is used, an error may be introduced.

Coastal refraction. As indicated in article 1006, a radio wave crossing a coast line at an oblique angle undergoes a change of direction due to difference in conducting and reflecting properties of land and water. This is sometimes called **land effect.** It is avoided by not using, or regarding as of doubtful accuracy, bearings of waves which cross a shore line at an oblique angle. If the transmitter is near the coast, negligible

error is introduced because of the short distance the waves travel before undergoing refraction.

Polarization error. As indicated in article 1008, the direction of travel of radio waves may undergo an alteration during the confused period near sunrise or sunset, when great changes are taking place in the ionosphere. This error is sometimes called **night effect.** The error can be minimized by averaging several readings, but any radio bearings taken during this period should be considered of doubtful accuracy.

Reciprocal bearings. Unless a radio direction finder has a vertical sensing wire (art. 1103), there is a possible 180° ambiguity in the reading. If such an error is discovered, one should take the reciprocal of the *uncorrected* reading, and apply the correction for the new direction. If there is doubt as to which of the two possible directions is the correct one, one should wait long enough for the bearing to change appreciably and take another reading. The transmitter should draw *aft* between readings. If the reciprocal is used, the station will appear to have drawn *forward.* A reciprocal bearing furnished by a direction finder station should not be used because the quadrantal error is not known, either on the given bearing or its reciprocal.

In general, good radio bearings should not be in error by more than 2°. However, conditions vary considerably, and skill is an important factor. By practicing frequently when results can be checked by visual observation or by other means, one can develop skill and learn to what extent radio bearings can be relied upon under various conditions. Bearings taken ashore should be of slightly greater accuracy than those taken aboard ship. Shore stations indicate bearings of doubtful accuracy. These stations should not be asked to estimate the size of the probable error.

1204. Using radio bearings.—A bearing obtained by radio, like one determined in any other manner, provides means for establishing a line of position. By heading in the direction from which the signal is coming, one can proceed toward, or **home** on, the transmitter. In thick weather one should avoid heading directly toward the source of radiation unless he has reliable information to indicate that he is some distance away. In 1934 the Nantucket Lightship was rammed and sunk by a ship homing on its radiobeacon.

Radio waves, like light, travel along great circles. Except in high latitudes, visual bearings can usually be plotted as straight lines on a Mercator chart, without significant error. Radio bearings, however, are often observed at such positions with respect to the transmitter that the use of a rhumb line is not satisfactory. Under these conditions it is customary to apply the **conversion angle** (art. 821) as a correction to the observed angle, to find the equivalent rhumb line. Such a correction is not needed when a bearing is plotted on a gnomonic chart or one on which a straight line is a good approximation of a great circle. In other situations, a correction may be necessary.

If the transmitter and receiver are on the same meridian, or are both on the equator no correction is needed because rhumb lines and great circles coincide under these conditions. The size of the correction increases with degree of departure from these conditions, and with greater distance between transmitter and receiver.

Conversion angles are given in table 1. This table is used to convert great circle to rhumb line directions or vice versa as in great circle sailing, radio, and consol bearings (art. 1206). If the difference of longitude is not more than 4°5, and the mid latitude between transmitter and receiver is not more than 85°, the first part of the table should be used. The simplifying assumptions used in the computation of this part of the table do not introduce a significant error within the limits of the table.

The sign of the correction can be determined by referring to the rules given at the bottom of each page of table 1. These follow from the fact that the great circle is

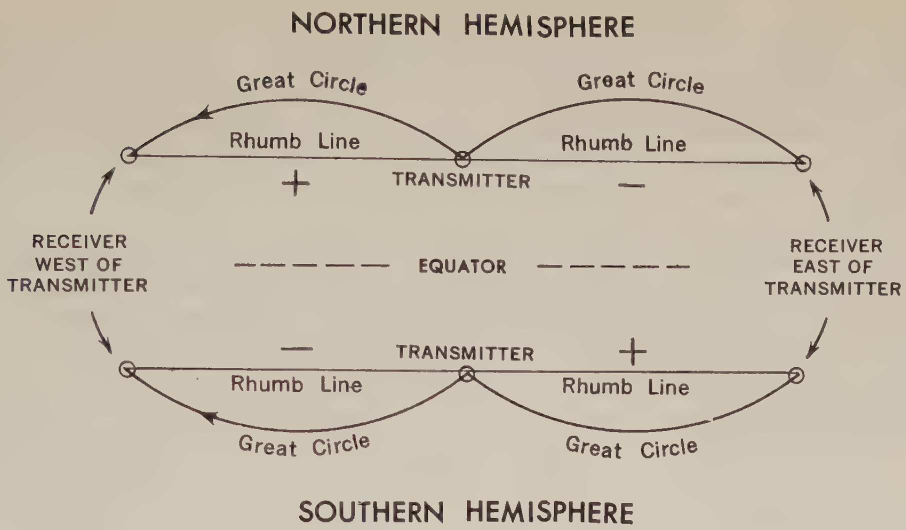

FIGURE 1204.—Sign of conversion angle correction to radio bearings.

nearer the pole than the rhumb line. It can be visualized by means of a simple sketch, as shown in figure 1204.

Example.—The DR position of a ship is lat. 42°15′.2 N, long. 9°48′.6 W. A radio bearing is taken on Cabo Montedor Light Station, at lat. 41°45′00″ N, long. 8°52′20″ W. The reading, corrected for calibration error, is 125°.5.

Required.—The equivalent rhumb line bearing.

Solution.—

	Latitude	*Longitude*
Receiver	42°15′.2 N	9°48′.6 W
Transmitter	41°45′.0 N	8°52′.3 W
Difference	30′.2	56′.3=0°.9
Mid latitude	42°.0	
Correction	(+) 0°.3 (from table 1)	
Great-circle bearing	125°.5	
Rhumb line bearing	125°.8	

Answer.—B 125°.8.

Radio bearings are plotted and labeled as any other bearing line (art. 904). If it is desired to indicate the nature of the bearing, the word "radio" might be added to the label, preferably below the line. Since radio bearings are generally somewhat less accurate than visual bearings, and often are observed at greater distances, positions obtained by them are generally considered of insufficient accuracy to be termed fixes, and so are usually considered estimated positions (art. 913). However, judgment should govern the reliance to be placed upon such positional information. A series of such positions may provide the basis for elimination of random errors, giving a reliable fix unless systematic errors (art. 2903) are present.

Some navigators estimate or assume a probable error (usually of ±2° unless conditions suggest another value) and plot lines on each side of the bearing line to indicate the probable area within which the vessel is presumed to be located.

Radio bearings furnished by a direction finder station have been corrected for known errors at the receiver, but not for conversion angle. The latter should be applied by the user.

1205. Distance finding stations.—At some locations a radio signal is synchronized with a sound signal which may be transmitted through either air or water. The

travel time of the radio signal is negligible compared to that of the sound signal. Consequently, the difference in time between reception of the two signals is proportional to the distance from the station. The distance in nautical miles is equal to the number of seconds of time interval divided by 5½ if the sound travels through air, or by 1¼ if through water (or multiplied by 0.18 or 0.8, respectively). The distance so found is from the origin of the *sound* signal, which might differ somewhat from that of the radio signal. The distance may be in error by as much as ten percent.

A light, portable, floating beacon, designed for use primarily in surveying, transmits radio signals through the air when triggered by a suitable sound signal. Determination of distance by the use of such a beacon is called **radio acoustic ranging (RAR).**

1206. Consol is a long-range, short-base-line, hyperbolic system operating in the 250–350 kc frequency range. The three antennas constituting a station are spaced at intervals of about three wave lengths. Beyond a distance of about 25 miles from the center station the lines of position can be considered great circles with negligible error. In use, the system is considered a directional one, the hyperbolic portion of the lines not being used.

The radiation pattern of each station consists of alternate sectors of dot and dash signals, the sectors averaging 15° in width. During the "keying" cycle of 30 or 60 seconds, this pattern rotates, the **equisignal** between dots and dashes moving through one sector. During this period, 60 signals (either dots or dashes) are transmitted. At any point along the dividing bearing between sectors at the beginning of the cycle, 60 dots or 60 dashes should be received. Along any other bearing line the count of 60 is distributed between the two types of signal. The relative number of each, and their order, is related to the bearing of the receiver.

The total count is generally less than 60 because the dot and dash sectors overlap, one type signal gradually fading as the other becomes stronger. The equisignal boundary is the line along which both signals are of equal intensity and neither can be distinguished. Several signals may be lost during passage of this sector. The number of signals lost (60 minus the actual count) should be distributed equally between the dots and dashes. If the difference is an odd number, the smaller correction should be applied to the count received first, because the ear can generally follow a fading signal to a lower degree of contrast than it can detect the first signal of a new series. This is particularly true when dots are received first. Thus, if the count is 25 dots and 30 dashes, the total is 55, and 5 signals have been lost in the equisignal sector. The corrected count is 25+2=27 dots, and 30+3=33 dashes.

The great-circle bearing corresponding to the count is determined by referring to H.O. Pubs. Nos. 117–A and 117–B, a separate table being given for the dot and dash sectors of each station. If plotting is to be done on a Mercator chart, the conversion angle correction should be applied using the table given in H.O. Pubs. Nos. 117–A and 117–B. Table 1 may also be used; however, the entering arguments of transmitter and receiver must be reversed. Special charts showing the lines or graduations have been prepared by some foreign countries.

The time of observation of a consol line of position is the moment at which the equisignal is heard.

Under favorable conditions, the coverage area for a consol station extends outward for about 1,000 to 1,200 miles by day, and 1,200 to 1,500 miles by night, over water. Over land, or at any time that the noise level is high, these ranges may be reduced materially. The accuracy varies considerably over the pattern. Directionally, it is greatest along the great circle through the center antenna and perpendicular to the line of antennas. At an angle of 60° to this perpendicular, the accuracy drops to a minimum usable value. Therefore, there is a usable sector of about 120° on each side of the line of antennas, with an unusable sector of about 60° at each end of this line.

In terms of distance, the greatest angular error occurs within the range in which sky waves and ground waves mingle, between about 250 and 400 miles from the station.

As a very general rule, for 95 percent of the time when ground waves are received, the error over water is not more than about one-third degree along the perpendicular, increasing to about twice this value at an angle of 60° to the perpendicular. In terms of miles, this is about one mile error for each 180 miles from the station along the perpendicular, and each 90 miles along the bearing line 60° from the perpendicular. For sky waves these values are about doubled, and when sky waves and ground waves are near the same amplitude, the error may be considerably larger. These values refer to single observations. The error is generally reduced by taking the average of several readings. On many occasions a good dead reckoning position is more reliable than a position obtained by consol. However, the method is valuable when the position is considerably in doubt, and is a useful check to prevent gross errors by other methods. If the position is so seriously in doubt that the sector is uncertain, a bearing by radio direction finder should resolve the ambiguity.

A reading cannot be made oftener than once every one or two minutes, depending upon the cycle of operation. Each 30- or 60-second "keying cycle" is followed by a period of equal length, during which a continuous tone and identification are transmitted. No special equipment is required beyond an ordinary medium frequency communication receiver, and very little skill or training is needed.

Consol is a British development of a German system known as **sonne,** which in turn evolved from the nonrotating **elektra.** There are several consol installations along the coasts of western and northern Europe. Two stations of an American version, called **consolan,** are installed on the east and west coasts of the United States. The Japanese also have a version.

1207. Radio ranges.—The airways of the United States and some other countries are marked by a series of distinctive radiobeacons called **ranges.** Under suitable conditions, these are useful in marine navigation.

Two different types of ranges are in use. The older low frequency **four-course range** consists of two Adcock antennas (art. 1104) so oriented that their signal areas occupy sectors, usually about 90° each. The edges of the sectors overlap to form narrow equisignal sectors or "beams" directed along the airways. One antenna transmits the Morse code letter *A* (• ▬), and the other the letter *N* (▬ •). These signals are so synchronized that when they are received with equal intensity, they interlock to form a single monotone "on-course" signal. As the equisignal sector is left, one signal predominates. As the angle from the center of the equisignal sector increases, the predominating signal becomes more prominent and the monotone fades. The area near each side of the equisignal sector is called a "twilight sector."

Some equisignal sectors extend out to sea. Their locations and the identification of the *A* and *N* sectors are shown on appropriate aeronautical charts. A marine navigator equipped with such information may find the ranges useful for determining bearings, or even for homing.

A newer type range eliminates the four-course limitations of the older ones by transmitting a rotating pattern, using very high frequency signals. Two such systems, **tacan** for military aircraft and **omnirange** (**VOR**) for others, together with electronic equipment for determining distance by an interrogator-transponder (art. 1108), are located at each installation, called a **vortac** station. By means of the special receiving and indicating equipment needed, one can determine either (1) bearing and distance at any time by automatic dial and meter indications, or (2) direction to turn to arrive at a selected "radial" (bearing). Because of its limited application to marine navigation, the special equipment is not normally carried aboard ship.

1208. Radar determines distance by measuring the time required for a radio signal to travel from a transmitter to a "target" and return, either as a reflected "echo" (primary radar) or as a retransmitted signal from a transponder (art. 1108) triggered by the original signal (secondary radar). The name is derived from **ra**dio **d**etection **a**nd **r**anging. Since radar uses a directional antenna, the direction of the target is also determined, but with somewhat less accuracy than the distance.

In a radar set, signals are generated in a transmitter by a timing circuit so that energy leaves the antenna in very short bursts or "pulses." During transmission of a pulse, the antenna is connected to the transmitter but not the receiver. As soon as the pulse leaves, an electronic switch disconnects the antenna from the transmitter and connects it to the receiver. Another pulse is not transmitted until after the preceding one has had time to travel to the most distant target within range, and return. Since the interval between pulses is long compared with the length of a pulse, strong signals can be provided with low *average* power.

From the receiver, the return signal goes to the indicator. This consists of a cathode ray tube (art. 1019) and appropriate circuits. Many types of display have been devised, a number of them to meet specialized requirements. For navigational use, the earliest type of display was the **A-scope.** The principle of this scope is illustrated in figure 1208a. At A a pulse leaves the antenna of a ship, and a vertical deflection appears at the start of the horizontal trace on the scope face. At B the pulse has traveled some distance outward from the antenna. A short horizontal line appears after the vertical deflection on the scope face. The length of this line is directly proportional to the distance traveled by the pulse. At C the pulse encounters a target with a reflecting surface. At D the original pulse has moved on beyond the target, but part of its energy has been reflected back toward the transmitter. At E the echo has arrived back at the transmitting craft, causing a vertical deflection of the horizontal trace. The height of this deflection is directly proportional to the strength of the returning signal. At F the echo has proceeded on past the transmitting ship, and the trace is completed.

This sequence is repeated a great many times, perhaps 1,000 per second, the rate being called the **pulse repetition rate** (**PRR**) or **pulse recurrence rate.** The start of each trace is synchronized with transmission of the signal so that each trace is a repetition of the previous one, if slight changes in relative positions of transmitting ship, target, and antenna orientation are neglected. Therefore, the trace and all deflections appear as a continuous line. The distance between leading edges of the vertical deflections, or "pips," is directly proportional to range. A change of range alters the position of the second pip. The orientation of the antenna is an indication of direction. A pip appears only when the antenna is pointed toward the target.

The type of presentation now most commonly used for navigational radar is called the **plan position indicator** (**PPI**). On this presentation the sweep starts at the center of the tube face and moves outward along a radial line which rotates in synchronization with the antenna. Instead of being deflected, the trace glows with greater intensity (brightness) at the appropriate places. Because of the persistence of the tube face coating, the glow continues after the trace rotates on past the target, resulting in a maplike presentation on the scope. This presentation is shown in figure 1208b.

On a PPI, the range of a target is proportional to the distance of its echo signal from the center of the scope. This may be measured by a series of visible concentric circles at established distances from the center, or by means of an adjustable ring synchronized with a counter. Bearing is indicated by the direction of an echo signal from the center of the scope. To facilitate measurement of direction, a movable, radial, guide line or **cursor** is provided, and a compass rose is placed around

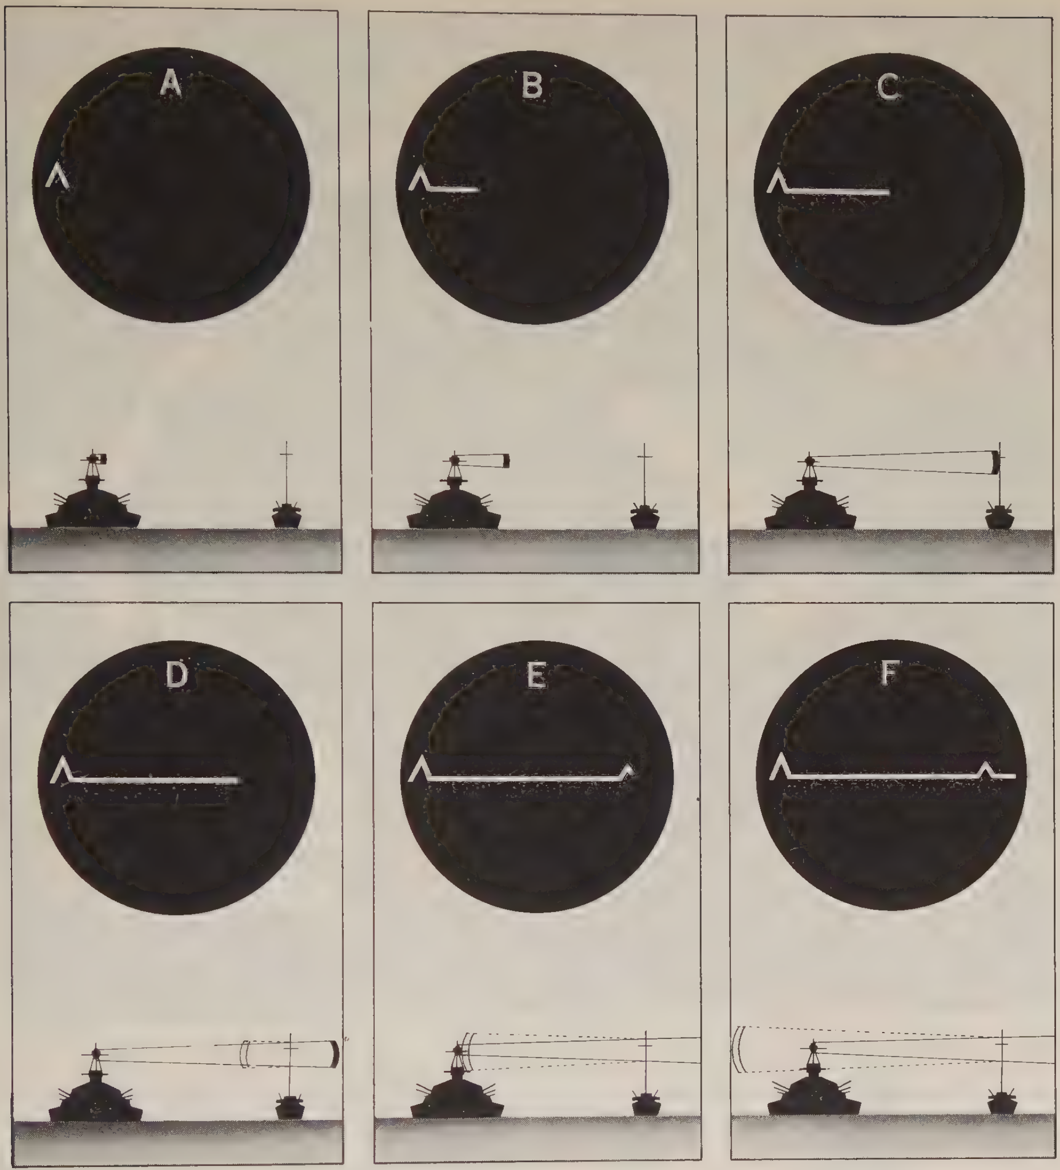

FIGURE 1208a.—A-scope.

the outside of the scope. In the "heading-upward" presentation, relative bearings are indicated, the top of the scope representing the direction of the ship's head. In the "north-upward" presentation, gyro north is always at the top, regardless of the heading. True bearings are indicated if there is no gyro error. On this type presentation a radial line is customarily provided at the heading of the vessel.

Provision may be made for offsetting the center of the PPI presentation from the center of the tube face, to permit large-scale observation of distant targets in one direction. With "true motion" radar, the center of the tube face continues to represent the same geographical position until reset. The actual motion of all moving objects, including one's own vessel, appears on the scope, instead of the relative movement usually shown.

Other modifications have been devised. In some installations a **repeater** duplicates the presentation, making the information available at a distance from the radar.

Since the receiver is disconnected during transmission of a signal, no echo can be received during this period. As a result, there is a minimum range at which objects can be detected. The shortest pulses are about 0.1 microsecond in duration, or approximately 98 feet long. Since the time measurement is of the *round trip* as the signal travels to the target and the echo returns, the range is *half* the distance corresponding to the measured time interval. Therefore, a minimum range of about 49 feet is theoretically possible with a pulse of 0.1 microsecond. However, the *practical* minimum range is somewhat greater because of **sea return** of echoes from the water near the ship, where the signals strike the surface of the sea almost vertically. A practical minimum of 50 yards is considered excellent.

The maximum range is limited by the power, nature of the target, and by the curvature of the earth, since radar operates in the higher frequencies that are essentially line-of-sight. The **radar horizon,** at which rays from the transmitting antenna are tangent to the surface of the earth, is at a distance about 15 percent greater than that

of the visible horizon (tab. 8). Under conditions of abnormal refraction, both visible and radar horizons may be extended to greater distances.

1209. Scope interpretation.—With practice, one can acquire considerable skill in interpreting the signals appearing on the radar scope face. Some of the factors to be kept in mind in interpretation are the following:

Resolution in range. In part *A* of figure 1209 a transmitted pulse has arrived at the second of two targets of insufficient size or density to absorb or reflect all of the energy of the pulse. While the pulse has traveled from the first to the second target, the echo from the first has traveled an equal distance in the opposite direction. At *B* the transmitted pulse has continued on beyond the second target, and the two echoes are returning toward the transmitter. The distance between leading edges of the two echoes is *twice* the distance between targets. The correct distance will be shown on the scope, which is calibrated to show *half* the distance traveled out and back. At *C* the targets

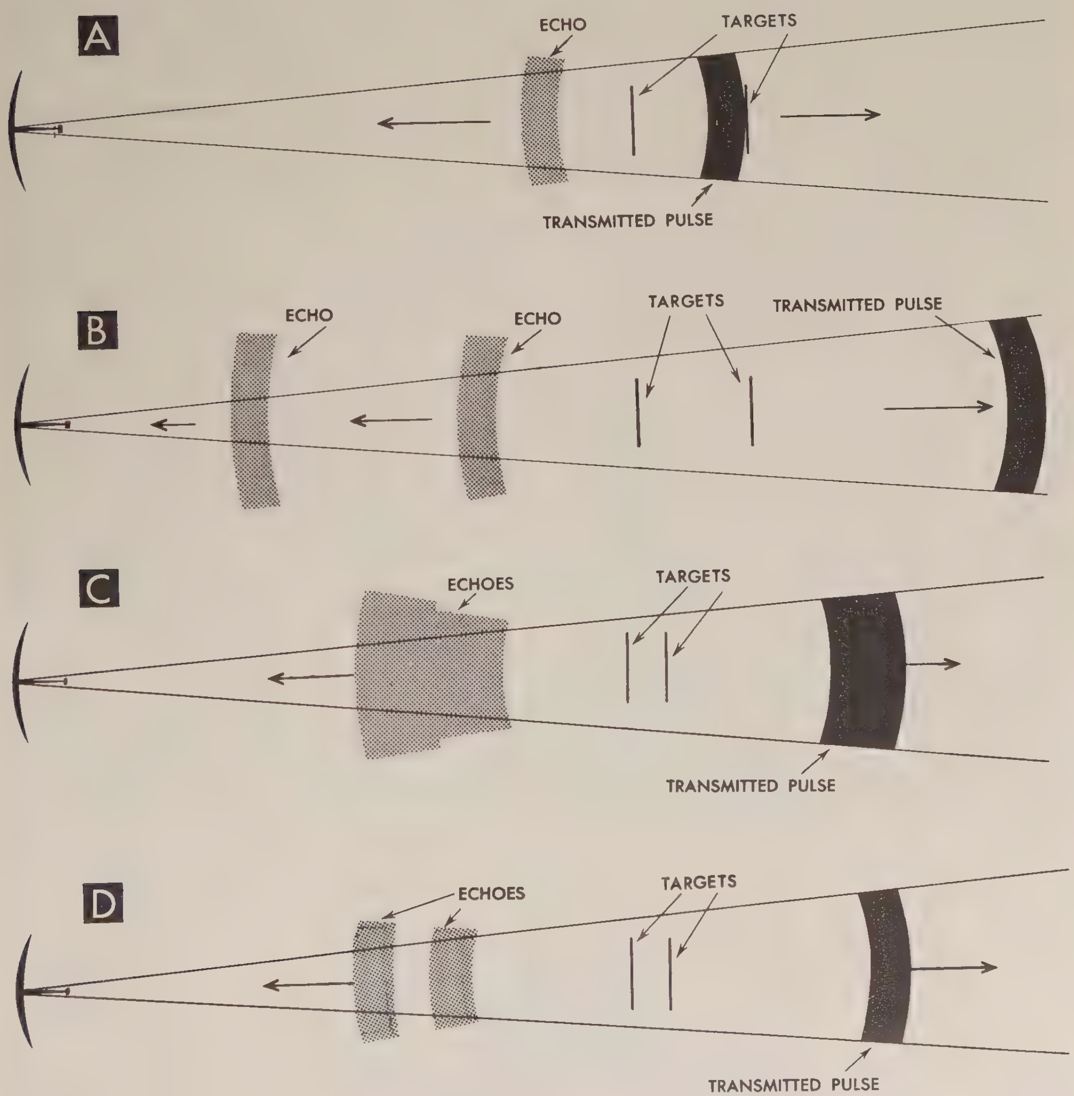

FIGURE 1209.—Resolution in range.

are closer together and the pulse length has been increased. The two echoes merge, and on the scope will appear as a single, large target. At D the pulse length has been decreased, and the two echoes appear separated. The ability of a radar to separate targets close together on the same bearing is called **resolution in range.** It is related primarily to pulse length, the minimum distance between targets that can be distinguished as separate ones being *half* the pulse length. This (half the pulse length) is the apparent depth or thickness of a target presenting a flat perpendicular surface to the radar beam. Thus, several ships close together may appear as an island. Echoes from a number of small boats, piles, breakers, or even large ships close to the shore may blend with echoes from the shore, resulting in an incorrect indication of the position and shape of the shore line.

Resolution in bearing is similar to that in range. A pulse proceeds outward along a narrow sector. As the beam rotates, energy is returned during the entire time that a target is "illuminated," the same as with a searchlight. A vertical target such as a mast is "seen" over the arc in which there is sufficient illumination to render it visible. On a radar PPI a target appears widened by an amount equal to the **beam width,** half the beam width being added to each side. Thus, the echoes from two or more targets close together at the same range may merge to form a single, wider echo. The ability to separate such targets is called **resolution in bearing.** In angular units it is dependent primarily upon beam width, a narrower beam having a higher resolution. In terms of distance between targets, range is also important, resolution increasing as range decreases.

Height of antenna and target. If the radar horizon (art. 1208) is between the transmitting vessel and the target, the lower part of the target will not be visible. A large vessel may appear as a small craft, a shore line may appear at some distance inland. Areas within radar shadows (art. 1009) may not be visible at all.

Reflecting quality of target. Echoes from several targets of the same size may be quite different in appearance. A metal surface is a better reflector of radio waves than a wooden surface. A surface perpendicular to the beam returns a stronger echo than a nonperpendicular one. For this reason, a gently sloping beach may not be visible. A vessel encountered broadside returns a stronger echo than one heading toward or away from the radar vessel. In some instances, the strength of an echo can be increased by means of a **corner reflector.** This is a device with several reflecting surfaces so arranged that a radar signal from any direction is returned toward its source. Corner reflectors are fitted to a number of buoys (labeled "Ra Ref" on the chart), and are carried in some lifeboats. The strength of a returning echo can be *reduced* by coating a surface with radar absorbent material.

Frequency. As the frequency is increased, reflections occur from smaller targets. Thus, a ten-centimeter radar generally penetrates fog, rain, snow, etc., while a three-centimeter radar receives returns from such obstacles, and can be used to track storms. Radar frequencies are sometimes indicated by "band," as follows:

Band	*Frequency (mc)*	*Approx. wave length (cm)*
P	225–390	100
L	390–1,550	30
S	1,550–5,200	10
X	5,200–11,000	3
K	11,000–36,000	1
Q	36,000–46,000	0.75
V	46,000–56,000	0.6

A C-band extending from 3,500 mc to 5,850 mc is sometimes mentioned.

Scope interpretation is complicated somewhat by the presence of unwanted signals from atmospheric noise, sea return, precipitation, etc. Collectively, this is called **clutter.** Generally, it is strongest near the vessel and gradually decreases with increased range, because of reduced sea return. Strong echoes can sometimes be detected by reducing the volume or "gain" of the receiver (not the image intensity of the indicator), so that weaker signals will not appear. Even when the amplitude of the clutter is about the same as that of desired signals, the latter can sometimes be detected by watching the scope during several rotations of the antenna. At each rotation the signals from targets remain at about the same place, and of about the same magnitude, while those from waves, noise, etc., fluctuate, appearing different on each revolution. Floating ice or a small boat may not be detected at any range if the waves are high. A rough surface returns a stronger echo than a smooth surface.

Sometimes a signal appears on a radar screen when there is no visible object at the point indicated, and no apparent source of the signal. This is called a **ghost.** It may be due to faulty operation of the radar set, or to an actual echo returned from a discontinuity in the atmosphere. Sometimes such discontinuities reflect light, also, producing images or apparent images similar to mirages and of seeming apparent reality. A similar condition occasionally occurs in the sea. This phenomenon is undoubtedly the basis of many reports of strange objects sighted visually or by radar. Sometimes such apparent objects exhibit incredible speed or maneuverability.

1210. Radar navigation.—Radar provides a means of establishing position, or keeping a vessel in safe water during periods of reduced visibility, or at considerable distance from shore, when other methods may not be available. Since both range and bearing can be obtained, a single identifiable object is needed. However, if a visual bearing is available, it should be more reliable than one obtained by radar. Since radar range is usually more accurate than radar bearing, a fix by two or more ranges is generally preferable to one obtained by two bearings or by range and bearing. However, accurate range requires reliable identification of the part of the target returning the echo. This is not always apparent when natural objects are used.

Radar beacons have been installed at some places. One type, called **ramark** (from **ra**dar **mark**), transmits continuously in all directions. On the scope of a radar receiving the signal a radial line appears at the bearing of the beacon. The beacon does not have to be within the range to which the scope is adjusted. A limited number of this type beacon has been installed for experimental use by ships.

Another type beacon, called **racon** from the words **ra**dar bea**con,** consists essentially of a transponder (art. 1108) which returns a coded signal when triggered by a signal from a radar transmitter. The code, consisting of a series of dots and dashes, provides identification of the beacon. The range and bearing are indicated by the position of the first character of the code on the PPI. This type beacon is used principally by aviators. Information on these installations is given in various aeronautical publications (art. 2802). Because the return signal is of a different frequency than the outgoing signal, radar equipment must provide for the change in frequency if racon signals are to be used. Echoes returning at the frequency of the outgoing signals do not appear on the scope.

In addition to the usual methods of piloting, radar is adapted to several methods of somewhat limited application. If a single prominent target is available in an operating area, a series of concentric circles and radial lines—a polar plot similar to that of a maneuvering board (art. 1212)—can be drawn on the chart and suitably labeled. If bearing and distance are measured frequently, an almost continuous fix can be obtained by spotting in the positions by eye. If a polar plot is made on a piece of transparent material to the same scale as the chart, the ranges and bearings of a number

of points can be plotted in quick succession, and the transparent material fitted to the chart by trial and error. The center of the plot is then the position of the radar.

Several models of **chart comparison unit** (**CCU**) have been devised. By means of this device, an image of the chart is superimposed over the PPI, or an image of the PPI is superimposed over the chart. Either method permits direct comparison of radar image and chart, if the two are of the same scale. Although distortion of the PPI presentation is not the same as that of the chart, an experienced person can usually effect a reliable match, providing reasonably accurate determination of position. A chart comparison unit designed to produce a virtual image of the chart on the face of the scope is sometimes called a **virtual PPI reflectoscope** (**VPR**).

Early models of the chart comparison unit were used with white-on-black charts designed especially for the purpose. Later models can be used with ordinary nautical charts. Various other special chart presentations have been devised for radar, but the present trend is toward modification of nautical charts to make relief and radar-conspicuous objects more prominent. This is accomplished primarily by shading and the use of additional contours.

Useful information can sometimes be obtained from radar scope photographs made at known positions on previous runs or by other vessels with comparable installations. In certain confined waters, notably along certain stretches of the Ohio River, a series of such photographs made with a typical radar installation have been combined to form a mosaic which presents a continuous maplike presentation. In some cases this mosaic has been printed in fluorescent ink on the regular chart. When the chart is illuminated by fluorescent light, the mosaic glows in a manner that resembles a PPI.

1211. Harbor radar.—At a number of ports, shore-based radar has been installed to assist in the movement of traffic during periods of low visibility. Each installation is tailored to fit its surroundings and requirements. A typical installation consists of a large antenna installed at a prominent point in the harbor, and one or more scopes manned by competent personnel with knowledge of local conditions. The installations are not intended to *control* shipping in the vicinity, but are considered advisory only. Upon their own request, vessels about to enter or leave port, or shift berth, are advised of traffic conditions, and other matters of concern. During passage between harbor entrance and the berthing area or anchorage, they may be warned of possible danger. Customarily, communication with the vessel is through the pilot, who comes aboard equipped with a portable radio. Resolution of present radars is not sufficiently great to permit docking a vessel by radar alone.

A secondary use of harbor radar is to detect drift of aids to navigation from their assigned stations. It is also used to assist a pilot vessel locate an entering ship, or to direct a vessel to a craft in distress or to any other desired point.

One of the principal problems associated with harbor radar is the identification of the echo from a vessel with which radio communication has been established. At least two systems for accomplishing this are under development.

1212. Radar as an anticollision device.—Radar has not materially reduced the number of collisions, as might have been anticipated. This may be due to any of a number of reasons, or probably to a combination of several. Among these are the following: uncertainty as to whether the other vessel has radar, failure to use radar information, lack cf confidence in radar, lack of appreciation of the limitations of radar, failure to act promptly, failure to establish prompt communication with the other vessel, uncertainty as to obligation under rules of the road, misinterpretation of radar information, difficulty of adequately visualizing a situation presented on a radar scope, and lack of knowledge of use to be made of radar information. Most of these can be summed up as lack of adequate training. There is record of radar actually

having been removed from vessels because it was considered a collision hazard. A better remedy would undoubtedly have been to instruct ships' personnel in proper use of this valuable aid.

Neither the international nor inland rules of the road provide special procedure for a radar-equipped vessel, which is therefore expected to obey the same rules applicable to other vessels. This is particularly important in view of the fact that radar is not infallible in detecting the presence of small vessels. In some cases the mere presence of radar is somehow believed to offer a protection or provide an immunity which does not in fact exist. If a vessel has radar, the equipment should be kept in good working condition and used whenever visibility is reduced. Even in clear weather it can be a valuable aid in evaluating a situation, although it is not a substitute for visual observation.

The principal value of radar as an anticollision device is its ability to give *early* information on the locations and movements of other vessels. Two fundamental problems are involved. The first is the determination of relative motion of two or more vessels if they maintain courses and speeds. The second is the determination of the action to take to produce a desired result. Both problems can be solved by a simple plot. Either a navigational or relative movement plot will suffice.

In the navigational plot, positions of one's own vessel are plotted at intervals of a few minutes. From each position the bearing and distance of the other vessel are plotted. From these positions the course and speed of the other vessel can be determined. The dead reckoning of both ships can be run ahead to determine where they will be at any future time. By trial and error, the point of nearest approach and the distance and bearing at this point can be determined. Similarly, the effect of changing course or speed can also be determined.

A somewhat simpler and more direct solution can be made by means of a relative movement plot. This is most easily performed on a polar plotting diagram such as a **radar plotting sheet** (H.O. 4665 series) or **maneuvering board,** H.O. 2665–20 (large size) or H.O. 2665–10 (small size, usually used). If such a plotting sheet is not available, one can easily be constructed, or any compass rose can be used. On these forms, position of one's own ship *remains* at the center, as on the usual PPI. Positions of the other ship are plotted from the position of one's own vessel.

Example 1.—A ship underway obtains the following radar bearings and ranges of another vessel at the times indicated:

Time	*Bearing*	*Range*
1510	030°	8,500 yds.
1512	029°	7,600 yds.
1514	026°.5	6,700 yds.
1516	024°	5,800 yds.
1518	023°.5	5,000 yds.

Required.—(1) The nearest approach of the two vessels.

(2) The bearing of the other vessel at the point of nearest approach.

(3) Time of arrival at the point of nearest approach.

Solution (fig. 1212a).—Let the distance between consecutive circles represent 1,000 yards.

(1) Plot each of the given positions from the center, and label each with the time. If the course and speed of each vessel are constant, the points should plot in approximately a straight line. This is the **relative movement line.** At any moment the other vessel is at *some* point on this line. The direction of this point is the bearing of the other vessel at the moment the point is occupied, and the distance between this point and the

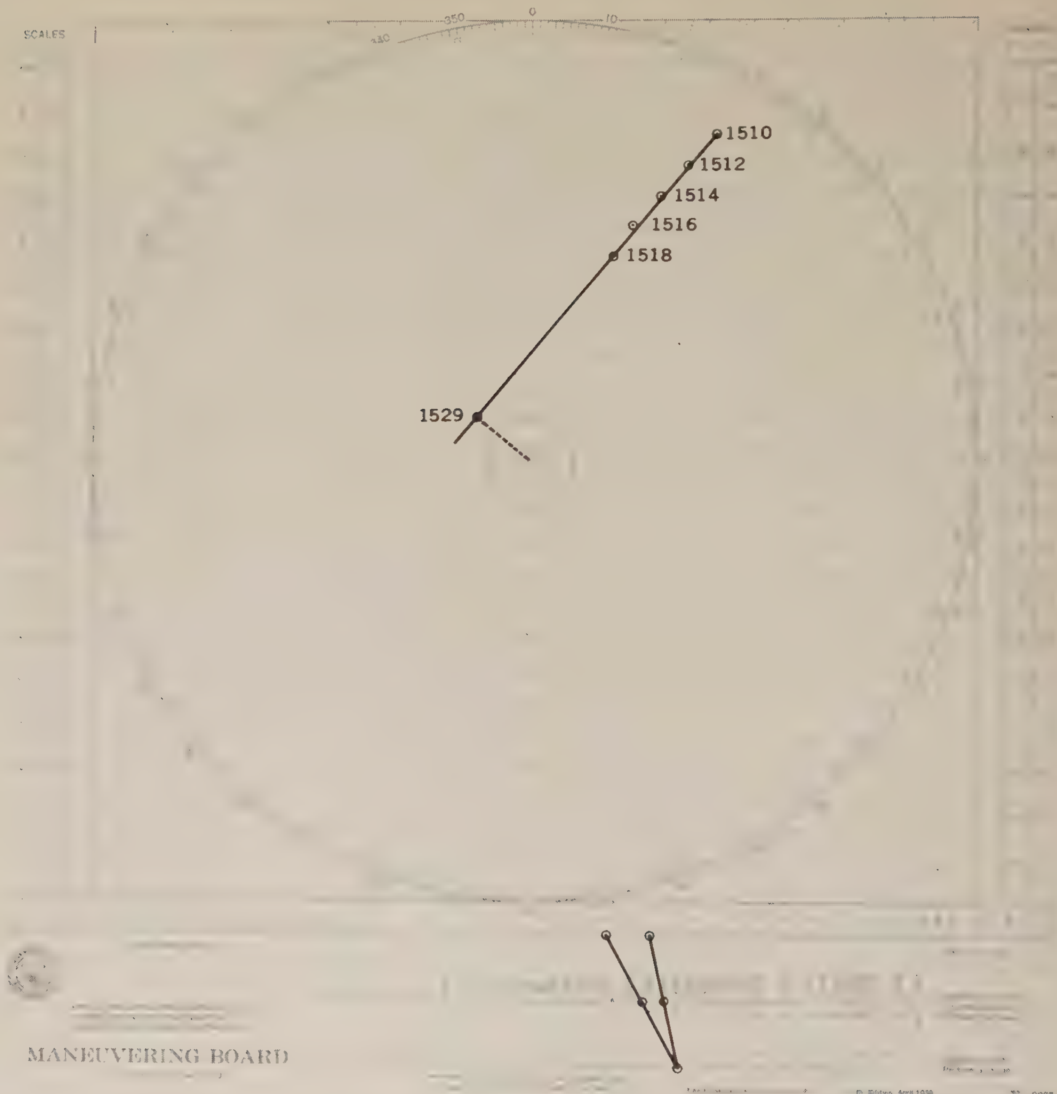

FIGURE 1212a.—Finding time, bearing, and range of nearest approach by relative plot.

center is the range. The direction of the relative movement line is the **direction of relative movement** (**DRM**) of the other vessel with respect to one's own vessel. The DRM of one's own ship with respect to the other vessel is the reciprocal of this line (as are the bearings). The length of the relative movement line in one hour is the relative speed or **speed of relative movement** (**SRM**). The DRM and SRM, representing *relative* motion, should not be confused with the actual course and speed of the other vessel. The nearest approach of the other vessel is on the relative movement line, at its nearest point to the center. The required distance is therefore the perpendicular distance from the center (own ship) to this line (extended). The graduations indicate this to be 1,500 yards.

(2) The direction of the perpendicular, 310°, is the bearing of the other vessel at the point of nearest approach.

(3) The time at which the other vessel is at the foot of the perpendicular is the time of arrival at the point of nearest approach. In this problem it can be determined by using a pair of dividers and stepping off a succession of two-minute runs along

the relative movement line. Another way is by means of the nomogram at the bottom of the diagram. By dividers, the distance between the 1510 and 1518 positions is measured, and also the distance between the 1518 position and the point of nearest approach. These are marked on the *center* line of the nomogram, being careful to distinguish between the "yards" and "miles" scales. A mark is placed at eight on the top line of the nomogram to represent the interval between 1510 and 1518. A straight line connecting the eight-minute mark on the top line with the corresponding distance mark on the middle line, if extended, intersects the bottom line at a point indicating the *relative* speed. A second line from this point, through the second distance mark on the middle line, if extended, intersects the top line at 11^m, the time needed for the other vessel to cover the distance along the relative movement line from the 1518 position to the point of nearest approach. Therefore, time of arrival at this point is $1518+11^m=1529$.

Answers.—(1) D 1,500 yds., (2) B 310°, (3) T 1529.

With the information given in example 1, and the course and speed of one's own vessel, a person can determine course and speed of the other vessel, a process called **tracking.** A speed vector diagram (art. O18) is used.

Example 2.—Find the course and speed of the other vessel of example 1, if own ship is on course 110°, speed 12 knots.

Solution (fig. 1212b).—Let the distance between consecutive circles represent two knots.

Draw the speed vector of own ship (12 knots in direction 110°), starting at the center. Label the outer end of this line *r*. Read the relative speed (SRM), 13.5 knots, from the bottom line of the nomogram of figure 1212a. Relative speed might also be determined by arithmetic. In eight minutes (1510–1518) the other vessel moves 1.8 miles (3,600 yards) relative to own ship. In 60 minutes it will travel $1.8\times\frac{60}{8}=13.5$ miles. From *r*, draw a line parallel to, and in the same direction as, the relative movement line, and measure off a speed of 13.5 knots. Label the end of the vector *m*. The line *rm* is the **relative speed vector,** its length representing the speed of relative movement, and its direction representing the direction of relative movement. A line from the center to *m* is the speed vector of the other vessel, its length representing the actual speed, and its direction the course.

Answers.—C 170°, S 14.7 kn.

It is good practice to continue plotting relative positions of the other vessel until it has passed. Any change in the direction of the relative movement line indicates a change of course or speed. After enough positions have been plotted to establish the new direction of the line, a new solution can be made. If the bearing becomes constant and the distance is decreasing, the two vessels are on collision courses, and unless remedial action is taken, a collision will take place.

It is good practice to start such a plot at the earliest practicable time, remembering that if ships are approaching head on, the *relative* speed is equal to the sum of their individual speeds. If the situation is seen to be a dangerous one, action can be taken in time to prevent a close situation. Many accidents are caused by waiting until the vessels are so close that a change by the other vessel, which may not have radar, brings the vessels together before there is time to detect the change and take action. Since the rules of the road regarding passing or crossing are not applicable until the vessels are *in sight* of each other, any action based upon radar information before the other vessel is sighted is in harmony with the law. Unless the intentions of the other vessel are known, it is good practice to prevent his close approach, if possible, by taking bold action early.

Example 3.—The "own ship" of examples 1 and 2 is capable of a maximum speed

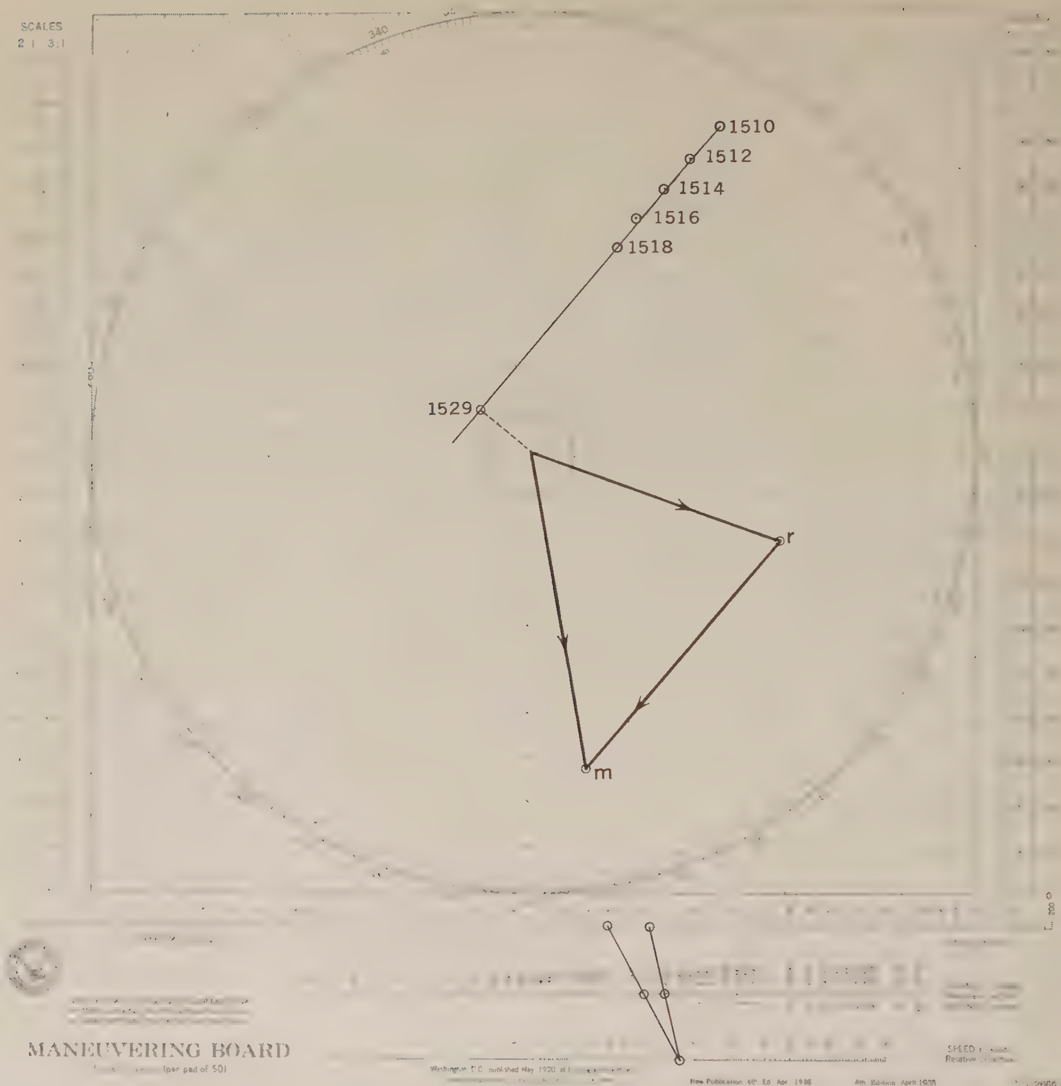

FIGURE 1212b.—Finding course and speed of other vessel, by relative plot.

of 16 knots. It is decided that at 1521 full speed will be used, and the course will be changed to prevent the ships from approaching closer than 3,000 yards.

Required.—The new course.

Solution (fig. 1212c).—Find the relative position of the other ship at 1521. This can be estimated from the previous plot, or determined accurately by connecting the relative speed (13.5 knots) on the bottom line of the nomogram with three minutes on the top line, and noting the point at which this line crosses the center line (1,350 yards), or mathematically, taking ⅜ the relative distance covered in eight minutes. The relative distance (1,350 yards) is measured off along the relative movement line from the 1518 position. From this point draw a new relative movement line tangent to the 3,000-yard circle. From m on the speed vector diagram, draw a line parallel but in the direction *opposite* to the new relative movement line. Label the intersection of this line and the 16-knot speed circle r'. A line from the center to this point is the speed vector of own ship. Its direction is the required course.

Answer.—C 134°.

The *minimum* speed at which the desired result can be obtained may be found by drawing a perpendicular from the center to the relative speed vector $r'm$. The direction of this perpendicular is the course at minimum speed. For this problem the values (not shown in the illustration) are 14.4 knots on course 160°. Since the relative speed vector would then be very short (the ships would be on nearly parallel courses at nearly the same speed), the distance between ships would change slowly. If the relative speed is known, the time to cover any relative distance can be found by nomogram or by arithmetic.

A number of variations of this problem may suggest themselves. With practice, one can acquire the ability to make approximate solutions mentally. Such mental solutions should be checked by plot. This is particularly important if the bearing is changing slowly. It is good practice to have the plot kept by one person who can observe the changing relationship as the vessels proceed. However, one should keep in mind the fact that although a plot adds to the value of radar, it is not a magic solution to all radar problems. It may not reflect small changes in course, and its indications are not instantaneous.

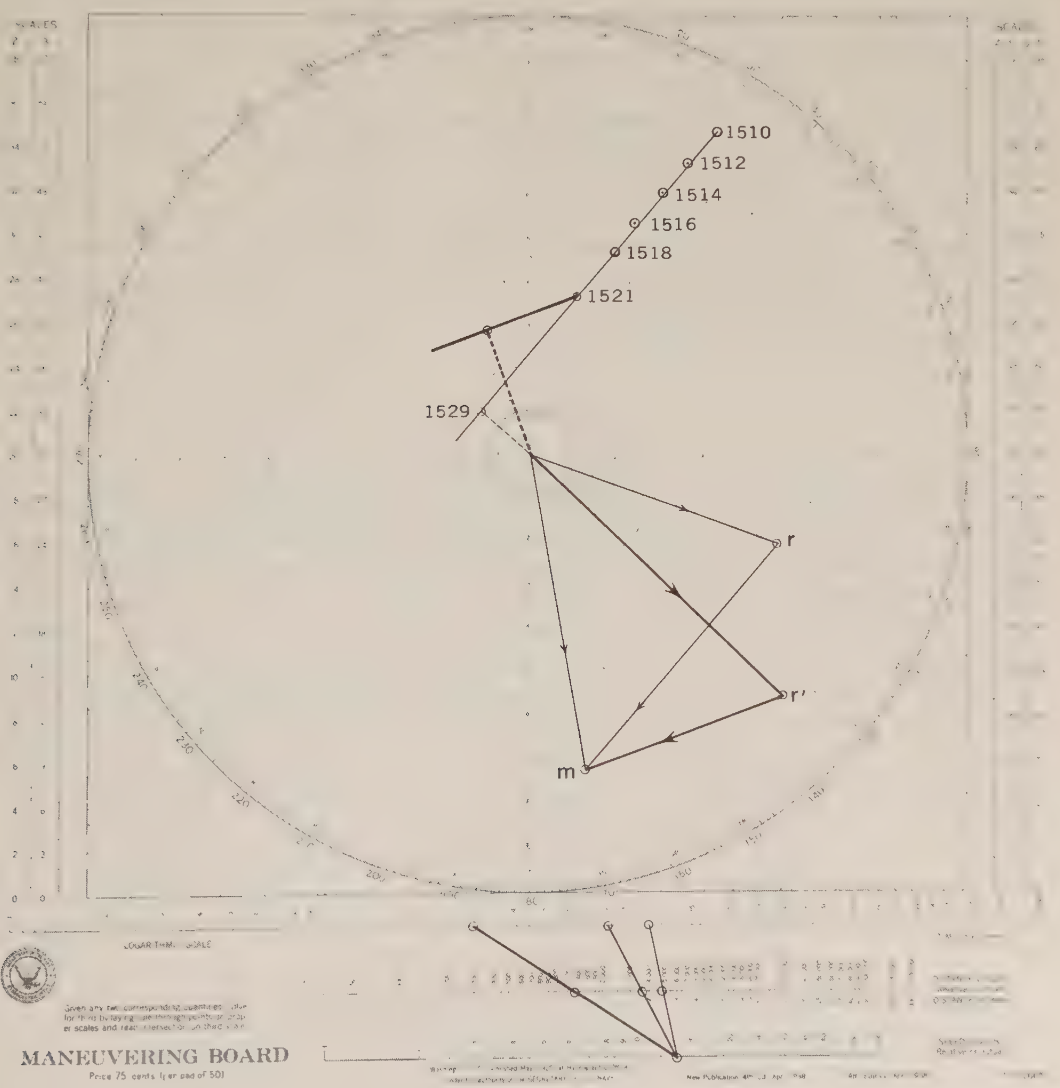

FIGURE 1212c.—Finding course at given speed to produce desired result, by relative plot.

1213. Shoran is a form of secondary radar (art. 1108) using two transponder beacons located ashore and a single indicator aboard ship to measure the distance from each beacon. By this means two distances are continually available, permitting rapid determination of position. Special charts are not needed, but where they have been provided, they show a number of concentric circles centered upon each beacon. Approximate positions can be plotted by inspection.

Shoran was developed during World War II to permit bombing through undercast. It provided such high accuracy that after the war it was further developed for possible use in surveying. Its use permitted measurement of distances over water or inaccessible terrain, thus providing means for more accurate positioning of offshore islands and other features inaccessible by previous methods.

The name **shoran** was derived from **sho**rt **ra**nge **n**avigation. A higher precision version used to meet the most exacting survey requirements is called **hiran,** from **hi**gh precision sho**ran.** Because of the high frequency used (230–310 mc), shoran is limited in range by the curvature of the earth. A lower frequency (1,900 kc) version permitting use by ships at distances of several hundred miles from shore was developed by the U. S. Coast and Geodetic Survey and called **electronic position indicator** (**EPI**). A British system similar to shoran, but with transmitters at the fixed ground stations and a transponder beacon at the mobile station, is known as **oboe.**

Since these systems provide simultaneous measurement of two distances, the *difference* in the two measurements might be used to provide a hyperbolic system (ch. XIII). However, for the use generally made of such equipment, the need for establishing hyperbolas would be a disadvantage.

1214. Pure-range Raydist measures distance electrically by phase comparison of beat frequency signals (art. 1108) resulting from transmission of signals at the two points between which the distance is to be measured. This method has had limited use, primarily in survey operations.

Hyperbolic Raydist is discussed in article 1311.

Problems

1204. The DR position of a ship is lat. 44°08ʹ.2 S, long. 62°56ʹ.9 W. A radio bearing is taken on Isla Leones Light Station, at lat. 45°03′03″ S, long. 65°36′33″ W. The uncorrected reading is 039°.5 relative, the ship being on true heading 205° at the moment the bearing is observed. The calibration table indicates a correction of (—) 2° should be applied.

Required.—The equivalent true rhumb line bearing.

Answer.—B 243°.5.

1212a. A ship on course 230°, speed 15 knots, obtains the following radar bearings and ranges of another vessel at the times indicated:

Time	*Bearing*	*Range*
0820	215°	24.0 mi.
0824	215°.5	23.4 mi.
0828	216°.5	22.8 mi.
0832	217°	22.3 mi.
0836	218°	21.7 mi.
0840	219°	21.2 mi.

Required.—(1) The nearest approach of the two vessels.

(2) The bearing of the other vessel at the point of nearest approach.

(3) Direction of relative movement (DRM).

(4) Speed of relative movement (SRM).

(5) Time of arrival at the point of nearest approach.

(6) Course and speed of the other vessel.

Answers.—(1) D 10.6 mi.; (2) B 278°; (3) DRM 009°; (4) SRM 9.7 kn.; (5) T 1033; (6) C 270°, S 10 kn.

1212b. At 0848 the other vessel of problem 1212a changes course to 034° and increases speed to 20 knots.

Required.—(1) The nearest approach of the two vessels if both maintain course and speed.

(2) New relative speed.

(3) Time of arrival at point of nearest approach.

Answers.—(1) D 0 (collision), (2) SRM 34.6 kn., (3) T 0923.

1212c. At 0858 the "own ship" of problem 1212b changes course to the *right,* coming to the course that will result in a nearest approach of five miles without changing speed.

Required.—(1) The new course.

(2) New relative speed.

(3) Time and distance at which "own ship" will be dead ahead of the other vessel.

(4) Time of arrival at the point of nearest approach if both vessels maintain course and speed.

(5) Bearing of the other vessel at nearest approach.

Answers.—(1) C 278°; (2) SRM 29.7 kn.; (3) T 0905, D 10.9 mi.; (4) T 0925; (5) B 152°.

FIGURE 1302a.—LORAN-A coverage.

CHAPTER XIII

HYPERBOLIC SYSTEMS

1301. Introduction.—The principles of hyperbolic systems are discussed in article 1109. The present chapter describes the distinctive features of some of the more widely used systems.

1302. Loran is a hyperbolic system of navigation by which difference in distance from two fixed points on shore is determined by measurement of the time interval between reception of pulse-modulated (art. 1016), synchronized signals from transmitters at the two points. The name **loran** is derived from **lo**ng **ra**nge **n**avigation. Since it operates in the 1,750 to 1,950 kc frequency range, both ground waves and sky waves can be used to provide coverage over an extensive area with relatively few stations. Since ships do not transmit, they can use loran without breaking radio silence.

Usually, stations of a pair are located from 200 to 400 miles apart, although they may be as close as 100 miles or as far as 700 miles. At one time several station pairs separated by distances of 1,000 to 1,400 miles were operated. In this **SS loran,** sky waves only were used. Generally, a number of stations are located so as to form a **chain,** with all but the end stations in the group being "double pulsing." In most parts of the coverage area (fig. 1302a), signals can be received from at least two pairs of stations, thus making it possible to obtain a fix by loran alone.

FIGURE 1302b.—A typical train of loran signals from a single transmitted pulse.

The range at which signals are received varies considerably with kind of signal (ground wave or sky wave), route of the signal (over land or water), time of day, atmospheric noise level, geographic region, ionospheric conditions, and possible directional properties of the receiving antenna.

As a general rule, ground-wave coverage during the day extends to about 700 miles in the Atlantic and 800 miles in the Pacific. At night the range is about two-thirds this amount. During daylight hours, relatively few sky-wave signals are received, but at night, signals arrive by so many different paths that a **train** of signals may be received from a single transmitted pulse. Figure 1302b shows a typical scope appearance of such a train near the limit of ground-wave coverage. All of the signals are from a single transmitted pulse. One-hop-E signals are received to a maximum distance of about 1,400 miles. Curvature of the earth prevents their reception at greater distances regardless of power of the transmitter. Beyond this, strong signals may be received by multihop-E waves or by one or more reflections from the F layer. Because of relatively large uncertainties in the lengths of the paths of such signals, and the increased uncertainty of identification, loran tables and charts do not provide facilities for their use. The extending of lines to provide coverage for such signals is not recommended. Reception of reliable signals on some occasions is no assurance that those received at other times can be trusted. Typical variation in appearance of ground-wave and sky-wave signals with time of day is shown in figure 1302c.

The range at which a ground-wave signal can be received is much less if the path is across land than if it is across water. For this reason loran stations are located so that signal paths are as much as possible across water in the direction of greatest importance, and it is desirable that the base line also be across water. The retarding effect varies greatly with the type of land, and is somewhat less when the land is not adjacent to the transmitter. The paths of sky waves are so high that signal strengths are not noticeably affected by land unless it is within about 20 or 30 miles of the transmitter or receiver.

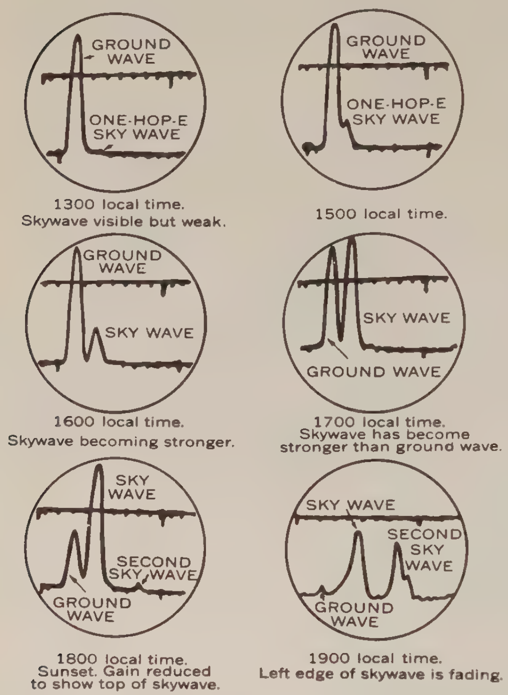

FIGURE 1302c.—Typical variation in appearance of signals with local time.

When the atmospheric noise level is high, signals which may otherwise be usable are lost in the clutter.

The areas near the base line extensions are excluded from the diagram of figure 1302a because of the relatively large error of position for a small error in the time difference reading.

Transmitting antennas are vertical, to avoid directional properties in the horizontal plane. Vertical receiving antennas are desirable for the same reason.

Pulse signals from each pair of stations are transmitted continually. Identification is by means of frequency and **pulse repetition rate** (**PRR**), sometimes called **pulse recurrence rate.** Frequency is identified by channel number, as follows:

Channel No.	*Frequency (kc)*	*Channel No.*	*Frequency (kc)*
1	1950	3	1900
2	1850		

The same frequency can be used for signals from a number of different station pairs, by varying the rate at which the signals are transmitted. Three **basic pulse repetition rates** are available, as follows:

Special (S) ---------------------------- 20 pulses per second,
Low (L) ---------------------------- 25 pulses per second,
High (H) ---------------------------- 33⅓ pulses per second.

The interval between the start of consecutive pulses is 50,000 μs for the special rate, 40,000 μs for the low rate, and 30,000 μs for the high rate. The special rate is retained for future use.

A further breakdown of repetition rate can be accomplished by varying the basic rate slightly. In practice, the difference between consecutive **specific pulse repetition rates** is 100 μs. The specific rates in use are identified by number, starting with 0 for the basic rate and increasing to 7 (eight rates), each higher number *increasing* slightly the rate at which signals are transmitted, and *decreasing* by 100 μs the interval between signals.

Thus, a total of 24 rates is available (if the special basic rate is used) for each of the four frequencies. The same rate may be used in areas so widely separated that

interference is not likely to occur. Each rate is identified by three characters. The first is a number identifying the frequency channel, the second a letter identifying the basic pulse repetition rate, and the third a number identifying the specific pulse repetition rate. Thus, the designation 1L7 indicates frequency channel 1, low basic pulse repetition rate, and specific pulse repetition rate 7. Stated differently, pulses are transmitted at intervals of 39,300 μs, on a frequency of 1950 kc. The term **rate,** implying the number of pulses per unit time, is now used for the full three-character designation, and even for the station pair, their signals, and the resulting hyperbolic lines of position and the tables and curves by which they are represented.

The system described in this article is sometimes called **standard loran** to distinguish it from a 100 kc or 180 kc experimental system called **low frequency loran,** which might provide ground-wave coverage over very great ranges but at reduced accuracy, and **loran-C,** an operational system of great range and high accuracy.

1303. The loran receiver-indicator.—The receiver used for loran signals is similar to that used in ordinary radio communication, except that it has no speaker. Signals are sent to an indicator consisting of a cathode ray tube (art. 1019) and the necessary timing circuits and controls. The major portion of the space needed for the equipment is occupied by the indicator.

On the face of the scope a visible line is produced by the spot of light formed at the point of impact of the moving beam of electrons. This line is divided into two parts, one above the other. The upper part is called the **A trace,** and the lower part the **B trace.** When the controls are set for a given rate, the length of the combined trace, in microseconds, is adjusted to the interval between beginning of pulses. Thus, if a reading is desired on rate 2H5, separate switches are set on 2, H, and 5 to control the frequency, basic pulse repetition rate, and specific pulse repetition rate, respectively. The combined length of the two traces is then 29,500 μs.

When the controls are thus set for a given rate, the signals of that rate appear as vertical deflections which remain stationary because a signal is received at the same part of each trace. Signals of the same basic pulse repetition rate, but of a different specific pulse repetition rate, appear to drift along the trace. Those of a *lower* rate drift to the right and those of a *higher* rate drift to the left. The greater the difference between the given rate and that of the signal, the faster the rate of drift.

The drift is due to the difference between the length of the combined trace and the time interval between the start of consecutive signals. Suppose the indicator is set for rate 2H3. The length of the combined A and B traces is 29,700 μs. A rate 2H2 signal is received at intervals of 29,800 μs. The spot of light forming the traces completes a cycle in 29,700 μs and moves an additional 100 μs before the next 2H2 signal is received. Each succeeding 2H2 signal appears 100 μs to the *right* (motion is left-to-right) of the previous one, and after 297 signals have been received (9 seconds), will have moved the entire length of both traces and returned to its original position. Signals of rate 2H5 will move to the *left* at twice the speed, completing the circuit in 4½ seconds. On some scopes a faint line called a **retrace** (fig. 1304a) can be seen connecting the ends of the two traces. This indicates the path of the spot of light in moving from the end of one trace to the beginning of the next, during a period of about 70 μs. These two periods of 70 μs are part of the total length of the combined trace.

Signals of the same frequency but another basic pulse repetition rate can be seen, but they appear as flickering signals called **ghosts,** which may drift faster than other signals. Each succeeding signal appears at a point 10,000 μs from the preceding one. Thus, every third or fourth signal may appear at about the same place, but the rate at any given place is so slow (approximately six or eight per second) that the deflection does not appear continuous. Since the spot of light is not deflected in most of its pas-

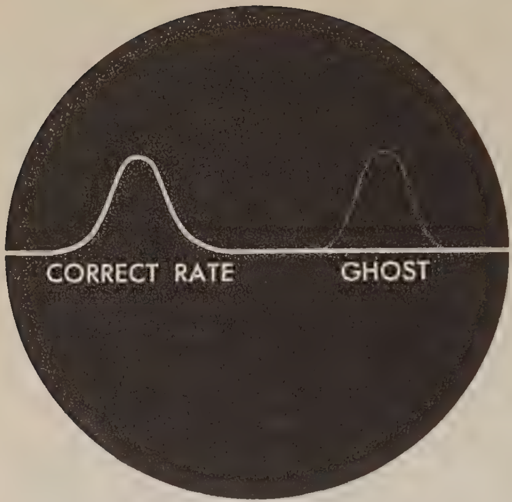

FIGURE 1303.—A signal of the correct basic pulse repetition rate, and a ghost.

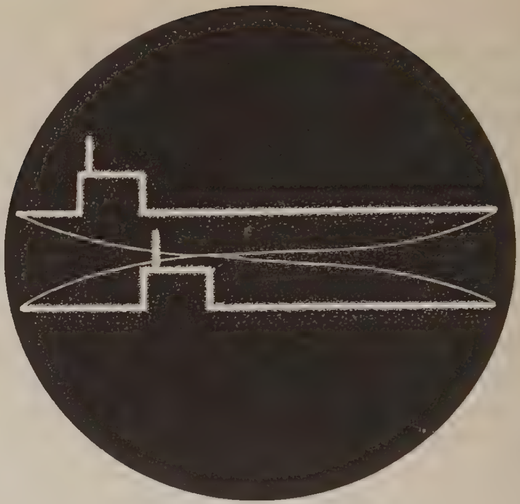

FIGURE 1304a.—The loran scope.

sages, the line appears continuous with the deflection superimposed on it. The appearance of a signal of the correct rate and a ghost is shown in figure 1303.

Strong signals from a frequency channel different from that to which the receiver is tuned may be received. This is called **spillover.** It can be detected by tuning to a different frequency. The frequency at which the signal appears strongest is the correct one.

1304. A loran reading.—Details of loran receiver-indicators differ, but the principles of all are the same. Near the start of each trace of a typical indicator, a portion of the visible line is raised to form **a pedestal,** as shown in figure 1304a. The pedestal of the A trace is fixed, but that of the B trace can be moved to nearly any location along the line.

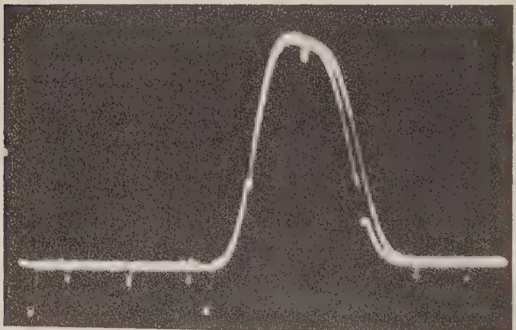

FIGURE 1304b.—Two loran signals properly matched.

When the entire cycle is shown, as in figure 1304a, a signal of 40 μs duration appears as a vertical line, as indicated. It can be moved right or left by means of a switch which temporarily shortens or lengthens the trace by a small amount, causing the signal to drift. After the correct signals have been identified, they are moved, if necessary, until the signal on the A trace is to the *left* of that on the B trace, and **mounted** near the left edge of the pedestal. The pedestal of the B trace is moved until the other signal is mounted near its left edge. By a series of successive magnifications, the left portions of the two pedestals are placed under each other and made to occupy the entire length of the original trace. The two traces are then brought to the same horizontal line, and one signal superimposed over the other, a process called **matching.** Figure 1304b is a photograph of a loran scope with signals properly matched, at greatest magnification. When the signals are matched, they occupy the same position with respect to the two pedestals. The reading is the distance (time separation) between the two pedestals, indicated by *downward* deflections of the traces, or by dial. At greatest amplification, the signals appear as in figure 1303 or figure 1304b.

A loran reading is influenced by three delays introduced in the transmission of the slave signal, as follows:

Half pulse repetition rate delay. A delay equal to half the interval between start of consecutive pulses is introduced so that one signal can be placed on each trace at approximately the same relative position. If this were the only delay, and a receiver were at some point on the center line, one signal would be directly under the other. Without the delay they would appear at the same place on the same trace. This delay is introduced for convenience in making a reading, and is not included in the reading.

Base line delay. If the half pulse repetition rate delay were the only one, readings would increase from zero along the center line to a maximum along each base line extension. Since both master and slave signals look alike, there would be no way of identifying them if the position of the receiver was sufficiently in doubt that it might be on either side of the center line. The base line delay, equal to the length of time needed for a signal to travel the length of the base line (6.18 μs times the length of the base line in nautical miles), causes the readings to increase from zero along the base line extension beyond the slave to a value of twice the base line delay along the base line extension beyond the master station. Because of this delay, the master signal can never appear to the *right* of the slave signal if one signal is placed on each trace.

Coding delay. With a reading near zero one might find difficulty at small scale in determining which signal was left and which was right. An additional delay of 500, 950, or 1,000 μs is provided to increase all readings by this amount. This increases the distance between the master signal and the slave signal when one is on each trace. This delay can be changed easily at the slave transmitter according to a prearranged schedule, to provide some measure of security in time of war.

The reading at any point is equal to 6.18 times the difference in distance (in nautical miles) of the receiver from the two stations (considered negative if nearer the slave), plus the base line delay, plus the coding delay. However, it is not necessary for the navigator to compute readings, because this is done electronically for the whole coverage area of each rate, and the information given in tables and special charts (art. 1307).

1305. Identification and use of various waves.—Travel times of ground waves and various sky waves differ, resulting in reception of a wave train (fig. 1302b) from a single transmitted signal. Since different readings are obtained with different combinations of signals, identification is important.

If a single wave is received, it is almost surely a ground wave. If a ground wave is received as part of a train of waves, it is the first or *left-hand* wave of the group. The position of the receiver relative to the transmitter is some guide. Within a few hundred miles of the station, the first signal is nearly always a ground wave, unless there is intervening land. Near the extreme limit of the coverage area, ground waves are not received. Between these limits is a **critical range** in which the first signal may be either a ground wave or sky wave. This critical range varies with time of day, location, and conditions, as discussed in article 1302. In general, it can be considered to be between about 600 and 900 miles by day, and between about 500 and 700 miles by night.

The *appearance* of the waves can be helpful in their identification. A ground wave is characteristically steady in shape and amplitude. Sky waves may at times appear as steady as ground waves, but such steadiness seldom lasts for more than a few minutes. Because of constant changes in the intensity (reflecting power) and height of the ionosphere (arts. 1007, 1008), and changing phase relationships, sky waves are subject to two characteristic fluctuations.

Changes in intensity, and changing phase relationships, cause changes in the strength of the reflected signal arriving at the receiver. This is called **fading.** It may

be a relatively small change in the amplitude of the signal, or it may be so severe that the signal disappears altogether for a short time. The complete cycle of fading from full strength to minimum and back to full strength may be completed in a period of less than a minute, or it may extend over several minutes.

Changes in height of the ionosphere cause the signal to move right or left along the trace. This motion is not apparent by itself, and equal changes in those parts of the ionosphere reflecting signals from the two transmitters has little effect on the reading. However, a change in intensity may result in shifting the reflecting surface to a higher level. When there are two or more such surfaces a short distance apart, **splitting** of the signal occurs, resulting in more than one crest of the same signal, close together. As the various reflecting surfaces change in intensity and height, the different crests move up and down relative to each other, and change their spacing.

It is good practice to watch the signals for several minutes before making a reading, to be sure of their identification and also to be sure that the *leading* edge of each is visible, for it is this edge, however weak, that should be matched. In a loran area the best practice is to make readings at regular intervals, at least once each hour. The changing appearance with time of day (fig. 1302c) should be helpful in identifying signals. Also, an inconsistency of one loran fix relative to such a series is an indication of possible error of identification.

In general, sky waves are steadier at greater distances from the transmitter, because reflection takes place over a larger area and local variations have less effect, and also because changes in height have less effect upon the length of the path. Therefore, the changes are less extreme. One-hop-E waves are usually steadier than multihop-E waves, or those reflected from the F layer (fig. 1302b). Changes in these signals are so great that intolerably large errors in readings may be introduced. For this reason and the uncertainty in identification of these waves, it is generally considered advisable to limit readings to ground waves and one-hop-E waves.

If a vessel is rolling heavily, all signals of a train may fade somewhat in synchronism with the roll. A weak ground-wave signal may flicker due to random noise signals which appear as continually-fluctuating **grass** on the trace. This momentary change is not easily confused with the slower fading.

For most rates, ground waves should always be matched if available. If ground waves are available from one station, but not from the other, the one-hop-E sky waves of both stations should be matched. In general, multihop-E waves and F waves should not be used. In some instances, where the base line is long, a correction table is provided for matching a ground wave from one station with a sky wave from the other. These corrections are given in the *Loran Tables*, H.O. Pub. No. 221, and in the *Catalog of Aeronautical Charts and Publications*, H.O. Pub. No. 1-V.

1306. Accuracy.—The accuracy of a loran fix depends upon the accuracy of the individual lines of position, and the angle at which the lines intersect (art. 906). The accuracy of individual lines of position depends upon the following factors:

Synchronization of signals. Transmission of loran signals is continuously monitored. Normally, the timing is correct to a fraction of one microsecond, but if the signals get out of synchronization by as much as two microseconds (five microseconds for rate 1L4), either the master or slave signals, or both, are made to **blink** to warn the user of the situation, so that readings on this rate can be avoided until the synchronization is restored, usually in a matter of minutes. Blinking is the shifting of signals right and left about 1,000 microseconds, at intervals of two seconds.

Position relative to transmitting stations. Accuracy is related to the spacing between consecutive lines of position separated by a constant difference of reading, as every microsecond. Lines are most closely spaced, giving highest accuracy, along the base

line between the stations, where an error of one microsecond in the reading produces an error of 0.081 mile, or 492 feet. From this the lines of position fan out, as shown in figure 1109. Near the base line extensions, an error of one microsecond in the reading produces an error of several miles in position. Any ground-wave reading within 25 μs of those of the base line extensions, or any sky-wave reading within 200 μs of those along these lines, should be considered of doubtful value.

Uncertainty in travel time of signal. The time needed for a signal to travel from the transmitter to the receiver depends upon the speed and distance. The speed is so nearly constant that the slight variations involved do not introduce a significant error. The distance between two points, however, depends upon the path followed by the wave. Ground waves follow the curvature of the earth with little variation, so that any error introduced by variations in the path is negligible. This is not true, however, of sky waves. Continual changes in the height and intensity of the ionosphere, as well as tilting of it from the horizontal, produce changes in the length of the path of the radio signal. The increased length of the sky-wave path over the ground-wave path *decreases* with greater distance from the transmitter. Along the center line, where the distance from the two transmitters is the same, the time *difference* is the same for sky waves as for ground waves. At other places, signals from one station are delayed more than those from the other. A **sky-wave correction** is provided in the loran tables and on the loran charts to convert a sky-wave reading to the equivalent ground-wave reading. At distances of 800 miles or more, carefully made sky-wave readings have an average error of about two microseconds. The error increases as the stations are approached, reaching an average value of about seven microseconds at a distance of 250 miles from one of the transmitters. This increased error is partly offset by closer spacing of the lines of position. However, since individual errors can be more than twice the average, the use of sky waves is not generally recommended within 250 miles of either station, and corrections for these areas are not usually tabulated.

Skill in making a reading. The principal source of error in making a reading is in identifying the signals. Patience and judgment are needed to avoid an error due to use of the wrong wave or failure to detect the true leading edge. With a reasonable signal-to-noise ratio, a careful operator should be able to match signals and read the indicator with an error not to exceed one microsecond. With patience, even very weak signals can be matched with an error of not more than a few microseconds.

Alignment of the indicator. Instructions for checking the "alignment" (adjustment) of the indicator are included in the instruction manual provided with each loran receiver-indicator. If the alignment is incorrect, errors may be introduced in the readings.

Incorrect location of transmitters. Computations are made for carefully determined positions of transmitters. However, where isolated stations require independent position determinations, the *relative* positions of the two stations may not be correct, however carefully determined, because of deflection of the vertical (art. 1610). When errors are established through usage, correction chartlets are provided in the loran tables and on loran charts. If the position of one station is found to be in error, the corrections are applicable in radial sectors around that station. If the positions of both stations are incorrect, the pattern is more involved.

Errors in loran tables and charts. Errors due to imperfections in tables and charts are negligible.

Plotting errors. Plotting of loran lines of position requires the same care as plotting of other navigational information if accurate results are to be obtained. For maximum accuracy, a large scale should be used.

1307. Loran lines of position.—Computation of the coordinates of points along various loran lines of position is performed electronically, allowance being made for

the spheroidal shape of the earth. The results are published in H.O. Pub. No. 221, *Loran Tables*. Several rates may be given in each volume, although a change is being made to publication of each rate in a separate pamphlet. From these computations, loran charts are prepared showing the lines of position at suitable intervals. Aeronautical loran charts are available for the entire coverage area, but relatively few nautical loran charts have been published. In areas where nautical loran charts are not available, either the tables or aeronautical charts can be used and the information transferred to the nautical chart.

The loran tables for each rate consist of a small-scale chartlet showing the pattern of the loran lines of position, and any corrections due to incorrect locations of the stations, a sky-wave correction table for one-hop-E waves, and the principal table giving coordinates of points on the lines of position. This table is entered with the loran reading in microseconds, and the latitude *or* longitude. For a line running in a generally north-south direction, the table is entered with the latitude, and the corresponding longitude is taken from the table. For an east-west line, the table is entered with longitude, and latitude is taken from the table. Two such points are thus determined and plotted, usually one on each side of the dead reckoning position. The straight line connecting them is an approximation of a small part of the line of position. Latitude and longitude are given at intervals of whole degrees, half degrees, or quarter degrees, depending upon the degree of curvature of the line. A separate column is given for each tabulated reading, at suitable intervals. An auxiliary tabulation labeled Δ (delta) gives the change in longitude or latitude (to 0ʹ.01) for a one-microsecond change in the reading. The main table should be entered with the *nearest* reading. If interpolation is toward a *smaller* reading, the printed sign of Δ should be reversed. Sample pages of a loran table are given in appendix BB.

Tabulated readings are for ground waves. Sky-wave readings are corrected to the equivalent ground-wave readings before entering the tables. A ground-wave reading is designated T_G, and a sky-wave reading T_S. If a ground wave is matched with a sky wave, the reading is labeled T_{GS} if the ground wave is from the master station, and T_{SG} if from the slave station. A line of position may appropriately be labeled with the time above the line and the identification below the line. It is good practice to give full identification, as 2H3 T_G 2154 or 1L0 T_S 1893 (T_G 1891).

Example 1.—The 1900 DR position of a ship is lat. 42°48ʹ.3 N, long. 62°28ʹ.3 W. About this time loran readings are obtained, as follows:

1859	1H4	T_S 6258
1900	1H2	T_G 2229

Required.—The 1900 fix, using appendix BB.

Solution.—Enter the sky-wave correction table of 1H4 with the dead reckoning position, and find the correction, (+)37, by double interpolation (art. P3). The equivalent ground-wave reading is 6258+37=6295. Enter the 6300 column of the 1H4 table, with the following results:

Long.	*Tab. lat.*	Δ	*Corr.*	*Lat.*
62° W	43°02ʹ.0 N	(+)56	(−)2ʹ.8	42°59ʹ.2 N
63° W	42°43ʹ.1 N	(+)51	(−)2ʹ.6	42°40ʹ.5 N

Next, enter the 2220 column of the 1H2 table, with the following results:

Lat.	*Tab. long.*	Δ	*Corr.*	*Long.*
42°30ʹ N	62°13ʹ.9 W	(−)18	(−)1ʹ.6	62°12ʹ.3 W
43°00ʹ N	62°33ʹ.9 W	(−)16	(−)1ʹ.4	62°32ʹ.5 W

Plot the two points of each line of position, and draw and label the lines. The common intersection of the two lines is the required fix, as shown in figure 1307a.

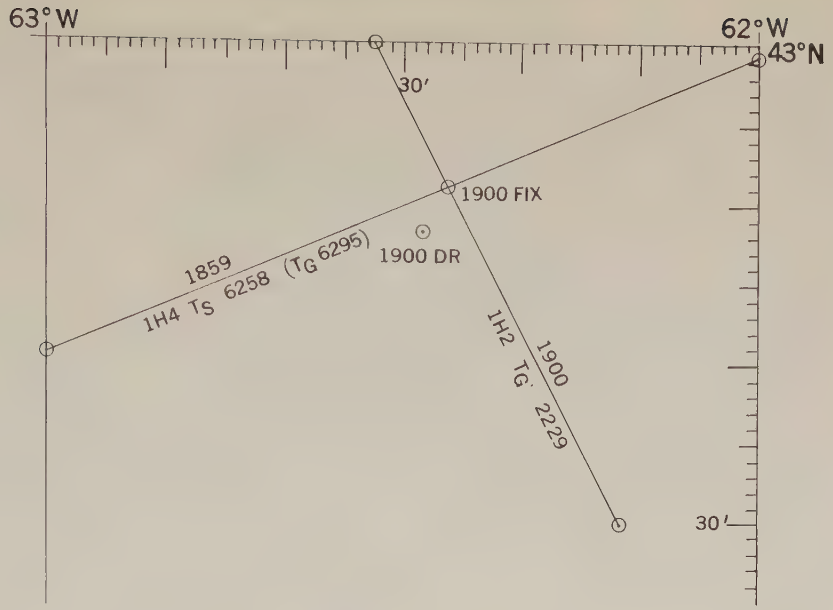

FIGURE 1307a.—A loran fix by table and plotting sheet.

Answer.—1900 fix: L 42°51.′0 N, λ 62°26.′2 W.

It is good practice to watch the scope for a few minutes before making a reading to be sure of correct identification of signals. If this is done for all rates before a reading is made, and sky-wave readings are made first, the intervals between readings can be kept to a minimum, and a skillful operator can often obtain two or three readings, over such a short period of time that the run between them can be ignored. However, where necessary, loran lines of position should be advanced or retired in the same manner as other lines of position (art. 908). If all readings are made within an interval of a few minutes, as customary, the position is considered a fix, rather than a running fix, following the practice of celestial navigation (art. 1707) rather than that of piloting (art. 909).

Figure 1307b is a reproduction, at half scale, of a small part of Hydrographic Office loran chart VRL–201. This small scale was chosen for illustration because it shows the pattern of loran lines in an area that is not congested by a large number of rates. A larger scale is recommended for marine navigation.

The plotted lines are for ground-wave readings. The small numbers near the intersections of printed meridians and parallels are one-hop-E sky-wave corrections at the intersections. On older charts the rate to which each applies is indicated both by color and by superscript. Italic type is used for high basic pulse repetition rate sky-wave corrections, and roman type for the low rate. On newer charts the rate is indicated in full, and both the rate indication and correction are printed in black (as 2L7 + 09), as shown in figure 1307b.

Eye interpolation can be used to locate lines between those printed. Graphs to facilitate such interpolation have been devised. They are available on a card published by the U. S. Navy Hydrographic Office as H.O. Misc. 11,691, and on some loran charts. When the correct position has been located, a short line is drawn parallel to the printed lines. The common intersection of the various lines of position, advanced or retired as necessary, is the fix.

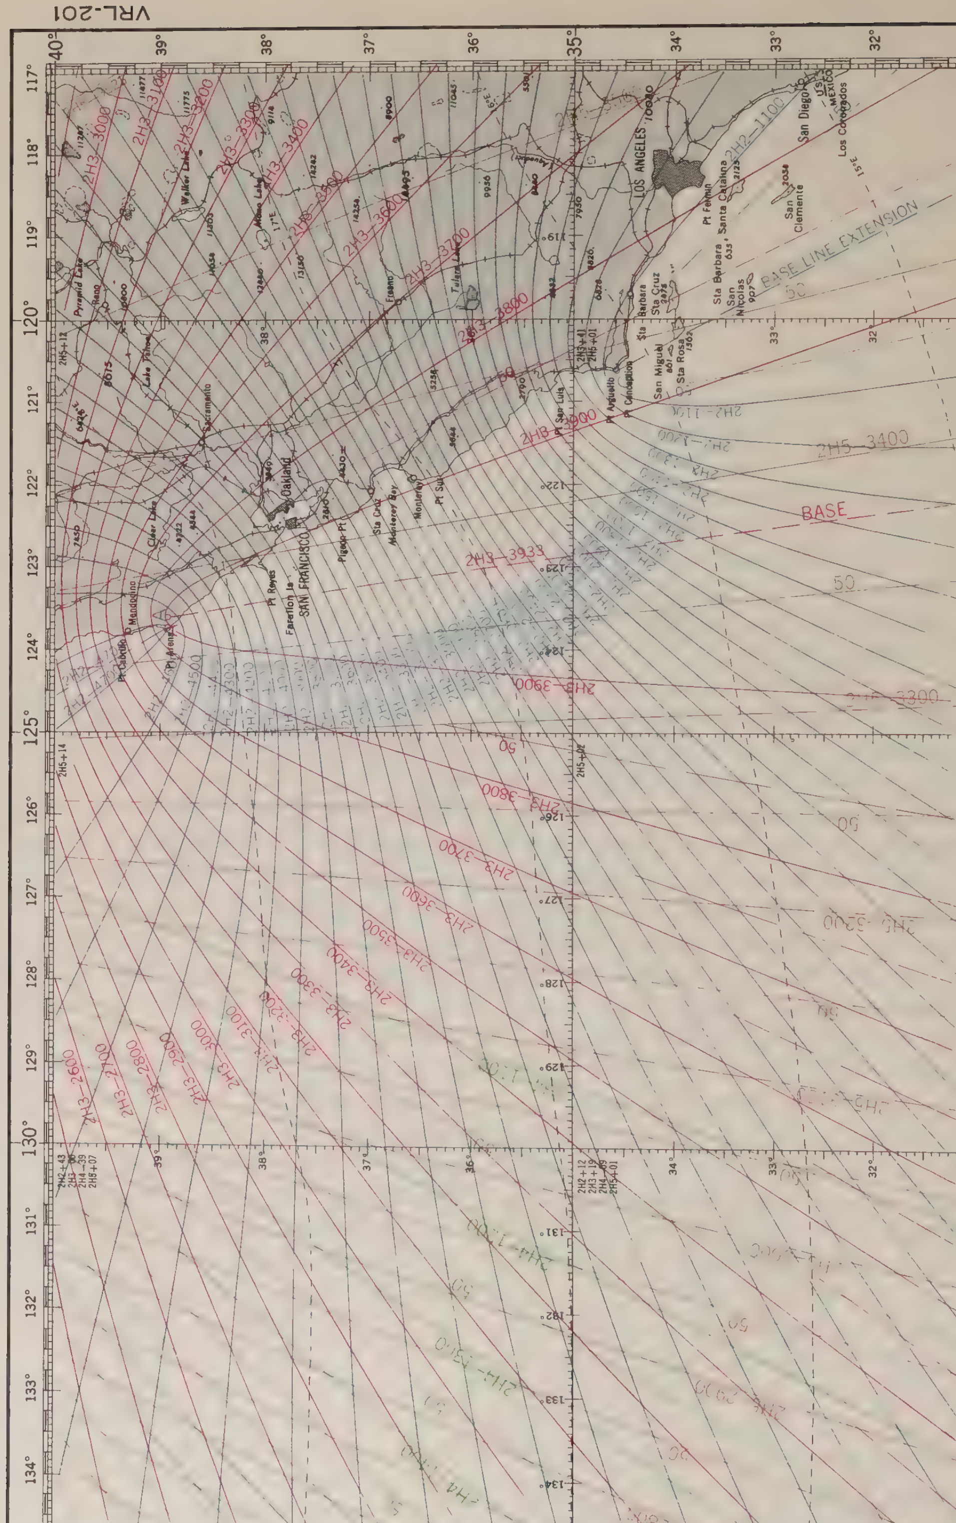

FIGURE 1307b.—Part of Hydrographic Office loran chart VRL-201, reduced 50%.

Example 2.—The 0600 DR position of a ship is lat. 39°06′ N, long. 126°41′ W. About this time loran readings are made in quick succession, as follows:

0559 2H5 T_S 3205
0600 2H2 T_G 4436
0601 2H3 T_G 3225.

Required.—The 0600 fix, using figure 1307b.

Solution.—By interpolation, find the sky-wave correction for the 2H5 reading. This is (+)10 μs, making the equivalent ground-wave reading 3205+10=3215 μs.

Locate the three readings by eye interpolation and draw short lines of position. At their common intersection, read the latitude and longitude.

Answer.—0600 fix: L 38°57′ N, λ 126°20′ W.

Do not expect high accuracy at such small scale.

Where a number of rates are available, only the three or four most useful ones may be shown on the chart. Thus, all or part of useful rates in an area may be omitted. Full information on the reliable coverage areas of all rates is included in the tables.

1308. Gee is a British hyperbolic navigation system in many respects resembling loran (arts. 1302–1307). In both systems the difference of the distances from two transmitters is determined by measurement of the time interval between reception of synchronized pulse-modulated signals (art. 1016). Gee operates in the 20–85 mc frequency range, and is therefore limited essentially to line-of-sight distances. However, refraction and ducting (art. 1006) sometimes extend the range somewhat, and sky waves are occasionally available. Because of this line-of-sight feature, the system is used largely by aircraft. At a height of 30,000 feet the operational range is considered to be about 400 miles.

Transmitting stations are arranged in groups of four, each group being considered a chain. One of the four is a master station controlling synchronization of the group. All stations of a chain operate on the same frequency. Pulses are two to ten microseconds in length. The master transmits at a pulse repetition rate of 500 per second. Two of the slaves transmit at a rate of 250 pulses per second, being synchronized with alternate pulses from the master. The third slave transmits at the rate of $\frac{500}{3}$ per second, being synchronized with each third pulse from the master. Signals from the third slave, and each alternate one from the master, consist of two pulses with a very short interval between them, the two being considered a double pulse constituting a single unit in the pulse repetition rate. Assuming a difference of 700 μs between reception of the master and synchronized slave signals, the sequence of transmitted signals would be as shown in figure 1308a. The spacing of signals at the receiver would depend upon its position relative to the transmitters.

On the scope of the indicator the trace is divided into two parts, as in loran, each part being 2,000 μs in length. When the single-pulse master signal is placed at the left part of the upper trace, the other signals might appear as shown in figure 1308b. The first part of the double-pulse master signal would be directly below the single-pulse master signal. The second part of this double-pulse signal is called a **ghost,** and is used only to identify that master signal used with the second slave. It therefore serves as identification of the first two slaves, which are *downward* deflections on small steps serving the same function as the pedestals of loran (art. 1304).

Since the first two slaves transmit at *half* the rate of the master, one appears on each trace. Each can be matched with the master signal with which it is synchronized, permitting two readings to be made with a single setting. Two magnifications are

provided, one of the **strobe** (the pedestal-like step) and the other of the central portion of the strobe. At greatest magnification, correctly matched signals appear as shown in figure 1308c. The third slave appears alternately on the two traces, but at such a rate that it seems continuous at both places. It is used only when a check is needed on the position determined by the first two slaves, or when these do not provide a reliable fix.

In the gee system, base lines are about 70 to 80 miles long, the appropriate length for the coverage area. Gee is considered a medium-base-line system. Readings

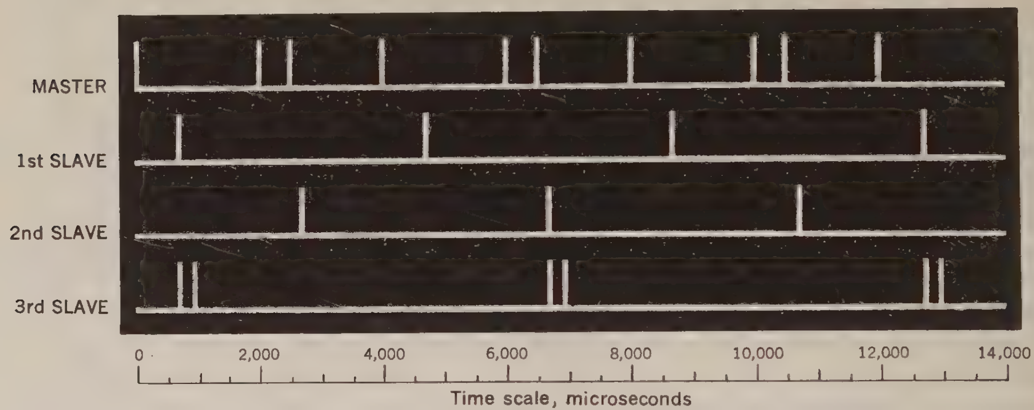

FIGURE 1308a.—Typical sequence of gee signals.

FIGURE 1308b.—Typical appearance of signals on a gee scope.

FIGURE 1308c.—Gee signals correctly matched.

are based upon direct waves. Under good conditions readings can be made with an error not exceeding 2/3 microsecond. As in other hyperbolic systems, maximum accuracy of position occurs along the base line, where a 2/3 microsecond time difference represents a distance of 0.054 mile, or 328 feet.

The Germans at one time used gee under the title **hyperbol.**

1309. Decca is a British hyperbolic navigation system using phase comparison for determining difference of distances from the transmitters. Each chain consists of one master and three slaves. In the ideal installation the slaves are equally spaced around the circumference of a circle 70 to 80 miles in *radius*, with the master at the center.

Each station transmits a continuous wave at a different frequency, the four fre-

quencies for a chain being in the ratio 5, 6, 8, and 9, and the entire group being in the 70–130 kc band. In a typical installation the master uses 85 kc and the slaves 70.833, 113.333, and 127.500 kc. For purposes of identification, these slaves are designated purple, red, and green, respectively.

The receiving unit consists of four receivers, one for each frequency, and circuits for comparing the phase of each slave signal with that of the master signal. If the signals are in phase at the time of transmission, they will also be in phase along the center line of each pair of transmitters. If a receiving unit were at the intersection of the center line and the base line, zero phase difference would be measured. If the unit then moved along the base line, the phase of signals from the station approached would decrease, and that of signals from the other station would increase. At a distance equal to *half* the wave length of the **comparison frequency** (the least common multiple of the two transmission frequencies), the signals would again be in phase, one signal being half a cycle less, and the other half a cycle more than at the center line. A line through all points having this phase relationship would be a hyperbola (assuming a plane surface). A series of such lines could be drawn, each representing a specific phase relationship.

Along the base line, the distance the receiving unit would travel from one in-phase condition to the next would be about 1157, 1446, and 1928 feet, respectively, for the three slaves operating at the frequencies stated above. The distance between in-phase hyperbolas becomes greater as the curves fan out from the base line. The area between any two consecutive in-phase hyperbolas is called a **lane.** Within each lane all phase-difference readings are available. The measurement is shown automatically on a dial called a **Decometer,** one being provided for each slave. If there were no way of determining in which lane the receiving unit was located, the position would need to be known to a high degree of accuracy to resolve the ambiguity. Lane identification is provided by periodic transmission of signals producing a coarser pattern. At short intervals each Decometer identifies the lane.

Each Decometer indicates hundredths of a lane width, and a series of Decca charts having hyperbolas printed in colors agreeing with the identification colors of the slaves permit determination of position by direct plot, as on loran charts (art. 1307). Two slaves provide a fix, the third serving as a check and permitting fixing in areas unfavorable to one of the slaves. To obtain a position, one has merely to read the Decometers and locate the common intersection of the two or three lines indicated. There is no manipulation of dials or matching of signals.

Since the reading is to a precision of 0.01 lane width, the theoretical accuracy is about 12, 14, and 19 feet, respectively, along the base lines between the master and each of the three slaves. The practical accuracy is considerably less, but still very good, the average error along the center line being about as follows, according to The Decca Navigator Company, Ltd.:

Nautical miles from master station	*Line of position errors in yards*	
	Day	*Night*
100	30	100
150	60	250
200	100	500
250	150	800

American tests indicate a somewhat greater error, with further increase with distance from the center line. The greater error by night is due to mingling of sky waves and ground waves. This factor reaches a maximum at a distance of about 350 miles. Signals of reasonable strength have been received at distances as great as 1,000 miles,

but the reliable day-and-night range is considered to be 240 miles. Even if good signals are received at greater distances, good fixes are not available because of the small angle of intersection of the lines of position, unless readings are taken from different chains.

Decca coverage extends over much of western Europe and parts of eastern Canada, the Persian Gulf, and the Bay of Bengal.

1310. Lorac is a hyperbolic system using phase comparison of beat frequencies (art. 1108) to measure difference of distances from transmitters. Each chain consists of a central station and two side stations. Some installations also have an additional station called the reference station. These stations provide two families of curves by which position can be determined.

The continuous-wave signals from the central station and one of the side stations are received at the second side station and also at the vessel. At each receiver, the two signals are combined to obtain a beat frequency signal in the audio frequency range (art. 1003). At the second side station, the beat frequency signal is used to modulate (art. 1016) the carrier wave of the transmitter at that station. This transmitter then sends a phase wave signal to the vessel. This received phase wave signal is compared with another phase wave signal produced at the vessel. The signal produced at the vessel is obtained from signals received from the central station and the first side station. The phase difference of these two phase wave signals varies with the position of the vessel, and depends on the difference in distances from the central station and the first side station. Thus, phase differences determine a family of hyperbolas. A second family of hyperbolas is produced similarly but from signals originated from the central station and the second side station.

As in Decca (art. 1309), the readings appear automatically and continuously on dials. Charts showing the lines of position are needed. Because of the frequencies used, in the 1,700 to 2,500 kc region, the lanes are very narrow, providing accuracies of the order of three feet along the base lines. However, the system does not provide a method of lane identification. It is intended primarily for use in surveying, where the survey vessel starts from a known position. *Changes* in lane are indicated automatically.

The name **Lorac** is derived from **lo**ng **r**ange **ac**curacy. It is intended for use for distances up to 100 to 150 miles by day and 75 to 100 miles by night. Accordingly, the base lines are about 35 miles long. The intended distances are considered long range for the surveying accuracy claimed.

1311. Hyperbolic Raydist is basically similar to Lorac (art. 1310), but differs in several respects. Raydist places one of the transmitters at the mobile station (the vessel), and uses frequency modulation (art. 1016) for relaying the audible signal. Indication can be provided at either the mobile station or one of the fixed stations, but a limited number of mobile stations can be accommodated simultaneously. The frequency range is 1,600 to 2,500 kc, although Raydist can also be used in the 100–150 kc and 30–40 mc regions. An accuracy of 25 feet has been attained at 50 miles. Under favorable conditions readings can be obtained at distances as great as 250 miles. As with Lorac, hyperbolic Raydist does not provide lane identification.

Pure-range Raydist is discussed in article 1214.

1312. Consol (art. 1206) is a short-base-line hyperbolic system providing a rotating pattern of dot-dash signals. Because of the short base line and the long ranges at which the signals are available, the system is used as a directional one.

1313. Sofar is a hyperbolic system using sound transmissions in the ocean. The speed of sound in sea water generally decreases with depth until a minimum is reached, below which the speed increases (art. 3503). The existence of such a minimum-speed

level permits transmission of sound over great distances, a range of more than 3,000 miles having been achieved. If a sound, as that of an explosion, is created in or near the minimum-speed level, and microphones are located at the correct depth, a single signal may be received at several widely spaced listening stations. The differences in time of reception at these stations define hyperbolas. The origin of the sound can be located by reference to a chart on which the hyperbolas have been printed. The name **sofar** is derived from **so**und **f**ixing **a**nd **r**anging.

Sofar was developed by the U. S. Navy, for possible use in search and rescue operations. One set of four sofar listening stations has been installed in the California-Hawaii area for experimental purposes. A small depth charge, dropped overboard by the craft, explodes at the proper depth. The time of reception of the signal at the four stations is automatically timed to an accuracy of about 0.1 second. Comparison of the times at the various stations provides readings which can be translated into position by reference to a sofar chart. Location of the stations is such that position can be determined within an elongated area about one and one-half miles wide and four miles long. About 20 minutes are needed for the sound to travel 1,000 miles. At this distance, a signal is heard over a period of about 12 seconds, gradually building up intensity to a maximum, with a sharp cut-off announcing the arrival of the direct signal, the instant of time measurement.

An intervening obstruction such as an island or seamount produces "shadows" which interfere with reception of sofar signals. One reason for selection of the California-Hawaii area as the site for the first installation is its freedom from obstructions.

Rafos ("sofar" spelled backwards) is the reverse of sofar, sound signals being produced at the shore stations and the differences in reception times being determined at the vessel, using a microphone lowered to the correct depth.

1314. Omega is an experimental, very low frequency, hyperbolic navigation system. The predicted fix accuracy of this system is 0.5 mile or better at a range of 5,000 miles. The basic system will have lanes approximately 15 miles wide over most of the coverage area. Lane identification can be provided by the use of a second frequency.

Problems

1307a. The 0630 DR position of a ship is lat. 42°52′.2 N, long. 62°28′.5 W. The ship is on course 330°, speed 20 knots. About this time loran readings are obtained, as follows:

0621	1H4	T_S	6254
0630	1H2	T_G	2193

Required.—The 0630 fix, using appendix BB. (Plot can be made directly on fig. 1307a.)

Answer.—0630 fix: L 42°50′.3 N, λ 62°32′.0 W.

1307b. The 2000 DR position of a ship is lat. 35°26′ N, long. 125°29′ W. About this time loran readings are made in quick succession, as follows:

1958	2H5	T_S	3115
2000	2H2	T_G	3356
2002	2H3	T_G	3523

Required.—The 2000 fix, using figure 1307b.

Answer.—2000 fix: L 35°29′ N, λ 128°25′ W.

PART FOUR

CELESTIAL NAVIGATION

PART FOUR

CELESTIAL NAVIGATION

CHAPTER XIV

NAVIGATIONAL ASTRONOMY

Preliminary Considerations

1401. Introduction.—**Astronomy** is that science which deals with the size, constitution, motions, relative positions, etc., of celestial bodies. **Navigational astronomy** is that part of astronomy of direct use to a navigator, comprising principally celestial coordinates, time, and the apparent motions of celestial bodies with respect to the earth. Sometimes it is called **nautical astronomy.**

1402. Apparent and absolute motions.—All celestial bodies of which man has knowledge are in motion. Since the earth itself is one of these moving bodies, the motion of other bodies, as seen by an observer on the earth, is **apparent motion.** If the earth were stationary in space, any change in the position of another body, relative to the earth, would be due only to the motion of that body. This would be **absolute motion,** or motion relative to a fixed point. But since it has been impossible to identify a fixed point in space, all motion of which man is aware is apparent, made up of a combination of the movement of the other body and the motions of the observer. A person without suitable instruments is not aware of motion in the line of sight, and therefore only motions across the line of sight are observed.

Since all motion is relative, one should be cognizant of the position of the observer when motions are discussed. When one speaks of planets following their orbits around the sun, he is placing the observer at some distant point in space, usually one of the poles of the ecliptic (art. 1419). When he speaks of a body rising or setting, the observer is on the earth. If he refers to a particular rising or setting, he must locate the observer at a particular point on the earth, since the setting sun for one observer may be the rising sun for another. At the same time it may be crossing the meridian of a third observer.

1403. The celestial sphere.—As one looks at the sky on a dark night, he is not aware of the differences in the distances to the various celestial bodies. They might easily be imagined as being equally distant from the earth, all located on the inner surface of a vast hollow sphere of infinite radius, with the earth at its center. This is the **celestial sphere** (fig. 1403). For most purposes of navigation it can be considered an actuality. Since the navigator is concerned primarily with apparent motion for an observer on the earth, this geocentric universe of Ptolemy (art. 121) is a useful concept. While the motions of various bodies relative to each other are important to the astronomer who predicts future positions of celestial bodies, and perhaps to the navigational scientist who designs navigation tables, the navigator speaks of bodies rising, crossing the celestial meridian, and setting, as though these were absolute motions.

1404. Units of astronomical distance.—The distances between celestial bodies, even those within a single family such as the solar system, are so great that terrestrial units are unsatisfactory to express them. The units commonly used for astronomical distances are:

Astronomical unit (AU), the mean distance between the earth and the sun, approximately 92,900,000 statute miles. The astronomical unit is often used as a unit of measurement of distance within the solar system.

FIGURE 1403.—The celestial sphere.

Light-year, the distance light travels in one year. Since the speed of light is about 186,000 statute miles per *second* and there are about 31,600,000 seconds per year, the length of one light-year is about 5,880,000,000,000 (5.88×10^{12}) statute miles, or 63,300 astronomical units. The light-year is commonly used for expressing distances to the stars and galaxies. Alpha Centauri and its neighbor Proxima, generally considered the nearest stars, are 4.3 light-years away. Relatively few stars are less than 100 light-years away, and the most distant galaxies thus far observed are 1.6 billion light-years away. However, most navigational stars are relatively close. Light travels from the sun to the earth in about 8⅓ *minutes*, and from the moon to the earth in about 1¼ *seconds*.

Parsec, the distance at which the **heliocentric parallax** (difference in apparent position as viewed from the earth and the sun) is 1″. At this distance a star would appear to change its position 2″ among the distant stars, if observed from points 180° apart on the earth's orbit. The name is derived from the first letters of the words **par**allax and **sec**ond. One parsec is equal to about 3.26 light-years Hence, even the

nearest star is more than one parsec away. This unit is used to express distances to stars and galaxies.

The difficulty of illustrating astronomical distances and sizes is indicated by the fact that if the earth were represented by a circle one inch in diameter, the moon would be a circle one-fourth inch in diameter at a distance of five feet, the sun would be a circle nine feet in diameter at a distance of nearly a fifth of a mile, and Pluto would be a circle half an inch in diameter at a distance of about seven miles. The nearest star would be one-fifth the actual distance to the moon.

1405. Magnitude.—The relative brightness of celestial bodies is indicated by a scale of stellar magnitudes. In the *Almagest* (art. 121) Ptolemy divided the stars into six groups according to brightness, the 20 brightest being classified as of the first magnitude, and the dimmest being of the sixth magnitude. In modern times, when it became desirable to define more precisely the limits of magnitude, a first magnitude star was considered 100 times brighter than one of the sixth magnitude, the approximate value of Ptolemy's ratio. Since the fifth root (art. O9) of 100 is 2.512, this number is considered the **magnitude ratio.** A first magnitude star is 2.512 times as bright as a second magnitude star, which is 2.512 times as bright as a third magnitude star, etc. A second magnitude star is $2.512 \times 2.512 = 6.310$ times as bright as a fourth magnitude star. A first magnitude star is $2.512^{20} = 100^4 = 100{,}000{,}000$ times as bright as a star of the twenty-first magnitude, the dimmest that can be seen through the 200-inch telescope.

Brightness is normally tabulated to the nearest 0.1 magnitude, about the smallest change that can be detected by the unaided eye of a trained observer. In the *American Ephemeris and Nautical Almanac* it is given to the nearest 0.01 magnitude, for precise astronomical purposes. All stars of magnitude 1.50 or brighter are popularly called "first magnitude" stars. Those between 1.51 and 2.50 are called "second magnitude" stars, those between 2.51 and 3.50 are called "third magnitude" stars, etc. Sirius, the brightest star, has a magnitude of (—) 1.6. The only other star with a negative magnitude is Canopus, (—) 0.9. At greatest brilliance Venus has a magnitude of about (—) 4.4. Mars, Jupiter, and Saturn are sometimes of negative magnitude. The full moon has a magnitude of about (—) 12.6, but varies somewhat. The magnitude of the sun is about (—) 26.7.

The Universe

1406. The solar system.—The **sun,** the most conspicuous celestial object in the sky, is the central body of the solar system. Associated with it are at least nine principal **planets,** of which the earth is one; a number of **satellites** accompanying some of the planets; thousands of **minor planets** or **asteroids;** multitudes of **comets;** and vast numbers of **meteors.**

1407. Motions of bodies of the solar system.—Astronomers distinguish between the two principal motions of celestial bodies, as follows: **rotation** is a spinning motion about an axis within the body, while **revolution** is the motion of a body in its elliptical **orbit** around another body, called its **primary.** For the satellites, the primary is a planet. For the planets and other bodies of the solar system, the primary is the sun. The entire solar system is held together by the gravitational force of the sun. The whole system revolves around the center of its galaxy (art. 1415) as a unit, and the galaxy is probably in motion relative to its neighboring galaxies. The motion of bodies of the solar system relative to surrounding stars is called **space motion.**

Rotation and revolution may be further classified as **synodic** or **sidereal.** During one synodic *rotation* the body makes one complete turn relative to the sun. On the earth it is called an **apparent solar day.** During one sidereal rotation the body makes

one complete turn relative to the stars. Because of motion of the body in its orbit, a sidereal rotation is either longer or shorter, by a small amount, than a synodic rotation. If both rotation and revolution are in the same direction (in the solar system they are both *east* for most bodies, that is, counterclockwise as seen from above the north pole) the sidereal rotation is shorter. During a synodic *revolution* a celestial body makes one trip around the sun, *as viewed from the earth.* Hence, the earth cannot have a synodic revolution. During a sidereal revolution, a celestial body makes one trip around its orbit with respect to the stars; to an observer on the celestial body, the sun would appear to make one trip around the celestial sphere, with respect to the stars. On the earth this is one year.

All of the planets are believed to be in rotation, although this point is in doubt in the case of Venus and, to a lesser extent, Mercury. The periods of rotation of these bodies have not been established because of the absence of visible surface markings of sufficient constancy to permit measurement. The period of Mercury has been established tentatively as 88 days. The rotation of all planets is from west to east, with the possible exception of Uranus (ū′rȧ·nŭs) (art. 1411).

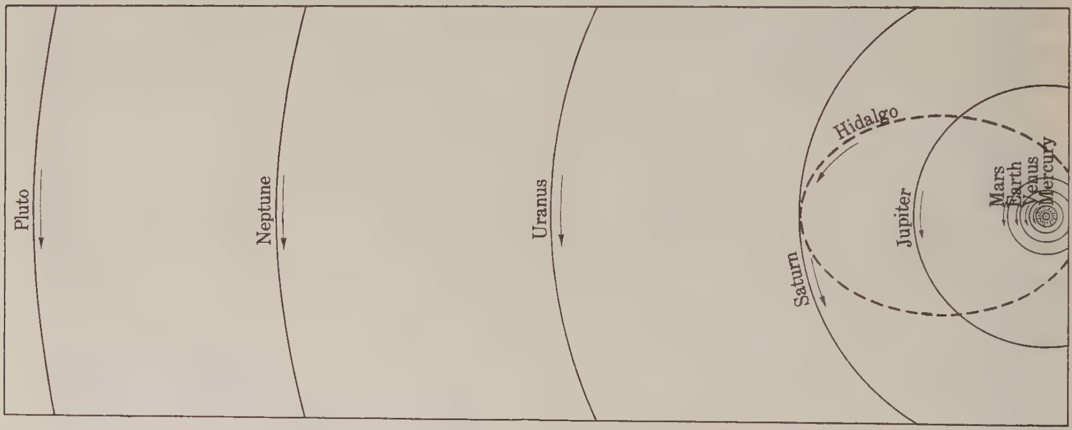

FIGURE 1407a.—Relative size of planetary orbits.

All of the planets revolve around the sun in nearly circular orbits. The flattening or **eccentricity** of the earth's orbit is only 0.017 (zero would be a circle). Some of the minor planets have orbits more eccentric than that of any principal planet (note the orbit of Hidalgo in fig. 1407a). The orbits of comets are highly eccentric. The orbits of all known planets except Pluto are in nearly the same plane, that of the ecliptic (art. 1419). The orbit of Pluto is inclined more than 17° to the ecliptic

The laws governing the motions of planets in their orbits were discovered by Johannes Kepler, and are now known as **Kepler's laws:**

1. *The orbits of the planets are ellipses, with the sun at a common focus.*

2. *The straight line joining the sun and a planet (the* **radius vector***) sweeps over equal areas in equal intervals of time.*

3. *The squares of the sidereal periods of any two planets are proportional to the cubes of their mean distances from the sun.*

In 1687 Isaac Newton stated three "laws of motion," which he believed were applicable to the planets. **Newton's laws of motion** are:

1. *Every body continues in a state of rest or of uniform motion in a straight line unless acted upon by an external force.*

2. *When a body is acted upon by an external force, its acceleration is directly proportional to that force, and inversely proportional to the mass of the body, and acceleration takes place in the direction in which the force acts.*

3. *To every action there is an equal and opposite reaction.*

From Kepler's laws and his own, Newton fashioned a single **universal law of gravitation**, which he believed applied to all bodies, although it was based upon observation within the solar system only:

Every particle of matter attracts every other particle with a force that varies directly as the product of their masses and inversely as the square of the distance between them.

According to these laws the planets remain in their orbits because of a balance of forces between the gravitational attraction of the sun and the tendency of the planet to continue in motion along a straight line. As a planet approaches closer to the sun, its gravitational attraction increases, but by Kepler's second law the speed increases, resulting in stronger centrifugal force. These laws (Newton's laws of motion) have been modified very slightly by Albert Einstein's **theory of relativity.**

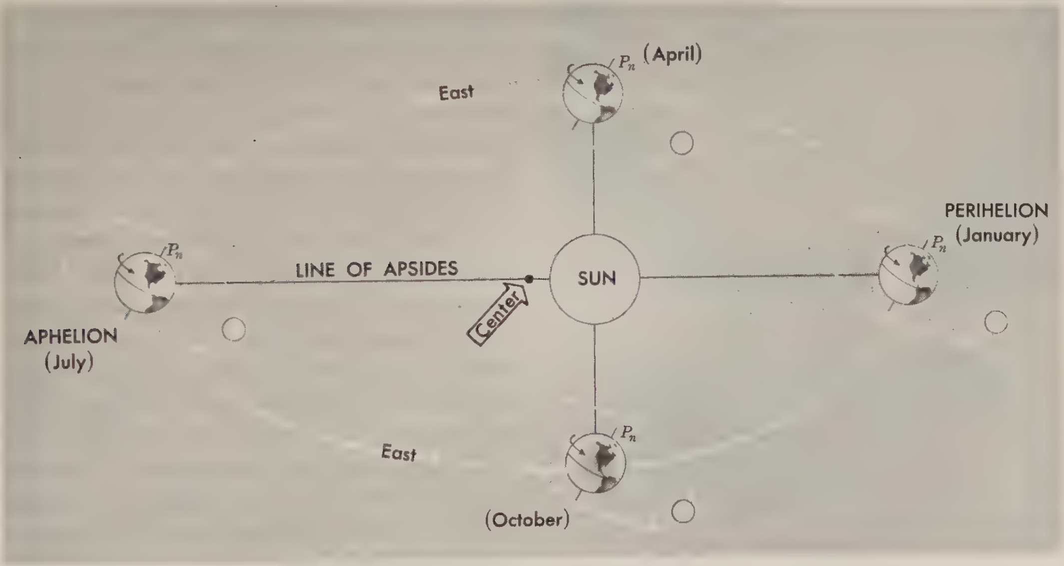

FIGURE 1407b.—Orbits of the earth and moon.

Both the sun and each body revolve about their common center of mass. Because of the preponderance of the mass of the sun over that of the individual planets, the common center of the sun and each planet except Jupiter lies within the sun. The common center of the combined mass of the solar system moves in and out of the sun.

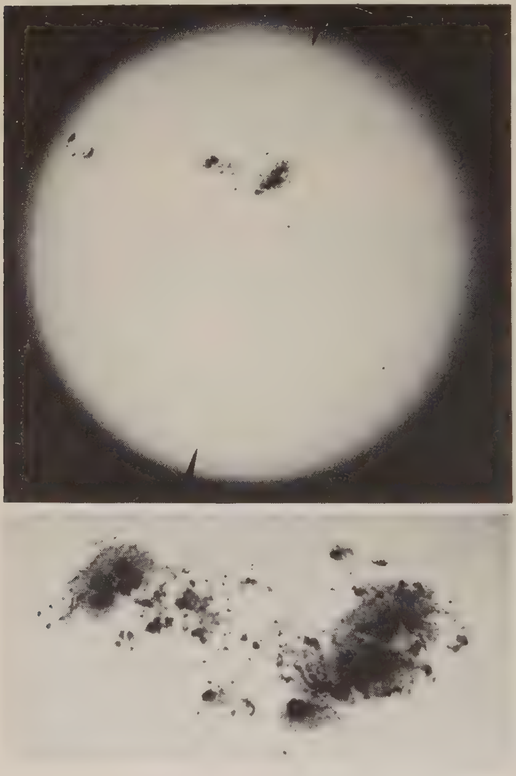
The various laws governing the orbits of planets apply equally well to the orbit of any body with respect to its primary.

In each planet's orbit that point nearest the sun is called the **perihelion.** That point farthest from the sun is called the **aphelion** (ă·fē′lē·ŏn). The line joining perihelion and aphelion is called the **line of apsides** (ăp′sĭ·dēz). In the orbit of the moon, that point nearest the earth is called the **perigee,** and that point farthest from the earth is called the **apogee.** Figure 1407b shows the orbit of the earth (with exaggerated eccentricity), and the orbit of the moon around the earth.

1408. The sun is the dominant member of the solar system because its mass is nearly a thousand times that of all other bodies of the solar system combined. It supplies heat and light to the entire system.

The diameter of the sun is about 866,000 miles. At the distance of the earth, varying between 91,300,000 and 94,500,000 miles, the visible diameter is about 32′. At the closest approach early in January the sun appears largest, being 32′.6 in diameter. Six months later the apparent diameter is 31′.5, the minimum.

Of the various physical features of the sun, one of particular interest is the appearance from time to time of **sun spots** on the surface (fig. 1408). These spots are apparently areas of cooler gas which have risen to the surface and appear dark in contrast to the hotter gases around them. In size they vary from perhaps 50,000 miles in diameter to the smallest spots that can be detected (a few hundred miles in diameter), and perhaps smaller. They generally appear in groups. At the start of each cycle of about 11 years the spots appear at a maximum distance of about 40° on each side of the solar equator. Succeeding spots of the cycle appear progressively closer to the solar equator, until a minimum solar latitude of 5° may be reached. The maximum number of sun spots occurs about midway in the cycle, when the spots are about 16° from the solar equator. The present cycle began in 1954, and should reach maximum activity late in 1959, with a new cycle beginning about 1965. Large sun spots can be seen without a telescope if the eyes are protected, as by the shade glasses of a sextant. Sun spots have magnetic properties. For one cycle all spots north of the solar equator are of positive polarity, and all those to the south are of negative polarity. During the next cycle, which may begin before the last spots of the old cycle have disappeared, the polarity is reversed. Sun spots are related to magnetic storms which adversely affect radio, including radio aids to navigation, on the earth. At such times the **auroras** (art. 2526) are particularly brilliant and widespread.



Courtesy of Mt. Wilson and Palomar Observatories.

FIGURE 1408.—Whole solar disk and an enlargement of the great spot group of April 7, 1947.

The sun rotates on its axis, the period of rotation varying from about 25 days at the solar equator to 34 days at the poles, but this fact has little or no navigational significance beyond its effect upon the changing positions of sun spots relative to the earth. The sun is moving approximately toward Vega at about 12 miles per second, or about two-thirds as fast as the earth moves in its orbit around the sun. The path of the sun toward Vega is called the **sun's way.** This is in addition to the motion of the sun around the center of its galaxy (art. 1415).

1409. Planets.—The principal bodies having nearly circular orbits around the sun are called **planets,** from a Greek word meaning "wandering." They were so named because they were observed to change position or "wander" among the "fixed stars"

which remained in about the same positions relative to each other. Because the sun and moon had a similar wandering motion, the ancients considered them planets, also.

Nine principal planets are known. In order of increasing distance from the sun, these are Mercury, Venus, Earth, Mars, Jupiter, Saturn, Uranus, Neptune, and Pluto. Of these, only four are commonly used for celestial navigation. These are Venus, Mars, Jupiter, and Saturn, sometimes called the **navigational planets.** The two planets with orbits smaller than that of the earth are called **inferior planets,** and those with orbits larger than that of the earth are called **superior planets.** The four planets nearest the sun are sometimes called the **inner planets,** and the others the **outer planets.** Jupiter, Saturn, Uranus, and Neptune are so much larger than the others that they are sometimes classed as **major planets.** Neptune and Pluto are not visible to the unaided eye, and Uranus is barely so, being of the sixth magnitude.

The orbits of the many thousand tiny **minor planets** lie chiefly between the orbits of Mars and Jupiter.

Six of the planets are known to have satellites, a total of 31 having been discovered. Mercury, Venus, and Pluto have no known satellites.

Various items of general interest regarding the planets are given in appendix F.

1410. The earth as a planet.—In common with other planets, the earth rotates on its axis and revolves in its orbit around the sun. These actual motions (discussed in articles 1416 and 1417) are the principal source of the apparent motions of other celestial bodies. Also, the rotation of the earth results in a deflection of water and air currents to the right in the northern hemisphere and to the left in the southern hemisphere. Because of the earth's rotation, the high tides on the open sea lag behind the meridian transit of the moon.

For most navigational purposes, the earth can be considered a sphere, but, like the other planets, the earth is approximately an **oblate spheroid,** or **ellipsoid of revolution,** being flattened at the poles and bulged at the equator. Therefore, the polar diameter is less than the equatorial diameter, and the meridians are slightly elliptical, rather than circular. The dimensions of the earth are recomputed from time to time, as additional and more precise measurements become available. Since the earth is not *exactly* an ellipsoid, results differ slightly when equally precise and extensive measurements are made on different parts of the surface. Hence, different "spheroids" are used for mapping various parts of the earth. That used for charts of North America was computed by the English geodesist A. R. Clarke in 1866. However, since Clarke did not clearly define his units, the U. S. Coast and Geodetic Survey in 1880 considered it desirable to adopt standard values which probably added about 170 feet to the diameter computed by Clarke. In 1880, also, Clarke himself made a new estimate of the size and shape of the earth but this has not been adopted by the United States. Although the Clarke spheroid of 1866 is still used for charting North America, the International Spheroid, based upon work done by Hayford in 1909–10, is considered a slightly better approximation of the size and shape of the earth. According to these calculations, the dimensions of the earth are:

Equatorial diameter $(2a)$	$=7{,}926.694$ statute miles	$=6{,}888.110$ nautical miles
Polar diameter $(2b)$	$=7{,}900.004$ statute miles	$=6{,}864.918$ nautical miles
Mean diameter	$=7{,}917.797$ statute miles	$=6{,}880.379$ nautical miles
$2(a-b)$	$=\quad 26.690$ statute miles	$=\quad 23.192$ nautical miles

$$\text{Oblateness}=\frac{a-b}{a}=\frac{2(a-b)}{2a}=\frac{26.690}{7{,}926.694} \text{ or } \frac{23.192}{6{,}888.110}=\frac{1}{297}.$$

The mean diameter is the average of the polar diameter and two equatorial diameters perpendicular to each other (the three dimensions of the solid), or $\frac{2(2a+b)}{3}$.

Because of unequal distribution of mass near the surface of the earth, the direction of gravity is tilted slightly at various places. The amount of tilt is called **deflection of the vertical** (art. 1610). If the surface of the spheroid is altered so as to be everywhere perpendicular to the direction of gravity, the earth is considered a **geoid.**

The average density (ratio of mass of the earth to mass of an equal volume of water) is 5.517. This is greater than that of any other planet, as far as is known (the density of Pluto has not been determined). The total mass is about 6,600,000,000,000,000,000,000 (6.6×10^{21}) short tons. Virtually all statements regarding the interior of the earth are matters of conjecture, but it is believed that the density increases from about three at the surface to about ten at the center, where the temperature is believed to be close to 5,000° F. The earth is generally considered to be composed of a solid shell several hundred miles thick surrounding a molten interior, but there is some evidence to support the belief that it is solid throughout.

Since gravity acts approximately toward the center of the planet, the direction "up" varies with the observer, being nearly perpendicular to the spheroid at all places. In general, gravity increases with latitude, because both the distance from the center of the earth and the centrifugal force decrease.

One of the conditions considered essential to life on any celestial body is the existence of an **atmosphere.** Whether or not a body has an atmosphere depends at least partly upon its **velocity of escape,** or the speed the molecules of the gas making up the atmosphere must attain to overcome the force of gravity. The velocity of escape of the earth is about 6.94 statute miles per second, at the surface, and decreases slowly with distance from the earth. Since the molecules of the earth's atmosphere rarely exceed this value for a sufficiently long time to escape, the earth has lost relatively little of its atmosphere. The velocity of escape is approximated by a space ship leaving the earth.

The total mass of air surrounding the earth is 5,800,000,000,000,000 (5.8×10^{15}) short tons. This is less than a millionth part of the mass of the entire earth. The average pressure exerted by this envelope of air is 14.696 pounds per square inch. The pressure decreases rapidly with altitude. About half of the atmosphere is within 18,000 feet (about 3.5 miles) of the surface. Breathing begins to be labored at 10,000 feet. Twilight extends to about 50 miles. Meteors generally appear at about 50 miles. Auroral phenomena may be as low as 40 miles, and may extend as high as above 500 miles (fig. 1410).

The lower portion of the atmosphere, the troposphere, is composed of the following elements, in addition to dust and water vapor:

Element	*Percent*
Nitrogen	78.08
Oxygen	20.95
Argon	0.93
Carbon	0.03
Neon	0.0018
Helium	0.000524
Krypton	0.0001
Hydrogen	0.00005
Xenon	0.000008
Ozone	0.000007 (increasing with altitude)
Radon	0.000000000000000006 (decreasing with altitude)

To the precision given, the first four elements total 99.9 percent.

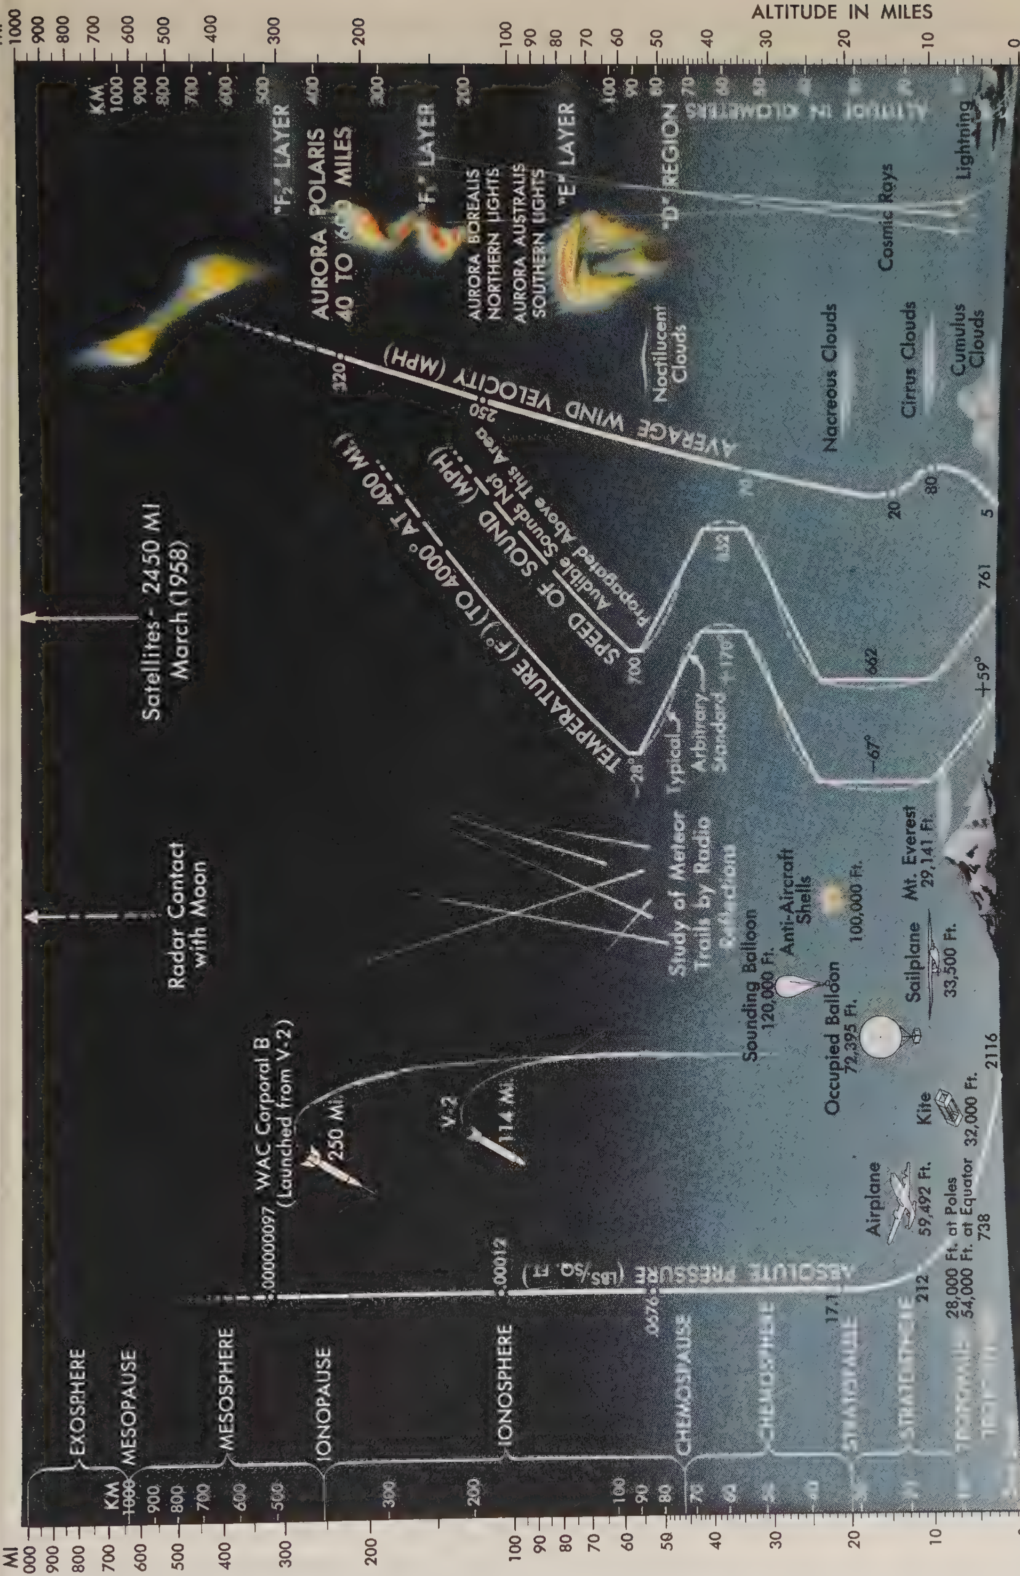


FIGURE 1410.—The earth's atmosphere. (A number of the records indicated have been exceeded since the illustration was prepared.)

Redrawn from art furnished by the Douglas Aircraft Co.

The atmosphere is considered to be composed of several distinctive layers, as follows (fig. 1410):

Layer	*Height* *Kilometers*	*Statute miles*	*Upper limit*
Troposphere	0–11	0–6.8	Tropopause
Stratosphere	11–32	6.8–19.9	Stratopause
Chemosphere	32–80	19.9–45.7	Chemopause
Ionosphere	80–400	45.7–248.5	Ionopause
Mesosphere	400–1000	248.5–621.4	Mesopause
Exosphere	Above 1000	Above 621.4	

In addition to providing life-sustaining oxygen, the atmosphere makes the earth a more habitable place by holding the moisture that produces rain, preventing an excessive change of temperature of several hundred degrees between day and night, shielding the surface from an overdose of cosmic rays, providing a medium to permit sound to occur, and providing the sky and cloud coloring that adds beauty to man's surroundings. If there were no atmosphere, stars would shine with a steady light day and night, the sky would be black, complete darkness would prevail in shadows, and there would be no twilight. It is the atmosphere that produces the refraction which causes celestial bodies to appear elevated in the sky (art. 1613).

1411. Other planets and the minor planets.—**Mercury** in some ways resembles the moon more than it does other planets. Its diameter is only about 50 percent larger than that of the moon and about the same as those of Jupiter's two largest satellites. Like the moon it has little or no atmosphere, and is believed to keep the same side turned toward its primary. Mercury's mass is only four percent that of the earth, and its orbit is so small that the planet is never seen more than about 28° from the sun. It is for this reason that Mercury is not commonly used for navigation. Near greatest elongation (art. 1422) it appears near the western horizon after sunset or the eastern horizon before sunrise. At these times it resembles a first magnitude star, and is sometimes reported as a new or strange object in the sky. As seen from the earth, Mercury goes through all the phases of the moon, and occasionally **transits** (crosses) the face of the sun, appearing as a tiny, dark, inconspicuous dot on the surface. Mercury has no known satellite.

Venus, like Mercury, has no known satellite, goes through the various phases of the moon, and may transit the sun. In size of orbit, sidereal period of revolution, diameter, volume, mass, density, and surface gravity it resembles the earth more than any other planet. Its orbit is more nearly circular than that of any other planet (eccentricity 0.007). At maximum brilliance, about five weeks before and after inferior conjunction (art. 1422), it has a magnitude of about (−)4.4 and is brighter than any other object in the sky except the sun and moon. At these times it can be seen during the day, and is sometimes observed for a celestial line of position. The surface of the planet has not been observed because it is covered by a layer of dense clouds or gases. Its period of rotation is believed to be of the order of four or five weeks.

Mars (fig. 1411) has a diameter only a little more than half that of the earth, and a mass of 11 percent as much, although its density is nearly 72 percent that of the earth. It has a thin atmosphere, but few clouds. Its day is only slightly longer than that on the earth, but its year is nearly twice as long. Being a superior planet (art. 1409), it is seen only in the full or gibbous phase (art. 1423). When nearest the earth, its apparent diameter is about eight times that at conjunction (art. 1422). Mars has two satellites. **Phobos** is about ten miles in diameter and has an orbit only about 50 percent greater than the diameter of Mars. To an observer on Mars it would appear about a third as large as the moon does to an observer on the earth, and would appear

to rise in the west and set in the east, going through three-fourths of its cycle of phases while above the horizon. It would do this twice each day, since its sidereal period of revolution is only about half the period of rotation of Mars. No other natural satellite is known to *revolve* faster than its primary *rotates*. **Deimos** is only about five miles in diameter, and at greatest brilliance would appear as a very bright star. About two days would elapse between rising and setting, during which it would go through the various phases twice.

Jupiter (fig. 1411), largest of the known planets, has more than twice the mass of all other known planets combined. Its density is low and its rotation fast (9^h50^m), resulting in a pronounced equatorial bulge. It is believed to have a dense, solid core, surrounded by lighter material, and a deep atmosphere of ammonia, methane, helium,

FIGURE 1411.—Mars, Jupiter, Saturn, and Pluto. First three photographed with 100-inch telescope, Pluto with 200-inch telescope.

and hydrogen. Two of Jupiter's twelve known satellites are about the same size as Mercury, and may have atmospheres. The four outermost satellites revolve from east to west, opposite to the general direction of revolution within the solar system.

Saturn (fig. 1411) is the only planet having a density less than that of water, yet it has a mass of nearly one-third that of Jupiter, and nearly three times that of all other known planets combined. Its composition is believed to be similar to that of Jupiter. It is more oblate than any other known planet. Perhaps the most interesting feature of this planet is its rings, composed of a great number of small solid particles spread out in three thin, flat rings more than 170,000 miles in diameter. The particles nearest the planet revolve more rapidly than those farther out, the innermost ones completing a revolution in less time than the planet completes a rotation. During half the 29.5-year sidereal period of revolution of the planet one side of the rings is

visible to observers on the earth, and during the second half of the period the opposite side is visible. Saturn has nine known satellites, the outermost one of which revolves from east to west.

Uranus is barely visible to the unaided eye, being of the sixth magnitude. It is a comparatively large planet, and probably is similar in composition to Jupiter and Saturn. The inclination of the equator of Uranus to the plane of the ecliptic is 98°, or 82° if the revolution is considered from east to west. Its five known satellites, all small, revolve in the equatorial plane, in the same direction as that of rotation of the planet.

Neptune is slightly smaller than Uranus, but has greater mass, and a longer period of rotation. Relatively little is known of this remote planet of the eighth magnitude. However, it is known to have two satellites, the larger (probably bigger than the moon) revolving from east to west.

Pluto (fig. 1411) was identified in 1930. It is of the 15th magnitude, and cannot be seen in small telescopes. In all but the 200-inch telescope it appears as a point of light. Its diameter is less than half that of the earth. Its orbit is the most eccentric and has the greatest inclination to the ecliptic of any of the known planets. At perihelion it is closer to the sun than Neptune, and there is some evidence to support the view that it was at one time a satellite of the larger planet.

Minor planets. About 1,500 of these tiny planets have been discovered, but it is estimated that there may be as many as 40,000 bright enough to be seen by the largest telescopes, when they are nearest the earth. The largest, **Ceres,** has a diameter of about 480 miles. All but a few are less than 100 miles in diameter. Since there is no known lower limit, there may be no distinction between minor planets and meteors. The combined mass of all minor planets probably does not exceed 0.1 percent that of the earth. The orbits, of various degrees of eccentricity and inclination to the ecliptic, lie mostly between those of Mars and Jupiter. However, at perihelion some of the minor planets are inside the earth's orbit. The orbit of **Hidalgo** is shown in figure 1407a.

1412. The moon is the only satellite of direct navigational interest, although the satellites of Jupiter were at one time used to determine Greenwich mean time, so that longitude could be found (art. 126). The rotation and revolution of the moon are both west to east, and both are of the same duration, $27^d07^h43^m11\overset{s}{.}5$ with respect to the stars (the **sidereal month**) and $29^d12^h44^m02\overset{s}{.}8$ with respect to the sun (the **synodical month**). Because there is no difference in the periods of rotation and revolution, the same side of the moon is always turned toward the earth. However, about 59 percent of the moon's surface has been seen, due to **libration. Libration in latitude** occurs because the axis of rotation is tilted about $6\overset{\circ}{.}5$ with respect to the axis of revolution. **Libration in longitude** occurs because the speed of revolution varies in accordance with Kepler's second law (art. 1407), while the rotational speed is essentially constant. **Diurnal libration** occurs because of the changing position of the observer relative to the moon, due to rotation of the earth. **Physical libration** is a small pendulum-like rotational oscillation of the moon with respect to its radius vector.

At **perigee** the moon is about 221,000 statute miles from the earth's center, and at **apogee** it is about 253,000 miles distant. The average distance is about 238,862 miles. Because of the relative nearness of the moon, its **geocentric parallax** (difference in position relative to the background of stars, as observed from the surface and center of the earth) is comparatively large. It is a maximum when the moon is on the horizon, when it is called **horizontal parallax.** The **equatorial horizontal parallax** for an observer at the equator, where the maximum radius of the earth is involved, is tabulated in the *Nautical Almanac* and the *American Ephemeris and Nautical Almanac*, and used in sextant altitude corrections given in the nautical and air almanacs. The

parallax varies from a maximum at the horizon to zero at the zenith. The parallax at any altitude is sometimes called **parallax in altitude.** The apparent diameter of the moon is approximately the same as that of the sun, but varies through wider limits. Because the moon is so near, the radius of the earth is an appreciable percentage of the distance between earth and moon, and the apparent diameter of the moon increases a measurable amount as its altitude increases (decreasing the distance from the observer). This apparent increase is called **augmentation** (fig. 1412). A similar effect for the sun is very small.

As with the planets and sun, the moon and earth both revolve around their common center of mass, which is about 2,900 miles from the center of the earth. It is this center of mass that describes the orbit of the earth (and moon) around the sun.

Because of its relative nearness and size, the moon is the principal source of the gravitational attraction that causes tides, although the sun has an appreciable effect, also. The action of these bodies in causing tides is described in article 3103. Because of the frictional action of tides, the rotation of the earth is slowing, the length of the day increasing about 0ˢ001 per century.

On the moon, the day is equal in length to the synodical month (about 29½ days). The earth would remain almost stationary in the sky for an observer on the 41 percent of the moon's surface always visible from the earth, would rise and set at about the same point on the horizon for one on the 18 percent which is sometimes visible, and would never appear for one on the 41 percent not seen from the earth.

Because of the relatively low velocity of escape (art. 1410) on the moon, 1.49 miles per second, this satellite has lost virtually all of its atmosphere, if it ever had one. Even water vapor is nonexistent, indicating an absence of water on the moon. Since there is practically no atmosphere, there is no sound, no twilight, and the temperature change between day and night is sudden and large, changing from perhaps (+) 200° F or more by day to about (−) 250° F by night. The sky is black and stars would be visible in broad daylight. Without water or air the moon has no clouds, no rain, no wind, no life. The numerous conspicuous "craters" are probably the results of meteor falls. There is no atmosphere to slow the meteors, and no erosion to erase the marks they leave. The "seas" are relatively flat plains. Some of the mountains are high, the maximum height on the visible side being nearly 30,000 feet. Gravity on the surface of the moon is about one-sixth that on the surface of the earth. The mass of the moon is about 1/82 that of the earth. The diameter of the moon is 2,160 miles. The size of the moon relative to the earth is greater than that of any other satellite relative to its planet.

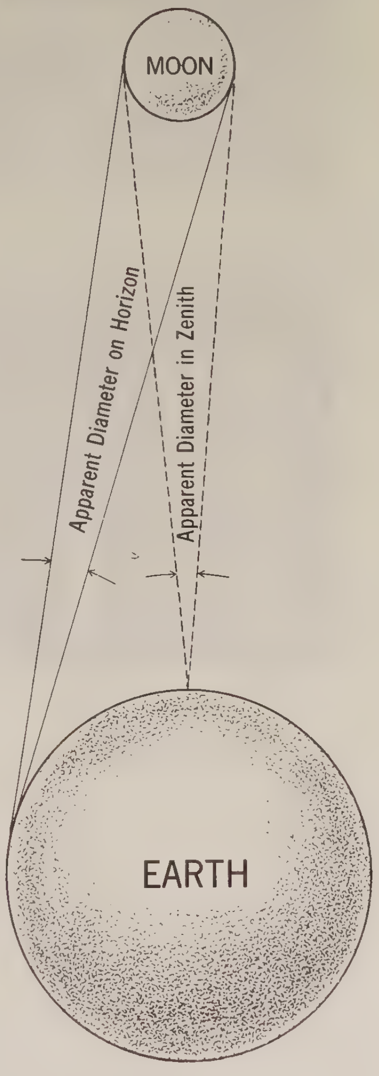

FIGURE 1412.—Augmentation.

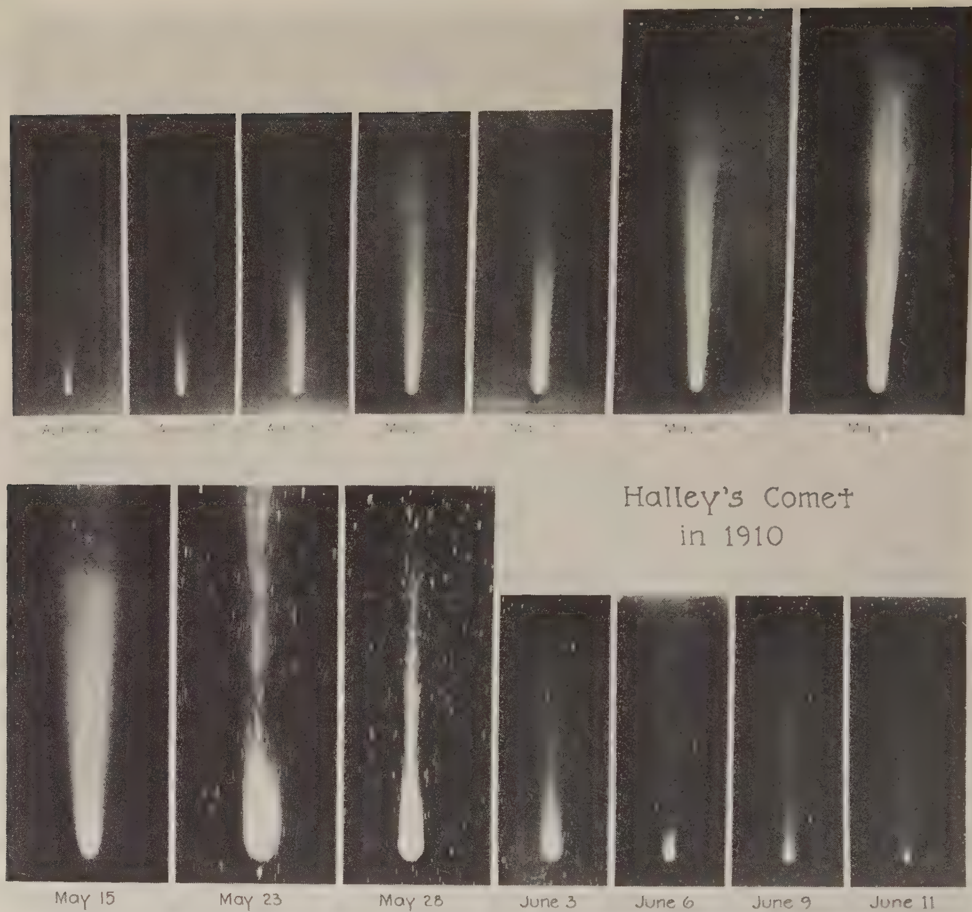
1413. Comets and meteors.—Comets are swarms of relatively small, widely separated, solid bodies held together by mutual attraction. Around this **nucleus,** a



Courtesy of Mt. Wilson and Palomar Observatories.

FIGURE 1413.—Halley's Comet; fourteen views, made between April 26 and June 11, 1910.

more spectacular, gaseous head or **coma** and **tail** may form as the comet approaches the sun. The tail is directed *away* from the sun, so that it follows the head while the comet is approaching the sun, and precedes the head while the comet is receding. The total mass of a comet is very small, and the tail is so thin that stars can easily be seen through it. In 1910 the earth passed through the tail of Halley's comet (fig. 1413) without noticeable effect.

Comets are erratic and inconsistent. Some travel east to west and some west to east, in highly eccentric orbits inclined at any angle to the ecliptic. The shortest period of revolution is about 3.3 years. Some periods are so long that astronomers speculate as to whether some comets may not come in from outside the solar system for a single trip around the sun, and then leave the solar system, never to return. In such a case the orbit would be approximately a **parabola** (art. O34).

Without their tails, which exist only when near the sun, comets are not spectacular. Because of the small size of their nuclei, which shine by reflected light from the sun, comets are visible for only a small part of their period of revolution, and this is the part of most rapid motion, in accordance with Kepler's second law (art. 1407). An average of about five comets is observed each year, and about two-thirds of these are identified as previously observed comets. Very few comets are ever visible without a telescope. The spectacular Halley's comet reached aphelion in 1948 and started back toward the sun. It is expected to reach perihelion about February, 1986.

Because of the great distances of the aphelion of some comets, a few astronomers have speculated that additional planets may exist beyond Pluto. This curiosity is heightened by the attempt of some astronomers to identify a **family of comets** with orbits of nearly equal size, similar to those associated with Jupiter, Saturn, Uranus, and Neptune. Massive planets may influence the orbits of comets, particularly at great distances from the sun.

Meteors, popularly called **shooting stars,** are tiny, solid bodies too small to be seen until heated to incandescence by air friction while passing through the earth's atmosphere. A particularly bright meteor is called a **fireball.** One that explodes is called a **bolide.** A meteor that is not consumed during its fall through the atmosphere, but lands as a solid particle, is called a **meteorite.** These are composed principally of iron, with some nickel, and smaller quantities of other material.

Vast numbers of meteors exist. It has been estimated that an average of about 1,000,000 bright enough to be seen enter the earth's atmosphere each hour, and many times this number undoubtedly enter, but are too small to attract attention. A faint glow sometimes observed extending upward approximately along the ecliptic before sunrise and after sunset has been attributed to the reflection of sunlight from quantities of such material. This glow is called **zodiacal light.** A faint glow at that point of the ecliptic 180° from the sun is called the **gegenschein** or **counterglow.** Comets may be an assemblage of a large number of meteors traveling together, and minor planets (art. 1411) may be larger meteors. **Meteor showers** occur at certain times of the year when the earth is believed to be passing through **meteor swarms,** the scattered remains of comets that have broken up. At these times the number of meteors observed is many times the usual number.

Since such large amounts of this material are in existence, much of it in an orbit near the ecliptic, and since the orbits of most minor planets lie between those of Mars and Jupiter, where astronomers compute the orbit of another planet should be located, it is possible that another planet may have existed there at one time and been disrupted, perhaps by an atomic explosion of hydrogen or other material. The estimated total mass of all meteors, comets, and minor planets would make a small planet, but if the material which has fallen on other planets and satellites, and perhaps some or all of the satellites themselves, are added, a sizeable planet might be accounted for.

1414. Stars are distant suns, in many ways resembling the body which provides the earth with most of its light and heat. Even the nearest star is too distant to be seen as more than a point of light in the largest telescope. If planets, satellites, comets, etc., accompany those distant suns, as they do the one nearby, they have not been detected. However, comparatively dark companions of planetary size are known to accompany some stars. Nonluminous stars may exist, since most of the **radio stars** (points from which radio energy emanates) are not marked by a body visible to observers on the earth. The distance of the stars is so great that none is known to have a **heliocentric parallax** (difference in apparent position as observed from the earth and the sun) of as much as 1″.

Stars differ in size from gaseous giants having diameters greater than that of the *orbit* of the earth, to dense dwarfs which may be no larger than the major planets. Although the size and density cover wide ranges, the mass does not differ greatly. Relatively few stars have more than five times or less than one-fifth the mass of the sun, which is also about average in size, density, and temperature. The color varies with the temperature. A very hot star, having a surface temperature of perhaps 20,000° K (Celsius absolute) or more, is bluish-white; while a cooler star, having a temperature of perhaps 2,000° K, is faintly reddish. In *Orion*, blue Rigel and red Betelgeuse, located on opposite sides of the belt, constitute a noticeable contrast.

Under ideal viewing conditions, the dimmest star that can be seen with the unaided eye is of the sixth magnitude. In the entire sky there are about 6,000 stars of this magnitude or brighter. Half of these are below the horizon at any time. Because of the greater absorption of light near the horizon, where the path of a ray travels for a greater distance through the atmosphere, not more than perhaps 2,500 stars are visible to the unaided eye at any time. The 200-inch telescope on Palomar Mountain permits stars as dim as the twenty-first magnitude to be seen. It has been estimated that there are about 1,000,000,000 of this magnitude or brighter. A long-term photographic exposure with the 200-inch telescope permits observation of about twice this number. There is no indication that this is more than a tiny fraction of the total number. However, the average navigator seldom uses more than perhaps 20 or 30 of the brighter stars. Stars which exhibit a noticeable change of magnitude are called **variable stars.** A star which suddenly becomes several magnitudes brighter and then gradually fades is called a **nova.** A particularly bright one is called a **supernova.**

Two stars which appear to be very close together are called a **double star.** If more than two stars are included in the group, it is called a **multiple star;** and if a large number appear in approximately spherical shape, it is called a **globular cluster.** A group of stars moving through space together, but not exhibiting the intimate relationship of a globular cluster, is called an **open cluster.** The Pleiades and some stars of the big dipper (with certain other stars) are examples of open clusters. A group of stars which *appear* close together, regardless of actual distances, is popularly called a **constellation,** particularly if the group forms a striking configuration. Among astronomers a constellation is now considered a region of the sky having precise boundaries so arranged that all of the sky is covered, without overlap. The ancient Greeks recognized 48 constellations covering only certain groups of stars. Modern astronomers recognize 88 constellations. The constellation names and meanings are given in appendix I.

A cloudy patch of matter in the heavens is called a **nebula** (plural *nebulae*). If it is within the galaxy of which the sun is a part, it is called a **galactic nebula;** if outside, it is called an **extragalactic nebula.**

Stars rotate on their axes, and revolve around the center of their galaxy, in addition to influencing and being influenced by surrounding stars. Motion of a star through space, like that of any celestial body, is called **space motion.** That component in the line of sight is called **radial motion;** while that component across the line of sight, causing a star to change its apparent position relative to the background of more distant stars, is called **proper motion.**

1415. Galaxies.—A great number of the nebulae have been identified as extragalactic, and as telescopes became more powerful, it was discovered that these small cloudy patches are groups of stars, in many ways resembling the group of stars of which the sun is a part. Each such vast assemblage of stars constitutes an island universe as widely separated from others, comparatively, as individual stars in one group. Such a group is called a **galaxy.** It was not until well within the twentieth century that the sun was recognized as a part of such a galaxy, the **Milky Way.** In a galaxy the stars tend to congregate in groups called **star clouds** arranged in long spiral arms. The spiral nature is believed due to revolution of the stars about the center of the galaxy, the inner stars revolving more rapidly than the outer ones (fig. 1415). At the position of the sun, about two-thirds of the way out from the center, and nearly midway between "top" and "bottom," the period of revolution is about 200,000,000 years at the present speed of about 175 miles per second. This is nearly ten times the speed of the earth in its orbit. An average estimate of the size of a galaxy is that it is about 100,000 light

years in diameter, 15,000 light years thick at the center, and 5,000 light years thick near the outer edge, and that it contains perhaps 100,000,000,000 stars. This is about 100 times the number of stars that can be seen through the 200-inch telescope. Within the radius of 1,600,000,000 light years that man is able to penetrate there are perhaps 100,000,000 galaxies, although only a small fraction of this number has been actually observed.

The galaxies which have been discovered are observed to congregate in groups, somewhat similar to stars in a galaxy. Whether the part seen is but a small portion of a larger unit too vast to be seen with present instruments has not been established. Development work is being done to attempt to adapt the electron microscope for use with the telescope. By this means man hopes to see much more of what surrounds him in space, and perhaps to answer some of the questions which confront him.

Apparent Motion

1416. Apparent motion due to rotation of the earth is much greater than any other observed motion of celestial bodies. It is this motion that causes celestial bodies to appear to rise somewhere along the eastern half of the horizon, climb to maximum altitude as they cross the meridian, and set along the western horizon, at about the same point relative to due west as the rising point was to due east. This apparent motion along the daily path, or **diurnal circle,** of the body is approximately parallel to the plane of the equator. It would be exactly so if rotation of the earth were the only motion, and the axis of rotation of the earth were stationary in space (arts. 1417 and 1419).

The apparent effect due to rotation of the earth varies with the latitude of the observer. At the equator, where the equatorial plane is vertical (since the axis of rotation of the earth is parallel to the plane of the horizon), bodies appear to rise and set vertically. Every celestial body is above the horizon approximately half the time. The celestial sphere as seen by an observer at the equator is called the **right sphere,** shown in figure 1416a. Several unique relationships of the right sphere are discussed in article 1432.

For an observer at one of the poles, bodies having constant declination neither rise nor set (neglecting precession of the equinoxes and changes in refraction), but circle the sky, always at the same altitude, making one complete trip around the horizon each day. At the north pole the motion is left to right, and at the south pole it is right to left. Approximately half the stars are always above the horizon and the other half never are. This is modified somewhat by actual conditions, a description of which is given in chapter XXV. The **parallel sphere** at the poles is illustrated in figure 1416b.

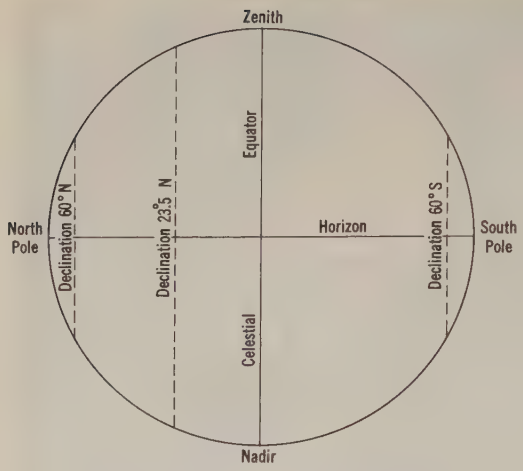

FIGURE 1416a.—The right sphere.

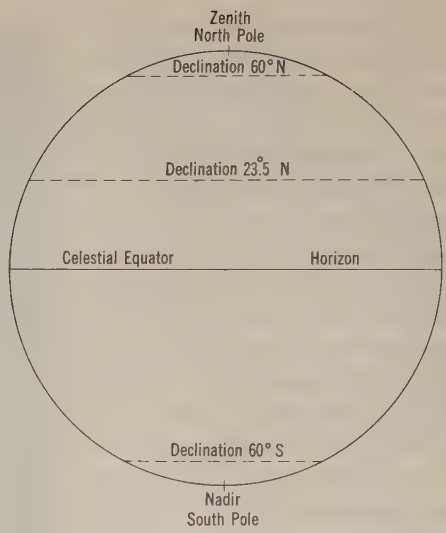

FIGURE 1416b.—The parallel sphere.

Between these two extremes, the apparent motion is a combination of the two. On this **oblique sphere,** illustrated in figure 1416c, **circumpolar** celestial bodies remain above the horizon during the entire 24 hours, circling the elevated celestial pole (art. 1426) each day. The stars of the big dipper and *Cassiopeia* are circumpolar for many observers in the United States. An approximately equal part of the celestial sphere remains below the horizon during the entire day. The southern cross is not visible to most observers in the United States. Other bodies rise obliquely along the eastern horizon, climb to maximum altitude at the celestial meridian, and set along the western horizon. The length of time above the horizon, and the altitude at meridian transit, vary with both the latitude of the observer and the declination of the body. Several useful relationships of the oblique sphere are indicated in article 1432. The relative portions of the celestial sphere that remain either above or below the horizon varies with the latitude, from none at the equator to 100 percent at the poles. At the polar circles (art. 1419) of the earth and beyond, even the sun becomes circumpolar. This is the land of the **midnight sun,** where the sun does not set during part of the summer, and does not rise during part of the winter.

This increased obliquity at higher latitudes explains why days and nights are always about the same length in the tropics, and the change of length of the day becomes greater as the latitude increases. It also explains why twilight lasts longer in higher latitudes. **Twilight** is that period of incomplete darkness following sunset and preceding sunrise. **Evening twilight** starts at sunset, and **morning twilight** ends at sunrise. The darker limit of twilight occurs when the center of the sun is a stated number of degrees below the celestial horizon. Three kinds of twilight are defined, depending upon the darker limit. These are:

Twilight	*Lighter limit*	*Darker limit*	*At darker limit*
civil	0°	−6°	Horizon clear and bright stars visible
nautical	0°	−12°	Horizon vague
astronomical	0°	−18°	Full night

The conditions at the darker limit are relative and vary considerably under different atmospheric conditions.

In figure 1416d the twilight band is shown, with the darker limits of the various kinds indicated. The nearly vertical celestial equator line is for an observer at latitude

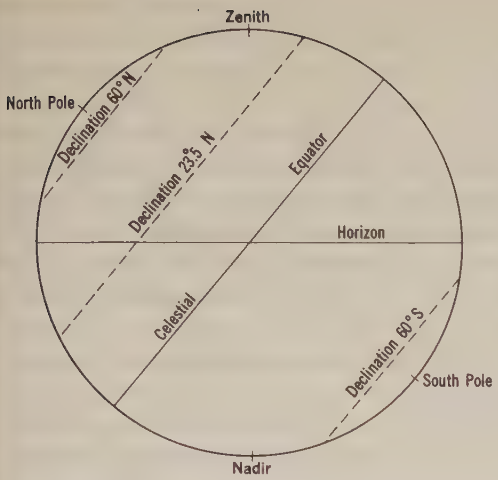

FIGURE 1416c.—The oblique sphere at lat. 40° N.

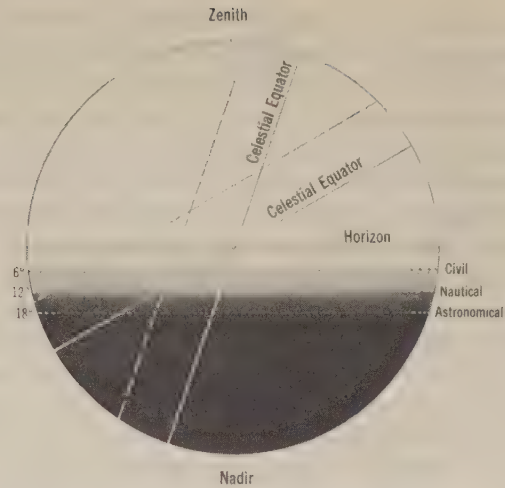

FIGURE 1416d.—The various twilights at lat. 20° N and lat. 60° N.

20° N. The nearly horizontal celestial equator line is for an observer at latitude 60° N. The broken line in each case is the diurnal circle of the sun when its declination is 15° N. The relative duration of any kind of twilight at the two latitudes is indicated by that portion of the diurnal circle between the horizon and the darker limit, although it is not directly proportional to the relative length of line shown, since the projection is orthographic (art. 319). The duration of twilight at the higher latitude is longer, proportionally, than shown. Note that complete darkness does not occur at latitude 60° N when the declination of the sun is 15° N.

1417. Apparent motion due to revolution of the earth.—If it were possible to stop the *rotation* of the earth so that the celestial sphere would appear stationary, the effects of the *revolution* of the earth would become more noticeable. In one year the sun would appear to make one complete trip around the earth, from west to east. Hence, it would seem to move eastward a little less than 1° per day. This motion can be observed by watching the changing position of the sun among the stars. But since both sun and stars generally are not visible at the same time, a better way is to observe the constellations at the same time each night. On any night a star rises nearly four minutes earlier than on the previous night. Thus, the celestial sphere appears to shift westward nearly 1° each night, so that different constellations are associated with different seasons of the year.

Apparent motions of planets and the moon are due to a combination of their motions and those of the earth. If the rotation of the earth were stopped, the combined apparent motion due to the revolutions of the earth and other bodies would be similar to that occurring if both rotation and revolution of the earth were stopped, as discussed in article 1418, but with different timing. Stars would appear nearly stationary in the sky, but would undergo a small annual cycle of change due to **aberration.** The motion of the earth in its orbit is sufficiently fast to cause the light from stars to appear to shift slightly in the direction of the earth's motion. This is similar to the illusion one has when walking in rain that is falling vertically, but appearing to come from ahead due to his own motion. The apparent direction of the light ray from the star is the vector difference (art. O18) of the motion of light and the motion of the earth, similar to that of apparent wind on a moving vessel (art. 3709). This effect is most apparent for a body perpendicular to the line of travel of the earth

in its orbit, for which it reaches a maximum value of 20″.5. The effect of aberration can be noted by comparing the coordinates (declination and sidereal hour angle) of various stars throughout the year. A change is observed in some bodies as the year progresses, but at the end of the year the values have returned almost to what they were at the beginning. That they do not return exactly is due to proper motion (art. 1418), precession of the equinoxes (art. 1419), and **nutation,** which is an irregularity in the motion of the earth due to the disturbing effect of other celestial bodies, principally the moon. **Eulerian motion** is a slight wobbling of the earth about its axis of rotation, often called **polar motion,** and sometimes **wandering of the poles.** This motion, which does not exceed 40 feet from the mean position, produces slight **variation of latitude and longitude** of places on the earth.

By the **calendar,** one year is of 365 days duration for **common years** and 366 days for **leap years.** A leap year is any year divisible by four, unless it is a century year, which must be divisible by 400 to be a leap year. Thus, 1900 was not a leap year, but 2000 will be. This calendar, now in general use, is called the **Gregorian calendar.** Astronomically, the year is not divisible into a whole number of days, and the present system will introduce an error of three days in about 10,000 years. The length of the year with respect to the vernal equinox (art. 1419) is about 365 days, 5 hours, 48 minutes, 46 seconds. This is the **tropical, astronomical, equinoctial, natural,** or **solar year.** Since the vernal equinox is in motion on the celestial sphere (art. 1419), this does not quite agree with the **sidereal year** of about 365 days, 6 hours, 9 minutes, 10 seconds, with respect to the stars. The period of revolution from perihelion to perihelion, about 365 days, 6 hours, 13 minutes, 53 seconds, is called the **anomalistic year.** These values vary slightly from year to year, and progressively over the years, as shown in appendix D.

1418. Apparent motion due to movement of other celestial bodies.—Even if it were possible to stop both the rotation and revolution of the earth, celestial bodies would not appear stationary on the celestial sphere. The moon would make one revolution about the earth each sidereal month (art. 1412), rising in the west and setting in the east. The inferior planets would appear to move eastward and westward relative to the sun, as explained in article 1422, staying within the zodiac. Superior planets would appear to make one revolution around the earth, from west to east, each sidereal period (app. F).

Since the sun (and the earth with it) and all other stars, as far as is known, are in motion relative to each other, slow apparent motions would result in slight changes of the positions of the stars relative to each other. This **space motion** (art. 1414) is, in fact, observed by telescope. That component of such motion across the line of sight, called **proper motion,** produces a change in the apparent position of the star. The maximum which has been observed is that of "Barnard's Star," which is moving at the rate of 10″.3 per year. This is a tenth-magnitude star, and hence not visible to the unaided eye. Of the 57 stars listed on the daily pages of the almanacs, Rigil Kentaurus has the greatest proper motion, about 3″.7. Arcturus, with 2″.3, has the greatest proper motion of the navigational stars in the northern hemisphere. In a few thousand years proper motion will be sufficient to materially alter some familiar configurations of stars, notably the big dipper.

1419. The ecliptic is the path the sun appears to take among the stars due to the annual revolution of the earth in its orbit. It is considered a great circle of the celestial sphere, inclined at an angle of about 23°27′ to the celestial equator, but undergoing a continuous slight change. This angle is called the **obliquity of the ecliptic.** This inclination is due to the fact that the axis of rotation of the earth is not perpendicular to its orbit. It is this inclination which causes the sun to appear to move north and

south during the year, giving the earth its **seasons,** and changing lengths of periods of daylight. This seasonal variation is one of the factors making the earth a desirable place on which to live.

Refer to figure 1407b. The earth is at perihelion early in January and at aphelion six months later. On or about June 21, about ten or eleven days before reaching aphelion, the northern part of the earth's axis is tilted toward the sun. The north polar regions are having continuous sunlight; the northern hemisphere is having its **summer** with long, warm days and short nights; the southern hemisphere is having winter with short days and long, cold nights; and the south polar region is in continuous darkness. This is the **summer solstice.** Three months later, about September 23, the earth has moved a quarter of the way around the sun, but its axis of rotation still points in about *the same direction in space.* The sun shines equally on both hemispheres, and days and nights are the same length over the entire world. The sun is setting at the north pole, and rising at the south pole. The northern hemisphere is having its **autumn,** and the southern hemisphere its spring. This is the **autumnal equinox.** In another three months, on or about December 22, the southern hemisphere is tilted toward the sun and conditions are the reverse of those six months earlier, the northern hemisphere having its **winter,** and the southern hemisphere its summer. This is the **winter solstice.** Three months later, when both hemispheres again receive equal amounts of sunshine, the northern hemisphere is having **spring** and the southern hemisphere autumn, the reverse of conditions six months before. This is the **vernal equinox.**

The word "equinox," meaning "equal nights," is applied because it occurs at the time when days and nights are of approximately equal length all over the earth. The word "solstice," meaning "sun stands still," is applied because the sun stops its apparent

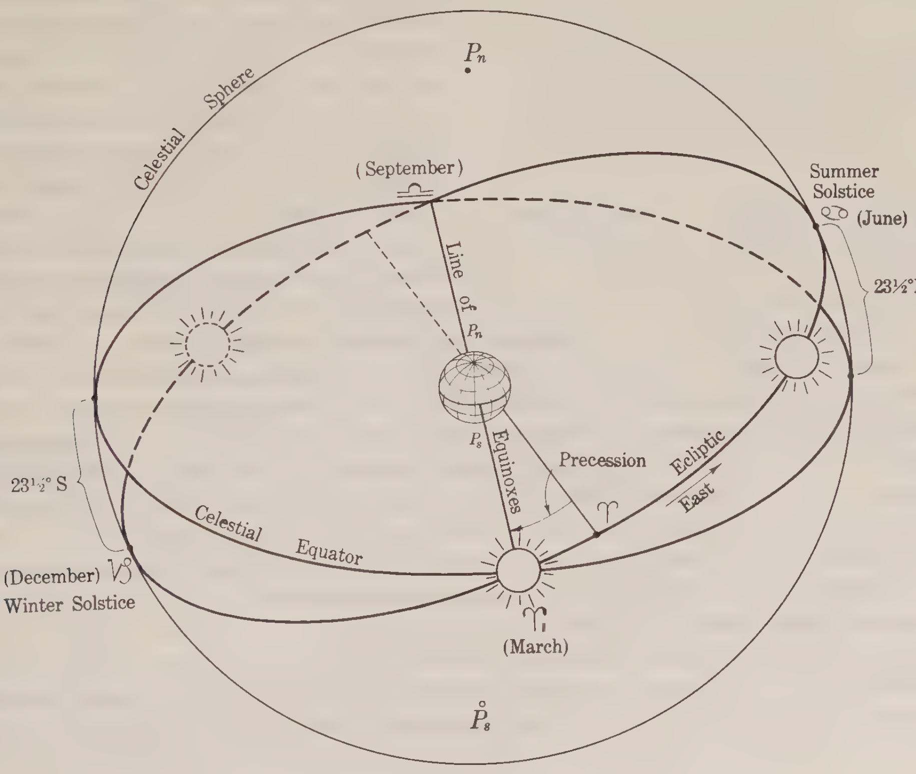

FIGURE 1419a.—Apparent motion of the sun in the ecliptic.

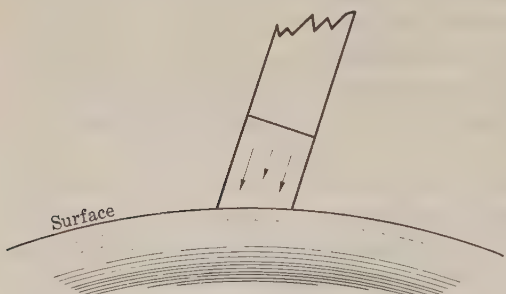
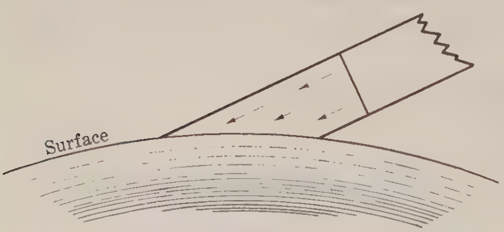
northward or southward motion and momentarily "stands still" before it starts in the opposite direction. This action, somewhat analogous to the "stand" of the tide (art. 3104), refers to the motion in a north-south direction only, and not to the daily apparent revolution around the earth. Note that it does not occur when the earth is at perihelion and aphelion (fig. 1407b). Refer to figure 1419a. At the time of the vernal equinox, the sun is directly over the equator, crossing from the southern hemisphere to the northern hemisphere. It rises due east and sets due west, remaining above the horizon about 12 hours. It is not exactly 12 hours because of refraction, semidiameter, and the height of the eye of the observer. These cause it to be above the horizon a little longer than below the horizon. Following the vernal equinox, the northerly declination increases, and the sun climbs higher in the sky each day (at the latitudes of the United States), until the summer solstice, when a declination of about 23°27′ north of the celestial equator is reached. The sun then gradually retreats southward until it is again over the equator at the autumnal equinox, at about 23°27′ south of the celestial equator at the winter solstice, and back over the celestial equator again at the next vernal equinox.



June 22



December 22

FIGURE 1419b.—Sunlight in summer and winter. Compare the surface covered by the same amount of sunlight on the two dates.

The sun is nearest the earth during the northern hemisphere winter. Hence, it is not the distance that is responsible for the difference in temperature during the different seasons. The reason is to be found in the altitude of the sun in the sky and the length of time it remains above the horizon. During the summer the rays are more nearly vertical, and hence more concentrated, as shown in figure 1419b. Since the sun is above the horizon more than half the time, heat is being added by absorption during a longer period than it is being lost by radiation. This explains the lag of the seasons. Following the longest day, the earth continues to receive more heat than it dissipates, but at a decreasing proportion. Gradually the proportion decreases until a balance is reached, after which the earth cools, losing more heat than it gains. This is analogous to the day, when the highest temperatures normally occur several hours after the sun reaches maximum altitude at meridian transit, and for the same reason. A similar lag occurs at other seasons of the year. *Astronomically*, the seasons *begin* at the equinoxes and solstices. *Meteorologically*, they differ from place to place.

By Kepler's second law, the earth travels faster when nearest the sun, as shown in figure 1419c. Hence, the northern hemisphere (astronomical) winter is shorter than its summer, the difference being about seven days.

Everywhere between the parallels of about 23°27′ N and about 23°27′ S the sun is directly overhead at some time during the year. Except at the extremes, this occurs twice, once as the sun appears to move northward, and the second time as it moves southward. This is the **torrid zone.** The northern limit is the **tropic of Cancer,** and

the southern limit the **tropic of Capricorn.** These names come from the constellations which the sun entered at the solstices when the names were first applied, more than 2,000 years ago. Today, the sun is in the next constellation toward the west, because of precession of the equinoxes, described below. The parallels about 23°27′ from the poles, marking the approximate limits of the circumpolar sun, are called **polar circles,** the one in the northern hemisphere being the **arctic circle** and the one in the southern hemisphere the **antarctic circle.** The areas inside the polar circles are the north and south **frigid zones.** The regions between the frigid zones and the torrid zones are the north and south **temperate zones.**

The expression "vernal equinox," and associated expressions, are applied both to the *times* and *points* of occurrence of the various phenomena. Navigationally, the vernal equinox is sometimes called the **first point of Aries,** because, when the name was given, the sun entered the constellation *Aries*, the ram (♈), at this time. This point is of interest to navigators because it is the origin of measurement of sidereal hour angle (art. 1426). The expressions **March equinox, June solstice, September equinox,** and **December solstice** are occasionally applied as appropriate, because the more common names are associated with the seasons in the northern hemisphere, and are six months out of step for the southern hemisphere.

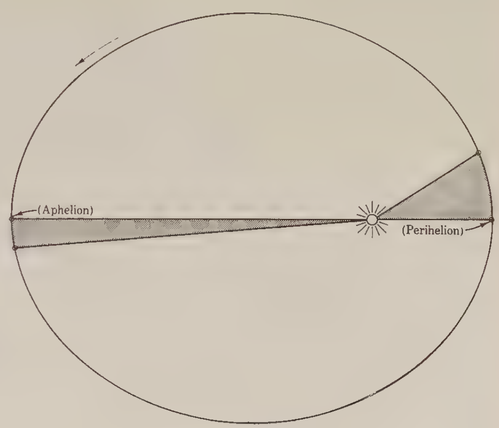


FIGURE 1419c.—Kepler's second law. Since the shaded areas are equal, speed at perihelion is greater than at aphelion.

The axis of the earth is undergoing a precessional motion similar to that of a top spinning with its axis tilted. In about 25,800 years the axis completes a cycle and returns to the position from which it started. Since the celestial equator is 90° from the celestial poles, it too is moving. The result is a slow westward movement of the equinoxes and solstices, which has already carried them about 30°, or one constellation, along the ecliptic from the positions they occupied when named more than 2,000 years ago. Since sidereal hour angle (art. 1426) is measured from the vernal equinox, and declination (art. 1426) from the celestial equator, the coordinates of celestial bodies would be changing even if the bodies themselves were stationary. This westward motion of the equinoxes along the ecliptic is called **precession of the equinoxes** (fig. 1419a). The total amount, called **general precession,** is about 50″27 per year (in 1958). It may be considered divided into two components, **precession in right ascension** (about 46″10 per year) measured along the celestial equator, and **precession in declination** (about 20″05 per year) measured perpendicular to the celestial equator. The annual change in the coordinates of any given star, due to precession alone, depends upon its position on the celestial sphere, since these coordinates are measured relative to the polar axis while the precessional motion is relative to the ecliptic axis (art. 1429).

Due to precession of the equinoxes, the celestial poles are describing circles in the sky. The north celestial pole is moving closer to Polaris, which it will pass at a distance of approximately 28′ about the year 2102. Following this, the polar distance will increase, and eventually other stars, in their turn, will beome the pole star. Similarly, the south celestial pole will some day be marked by stars of the false southern cross.

1420. The zodiac is a circular band of the sky extending 8° on each side of the ecliptic. The navigational planets and the moon are within these limits. The zodiac is divided into 12 sections of 30° each, each section being given the name and symbol ("sign") of the constellation within it. These are shown in figure 1420. The complete list of signs and names is given in appendix A.

The sun remains in each part for approximately one month. When the names were assigned, more than 2,000 years ago, the sun entered *Aries* (♈) at the vernal equinox, *Cancer* (♋) at the summer solstice, *Libra* (♎) at the autumnal equinox, and *Capricornus* (♑) at the winter solstice. Even though this is no longer true because of precession of the equinoxes, *The American Ephemeris and Nautical Almanac* still lists the sun as entering these constellations at the times of the equinoxes and solstices, for this has

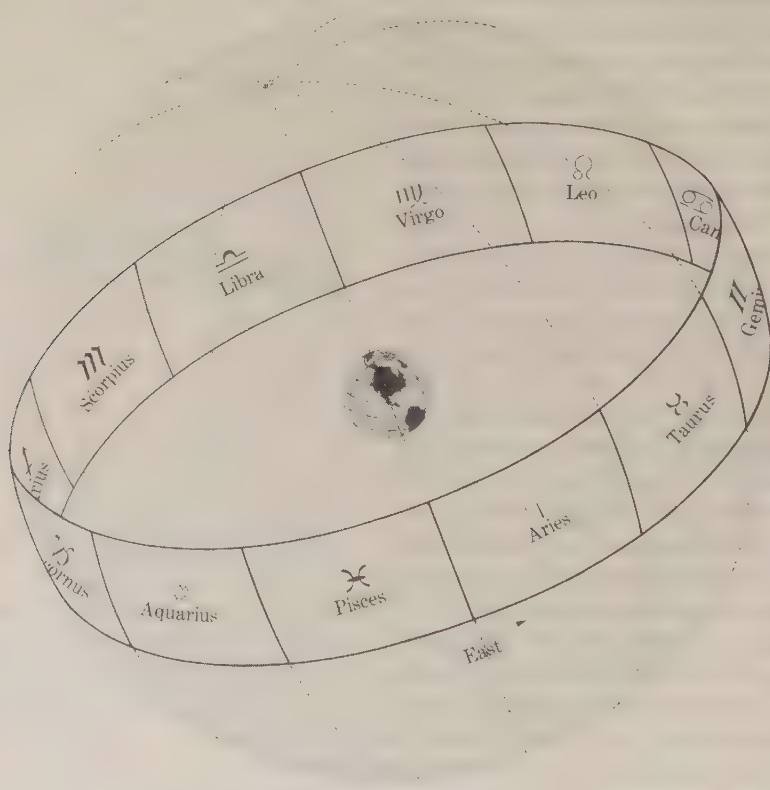

FIGURE 1420.—The zodiac.

come to be their principal astronomical significance. The pseudo science of **astrology** assigns additional significance, not recognized by scientists, to the positions of the sun and planets among the signs of the zodiac.

1421. Time.—Traditionally, astronomy has furnished the basis for measurement of time, a subject of primary importance to the navigator. The **year** is associated with the revolution of the earth in its orbit. The **day** is one rotation of the earth about its axis.

The *duration* of one rotation of the earth depends upon the external reference point used. One rotation relative to the sun is called a **solar day.** However, rotation relative to the **apparent sun** (the actual sun that *appears* in the sky) does not provide time of uniform rate, because of variations in the rate of revolution and rotation of the earth. The error due to lack of uniform rate of revolution is removed by using a fictitious **mean sun.** Thus, **mean solar time** is nearly equal to the *average* **apparent solar time.** Because

the accumulated difference between these times, called **equation of time,** is continually changing, the period of daylight is shifting slightly, in addition to its increase or decrease in length due to changing declination. Apparent and mean suns seldom cross the celestial meridian at the same time. The earliest sunset (in latitudes of the United States) occurs about two weeks *before* the winter solstice, and the latest sunrise about two weeks *after* winter solstice. A similar apparent discrepancy occurs at the summer solstice.

With an increase in precision of the instruments used for measuring the rotation of the earth, it became apparent that the speed of rotation is not constant, increasing slightly during the northern hemisphere spring, and decreasing during the opposite season. Other changes, more erratic, are also noted. These are in addition to the slowing due to tidal action (art. 1412), and are not fully explained. These changes have led the International Bureau of Weights and Measures to adopt the *year* as the basic unit for time, rather than the day, so that daily irregularities can be reduced or eliminated. Time based upon uniform division of the year is called **ephemeris time.** The atomic clock developed by the U. S. Bureau of Standards provides time which in some respects is superior to that based upon the daily rotation of the earth, but is inferior to that based upon the annual revolution of the earth around the sun. This device is based upon the motion of the atoms of ammonia molecules.

If the vernal equinox is used as the reference, a **sidereal day** is obtained, and from it, **sidereal time.** This indicates the approximate positions of the stars, and for this reason is the basis of star charts (art. 2204) and star finders (art. 2210). Because of the revolution of the earth around the sun, a sidereal day is about 3^m56^s *shorter* than a solar day, and there is one more sidereal than solar days in a year. One mean solar day equals 1.00273791 mean sidereal days. Because of precession of the equinoxes, one rotation of the earth with respect to the stars is not quite the same as one rotation with respect to the vernal equinox. One mean solar day averages 1.0027378118868 rotations of the earth with respect to the stars.

In tide analysis, the moon is sometimes used as the reference, producing a **lunar day** averaging 24^h50^m (mean solar units) in length, and **lunar time.**

Since each kind of day is divided arbitarily into 24 hours, each hour having 60 minutes of 60 seconds, the length of each of these units differs somewhat in the various kinds of time.

Time is also classified according to the terrestrial meridian used as a reference. **Local time** results if one's own meridian is used, **zone time** if a nearby reference meridian is used over a spread of longitudes, and **Greenwich** or **universal time** if the Greenwich meridian is used.

The subject of time is discussed in more detail in chapter XIX.

1422. Planetary configurations.—Since the orbit of an inferior planet lies within that of the earth, the planet and sun are nearly in line twice each synodic period of revolution of the inferior planet. When the sun is between the earth and the other planet, that planet is at **superior conjunction.** When the planet is between the earth and sun, it is at **inferior conjunction.** If the orbit of the planet had no inclination to the ecliptic, the planet would cross or **transit** the face of the sun at inferior conjunction and be eclipsed or **occulted** by the sun at superior conjunction. Occasionally this does occur.

Refer to figure 1422, showing orbits of the earth, Venus (an inferior planet), and Mars (a superior planet). As shown, the relative sizes of the orbits are correct, and the relative sizes of the planets are correct, but the planets are too large for their orbits and the sun, and the sun is too large for the orbits of the planets. The earth is considered stationary in its orbit. The positions of Venus are shown at superior and inferior

conjunctions. In moving eastward from one to the other, Venus appears to move to the left of the sun. As observed from the earth, the angle between lines to the sun and a planet, particularly an inferior planet, is called the planet's **elongation,** which may be designated east or west to indicate the apparent position of the planet relative to the sun. As Venus continues along its orbit, its elongation increases slowly until the planet arrives at the point where a straight line from the earth is tangent to its orbit, when the elongation becomes maximum. Here it is called **greatest elongation east.** As Venus continues along its orbit, its elongation decreases rapidly, becoming zero at inferior conjunction. Through the second half of its synodic period its elongation increases rapidly to **greatest elongation west,** and then decreases slowly to zero at the next

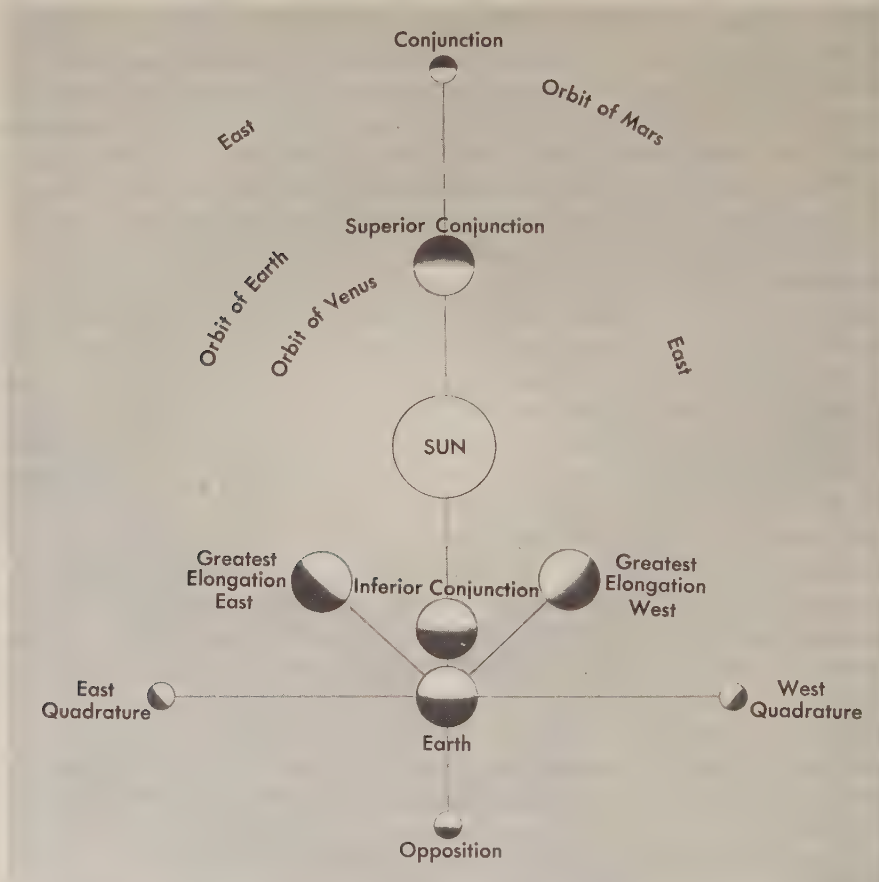

FIGURE 1422.—Planetary configurations.

superior conjunction. The greatest elongation of Venus is about 46°, but varies because its orbit and that of the earth are elliptical, and the phenomenon occurs at different points on the orbits.

The orbit of the planet Mercury lies inside that of Venus, and hence the greatest elongation is not as great, being about 28°. It is because the apparent position of Mercury is never far from the sun that this planet is not considered navigationally important. Since its synodic period of revolution is only 115.9 days, it is at conjunction a little oftener than once every two months. By comparison, Venus is at conjunction a little oftener than once every ten months, having a synodic period of revolution of 583.9 days.

As shown in figure 1422, an inferior planet goes through all phases of the moon (art. 1423), being "full" at superior conjunction, "new" at inferior conjunction, and at "quarter" when it reaches greatest elongation. A telescope is needed to see the phases.

For a superior planet the situation is different. Refer again to figure 1422. When the sun is between the earth and the planet, that planet (Mars in the illustration) is at **conjunction** (☌). The adjective "superior" is not needed because a superior planet, when on the opposite side is *away* from the sun, or at **opposition** (☍) and can never be at inferior conjunction. When its elongation is 90°, a superior planet is at east or west **quadrature** (□), depending upon its apparent position relative to the sun. Since a superior planet has a longer period of revolution than the earth, it *appears* to move westward around the sun, being at conjunction, east quadrature, opposition, west quadrature, and back to conjunction. It is at "full" phase at conjunction and opposition, and gibbous between.

Unless a planet is in the ecliptic, it is not directly in line with the earth and sun at conjunction and opposition. These points are defined as those at which either the sidereal hour angles (art. 1426) or the celestial longitudes (art. 1429) are the same (in the case of conjunction) or 180° apart (at opposition).

The apparent positions of the planets in relation to other members of the solar system, particularly the relationships shown in figure 1422, are called **planetary configurations.** The motions of planets with respect to the sun would be true, generally, with respect to the stars, also, if the earth were stationary in its orbit, as shown. However, because of the earth's motion around the sun, the sun appears to move eastward among the stars. This is usually the direction of apparent motion of the planets, too, and is called **direct motion.** When a planet is near opposition or inferior conjunction, its apparent *westerly* motion relative to the sun is greater than the apparent *easterly* motion of the sun relative to the stars, and the planet appears to move in a *westerly* direction relative to the stars. This is called **retrograde motion.**

The brightest planet in the western sky following sunset is popularly called the **evening star,** and the brightest planet in the eastern sky preceding sunrise is popularly called the **morning star.**

1423. Phases of the moon.—Relative to the sun, the moon makes one complete trip around the celestial sphere each synodical month (about 29½ days). As it does so, it goes through a cycle of aspects or **phases** to an observer on the earth, because the moon, like the planets, shines chiefly by reflected light from the sun. The orbit of the moon is inclined about 5° to the ecliptic, and undergoes a precessional motion called **regression of the nodes.** It is similar to precession of the equinoxes of the earth (art. 1419), and is chiefly responsible for nutation (art. 1417). However, the cycle is completed in a little more than 18 years, as compared with about 25,800 years for the earth.

Because of the small inclination of its orbit, the moon is never far from the ecliptic. At conjunction, when the moon passes nearly between the earth and sun, its illuminated portion is *away* from the earth (*toward* the sun), as shown in figure 1423. (In this illustration, the outer figures show various positions of the moon relative to the earth and sunlight. The inner circle of moons shows the appearance from the earth.) It is then a **new moon,** and may be barely visible because of **earthshine,** which is sunlight reflected from the illuminated side of the earth. To an observer on the moon, the "full earth" would be visible at this time, three and one-half times as great in diameter and nearly 40 times as bright as the full moon appears to an observer on the earth. Since it is at conjunction, the new moon rises, transits the celestial meridian, and sets at approximately the same time as the sun.

A day later the moon has moved about 12°2 eastward of the sun and a thin **crescent** appears on the side toward the sun, with the horns or **cusps** pointing away from the sun.

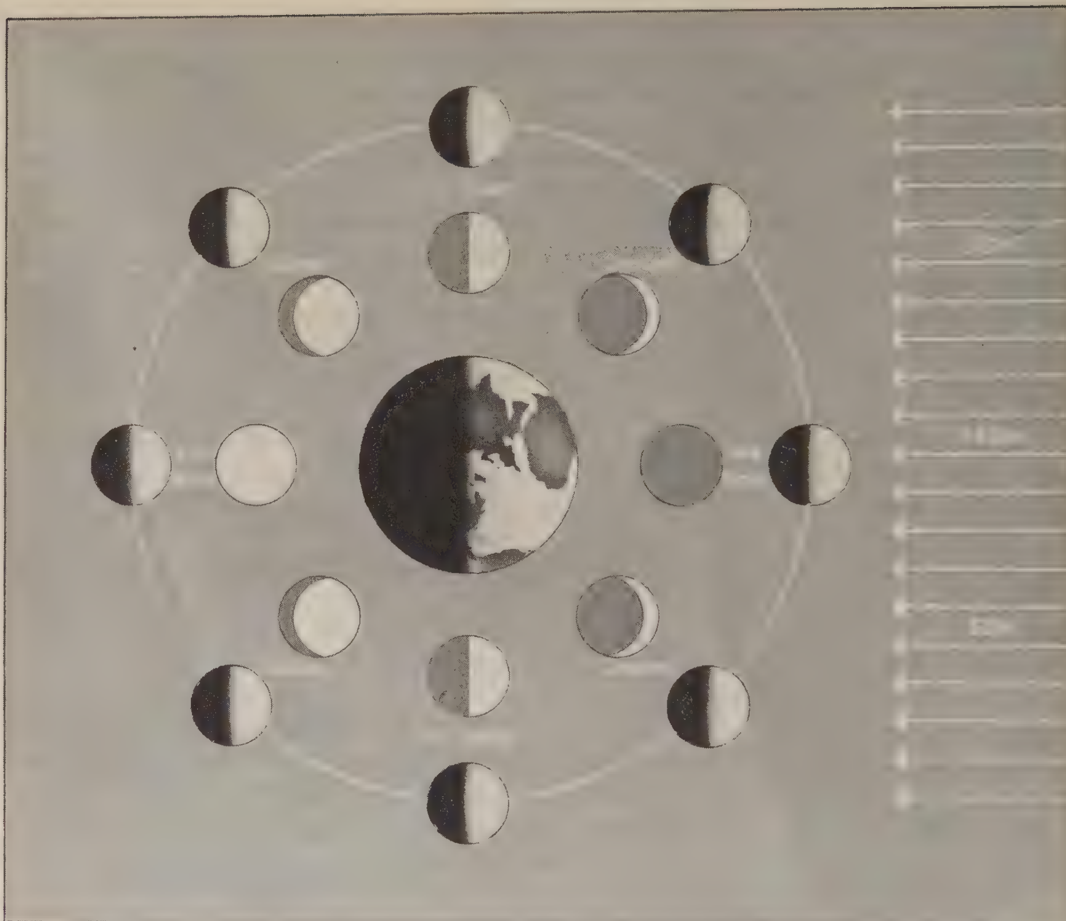

FIGURE 1423.—Phases of the moon. The inner figures of the moon represent its appearance from the earth.

The moon is low in the western sky after sunset. Because of glow from this illuminated portion, and the fact that the side of the earth toward the moon is not quite "full," that part of the moon illuminated by earthshine is not quite as bright. Each day the moon moves approximately 12°2 east, relative to the sun. As it does so, the crescent grows fatter, and the earthshine less conspicuous.

When the moon reaches quadrature, about a week after new moon, it is at **first quarter.** That half of the moon toward the sun is illuminated. The moon is now about 90° or six hours *behind* the sun. It rises about noon, is on the celestial meridian about 6 PM, and sets about midnight.

As the moon continues eastward on successive days, the line separating the illuminated and dark portions, called the **terminator,** moves on across the moon. The moon is now in the **gibbous** phase, which continues until the moon is at opposition, or **full moon.** It now rises about the time of sunset, reaches the celestial meridian about midnight, and sets about the time of sunrise.

On succeeding days the moon again becomes gibbous, and at quadrature it is at **last quarter,** rising about midnight, crossing the celestial meridian about 6 AM, and setting about noon. During the remainder of its cycle the moon again goes through the crescent phase and returns to new moon to start another cycle.

During the first half of the cycle, the moon is **waxing,** and during the second half it is **waning.** The elapsed time since new moon, usually expressed as days and tenths

of a day is called **age of the moon.** Since the moon appears to move *eastward* relative to the sun, crossing the meridian *later* each day, one day each synodical month is without a moonrise, and another is without a moonset.

The times of moonrise and moonset indicated above are approximate only. When the difference between the declination of the sun and moon is considerable, the times given may be in error by as much as several hours, particularly in high latitudes. The times of crossing the celestial meridian vary through smaller limits.

At full moon, the sun and moon are on opposite sides of the ecliptic. Therefore, in the winter the full moon rises early, crosses the celestial meridian high in the sky, and sets late; as the sun does in the summer. In the summer the full moon rises in the southeastern part of the sky (northern hemisphere), remains relatively low in the sky, and sets along the southwestern horizon after a short time above the horizon.

At the time of the autumnal equinox, that part of the ecliptic opposite the sun is most nearly parallel to the horizon. Since the eastward motion of the moon is approximately along the ecliptic, the delay in the time of rising of the full moon from night to night is less than at other times of the year. The full moon nearest the autumnal equinox is called the **harvest moon.** The full moon occurring about a month later is called the **hunter's moon.**

1424. Eclipses.—Because of the inclination of the moon's orbit with respect to the ecliptic, the sun, earth, and moon are usually not so nearly in line at conjunction and opposition of the moon that either the earth or moon passes through the shadow of the other. However, when this does occur, an **eclipse** takes place. Since the sun and moon are of nearly the same apparent size to an observer on the earth, an eclipse is a much more spectacular occurrence than the transit of an inferior planet across the face of the sun, or the occultation of a star or planet by the sun or moon (art. 1422).

When conditions are suitable, the moon passes between the sun and earth, as shown in figure 1424a. If the moon's apparent diameter is larger than that of the sun, the moon being near perigee, its shadow reaches the earth as a nearly round dot only a few miles in diameter. The dot moves rapidly across the earth, from west to east, as the moon continues in its orbit. Within the dot, the sun is completely hidden from view, and a **total eclipse** of the sun occurs. For a considerable distance around the shadow, part of the surface of the sun is obscured, and a **partial eclipse** occurs. In the line of travel of the shadow a partial eclipse occurs as the round disk of the moon appears to move slowly across the surface of the sun, hiding an ever-increasing part of it, until the total eclipse occurs. Because of the uneven edge of the mountainous moon, the light is not cut off evenly, but several last illuminated portions appear through the valleys or passes between the mountain peaks. These are called **Baily's Beads.**

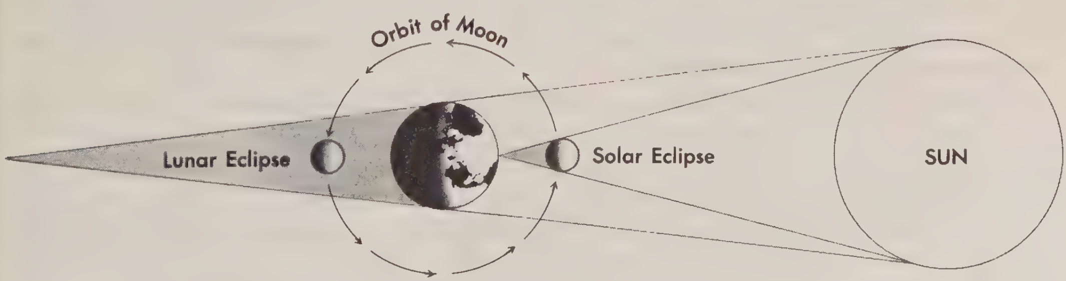

FIGURE 1424a.—Eclipses of the sun and moon.

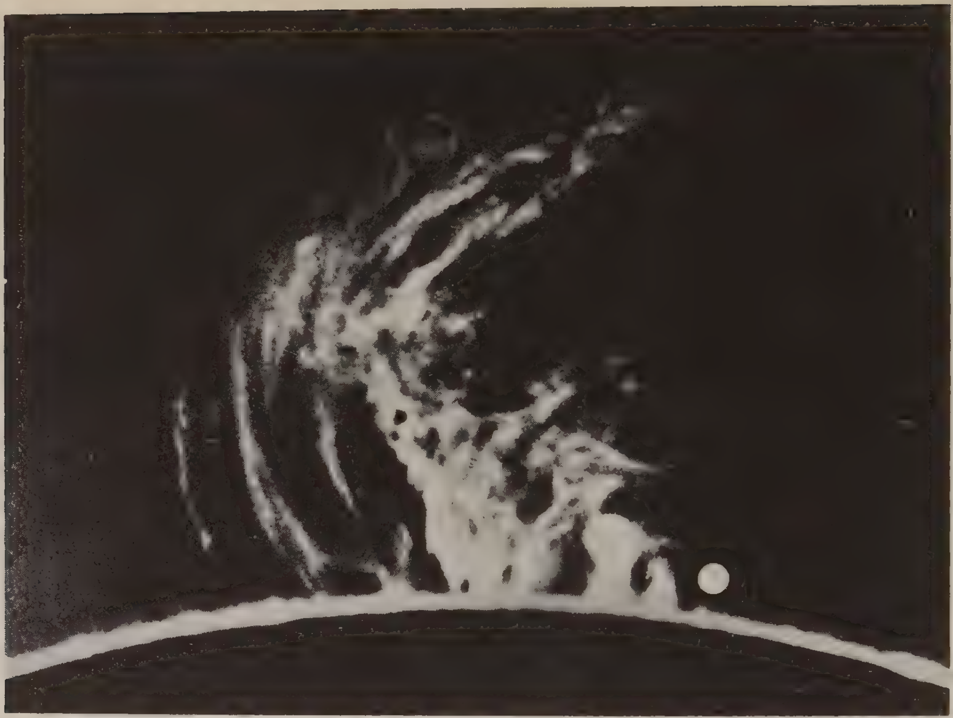

Courtesy of Mt. Wilson and Palomar Observatories.

FIGURE 1424b.—Solar prominence, 140,000 miles high, photographed in light of calcium. July 9, 1917. Small white disk shows relative size of earth.

A total eclipse is a spectacular phenomenon. As the last light from the sun is cut off, the solar **corona,** or envelope of thin, illuminated gas around the sun, becomes visible. Wisps of more dense gas may appear as **solar prominences** (fig. 1424b). The only light reaching the observer is that diffused by the atmosphere surrounding the shadow. As the moon appears to continue on across the face of the sun, the sun finally emerges from the other side, first as Baily's Beads, and then as an ever widening crescent until no part of its surface is obscured by the moon.

The duration of a total eclipse depends upon how nearly the moon crosses the center of the sun, the location of the shadow on the earth, the relative orbital speeds of the moon and earth, and (principally) the relative apparent diameters of the sun and moon. The maximum length that can occur is a little more than seven minutes.

If the apparent diameter of the moon is less than that of the sun, its shadow does not quite reach the earth. Over a small area of the earth directly in line with the moon and sun, the moon appears as a black disk almost covering the surface of the sun, but with a thin ring of the sun around its edge. This is an **annular eclipse,** and occurs a little oftener than a total eclipse.

If the shadow of the moon passes close to the earth, but not directly in line with it, a partial eclipse may occur without a total or annular eclipse.

An eclipse of the moon occurs when the moon passes through the shadow of the earth, as shown in figure 1424a. Since the diameter of the earth is about three and one-half times that of the moon, the earth's shadow at the distance of the moon is much larger than that of the moon. A total eclipse of the moon can last nearly one and three-quarters hours, and some part of the moon may be in the earth's shadow for almost four hours. During a total **solar eclipse** no part of the sun is visible because a

body (the moon) intervenes in the line of sight. During a **lunar eclipse** some light does reach the moon because of diffraction by the atmosphere of the earth, and hence the eclipsed full moon is visible as a faint reddish disk. A lunar eclipse is visible over the entire hemisphere of the earth facing the moon. Anyone who can see the moon can see the eclipse.

During any one year there may be as many as five eclipses of the sun, and always there are at least two. There may be as many as three eclipses of the moon, or none. The total number of eclipses during a single year does not exceed seven, and can be as few as two. There are more solar than lunar eclipses, but the latter are more numerous at any one place because of the restricted areas over which solar eclipses are visible.

The two points of intersection of the moon's orbit and the ecliptic are called **nodes,** and the line connecting them, the **line of nodes.** Eclipses occur when the sun, earth, and moon are nearly on this line, twice each **eclipse year** of 346.6 days. This is less than a calendar year because of regression of the nodes (art. 1423). In a little more than 18 years the line of nodes returns to approximately the same position with respect to the sun, earth, and moon. During an almost equal period, called the **saros,** a cycle of eclipses occurs. During the following saros the cycle is repeated with only minor differences.

Eclipses have considerable value in establishing additional facts about the sun and moon, and in determining distances between two widely separated points on the earth, at which accurate timing of the eclipse is made.

Coordinates

1425. Latitude and longitude are coordinates used for locating positions on the earth. Several types, differing slightly from each other, are defined. Three of these are discussed here.

Astronomical latitude is the angle (*ABQ*, fig. 1425) between a line in the direction of gravity (*AB*) and the plane of the equator (*QQ′*). **Astronomical longitude** is the angle between the plane of the celestial meridian and the plane of the prime meridian. These coordinates are customarily found by means of celestial observations. If the earth were perfectly homogeneous and level, these positions would be consistent and satisfactory. However, because of **deflection of the vertical** (art. 1610) due to uneven distribution of the mass of the earth, lines of equal astronomical latitude and longitude are not circles, although the irregularities are small. In the United States the prime-vertical component (affecting longitude) may be a little more than 18″, and the meridional component (affecting latitude) as much as 25″.

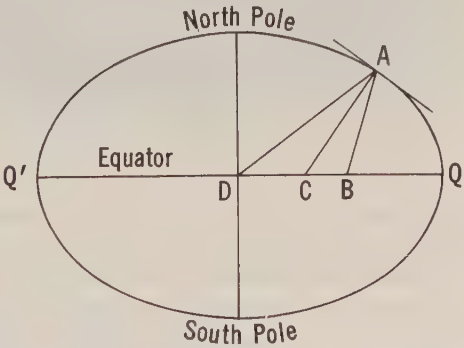

FIGURE 1425.—Three kinds of latitude at point *A*.

Geodetic latitude is the angle (*ACQ*, fig. 1425) between a normal to the spheroid (*AC*) and the plane of the equator (*QQ′*). **Geodetic longitude** is the angle between the plane defined by the normal to the spheroid and the axis of the earth, and the plane of the prime meridian. These values are obtained when astronomical latitude and longitude are corrected for deflection of the vertical. These coordinates are the ones used for charting, and are frequently referred to as **geographic latitude** and **geographic longi-**

tude, although these expressions are sometimes used to refer to astronomical latitude and longitude.

Geocentric latitude is the angle (*ADQ*, fig. 1425) between a line to the center of the earth (*AD*) and the plane of the equator (*QQ'*). This differs from geodetic latitude because the earth is a spheroid, rather than a sphere, and the meridians are ellipses. Since the parallels of latitude are considered to be circles, geodetic longitude is geocentric, and a separate expression is not used. The difference between geocentric and geodetic latitudes is a maximum of about 11.'6 at latitude 45°.

Because of the oblate shape of the earth, the length of a degree of geodetic latitude is not everywhere the same, increasing from about 59.7 nautical miles at the equator to about 60.3 nautical miles at the poles, as shown by table 6. The value of 60 nautical miles customarily used everywhere by the navigator is correct at about latitude 45°.

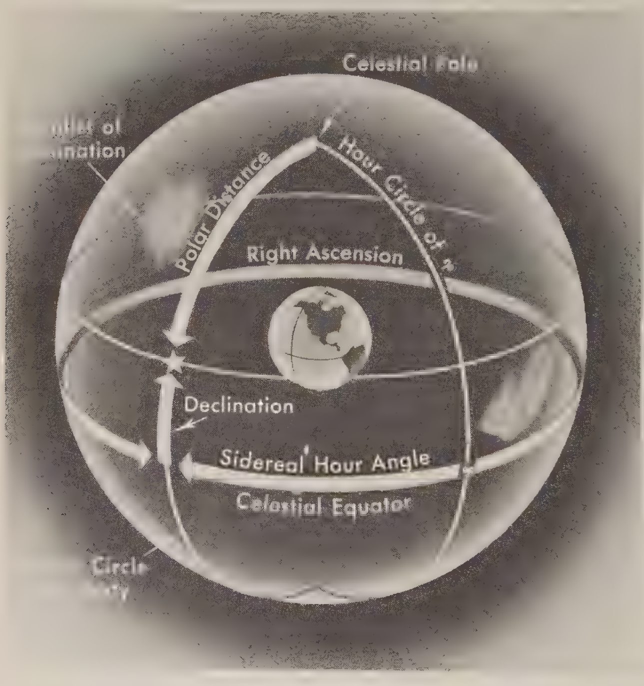

FIGURE 1426a.—Declination and sidereal hour angle.

1426. Celestial equator system.—Positions on the celestial sphere are located by any of several sets of coordinates analogous to latitude and longitude on the earth. The most directly related system is based upon the **celestial equator** (sometimes called **equinoctial**). This is the great circle formed on the celestial sphere by extension of the plane of the equator of the earth (fig. 1426a). **Declination** (**d**) is measured northward or southward from the celestial equator, similar to latitude on the earth. Like latitude, it is labeled N or S (sometimes (+) instead of N and (−) instead of S) to indicate the direction of measurement, and has a maximum value of 90° at the north and south **celestial poles,** which are directly over corresponding poles of the earth. The celestial pole above the horizon is called the **elevated pole,** and that below the horizon the **depressed pole.** The angular distance from a celestial pole, usually the elevated pole, is called **polar distance** (**p**). Polar distance is 90° *minus* declination if the body is between the celestial equator and the pole; otherwise it is 90° *plus* declination. A circle of the celestial sphere, parallel to the plane of the celestial equator, is called a **parallel of declination.** This would be the diurnal circle (art. 1416) of a body having constant declination.

A great circle through the celestial poles and the zenith (art. 1428) of an observer is his **celestial meridian** (fig. 1426b). That half which includes his zenith, and ends at the celestial poles, is called the **upper branch.** The other half is the **lower branch.** A reference to a celestial meridian is generally understood to mean the upper branch unless the lower branch is specified. The celestial meridian remains stationary over a meridian on the earth, and does not participate in the daily apparent rotation of the celestial sphere. A similar great circle of the celestial sphere, but related to a point on that sphere, or to a celestial body, is called an **hour circle** or **circle of declination**

(fig. 1426a). The hour circle through the point vertically above an observer coincides with his celestial meridian.

The hour circle through the vernal equinox (art. 1419) is used as a reference somewhat analogous to the prime meridian on the earth. It is the origin from which **sidereal hour angle** (**SHA**) is measured, westward through 360°. Thus, sidereal hour angle is similar to longitude on the earth, except that longitude is measured either eastward or westward through 180°. If the vernal equinox and all celestial bodies were fixed points, both declination and sidereal hour angle of celestial bodies would remain the same, but these coordinates change as a body alters its position on the celestial sphere, and also as precession of the equinoxes (art. 1419) takes place, resulting in movement of the vernal equinox and celestial equator. Sidereal hour angle is used primarily by navigators. Astronomers usually measure *eastward* in time units, through 24 hours. This quantity is called **right ascension** (**RA**). Thus, converted to the same units, $SHA+RA=360°=24^h$.

Measurement is often made from a celestial meridian rather than from the hour circle of the first point of Aries. This is another form of **hour angle** (**HA**) which, like sidereal hour angle, is measured westward through 360° (fig. 1426b). It is usually designated **Greenwich hour angle** (**GHA**) or **local hour angle** (**LHA**) depending upon whether the Greenwich or local celestial meridian is used as the reference. If measurement is made from the local celestial meridian, *either* eastward or westward through 180°, similar to measurement of longitude on the earth, the quantity is called **meridian angle** (**t**). This is the angle between the plane of the celestial meridian of the observer and the plane of the hour circle of the body. Because of the apparent daily rotation of the celestial sphere, hour angle continually increases, but meridian angle increases from 0° at the celestial meridian to 180° W, which is also 180° E, and then decreases to 0° again. The rate of change for the mean sun (art. 1421) is 15° per hour. The rate of all other bodies except the moon is within 3′ of this value. The average rate of the moon is about 14°5.

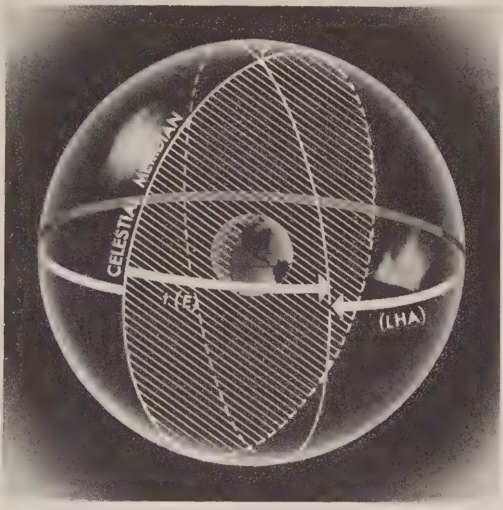

FIGURE 1426b.—Local hour angle and meridian angle.

As the celestial sphere rotates, each body crosses each branch of the celestial meridian approximately once a day. This crossing is called **meridian transit** (sometimes called **culmination**). It may be called **upper transit** to indicate crossing of the upper branch of the celestial meridian, and **lower transit** to indicate crossing of the lower branch.

1427. Time diagram.—To an observer outside the celestial sphere (if this were possible), at such a distance that his view would be orthographic, the outer limit of the sphere would appear as a great circle. If he were over one of the celestial poles, the circle would be the celestial equator. Parallels of declination would appear as circles concentric with, but usually smaller than, the celestial equator. Hour circles would appear as radials. If the observer were over the *south* celestial pole and rotating with the earth, the celestial sphere would appear to rotate in a counterclockwise direction. The difference in hour angle of any two bodies would be indicated by the angle between

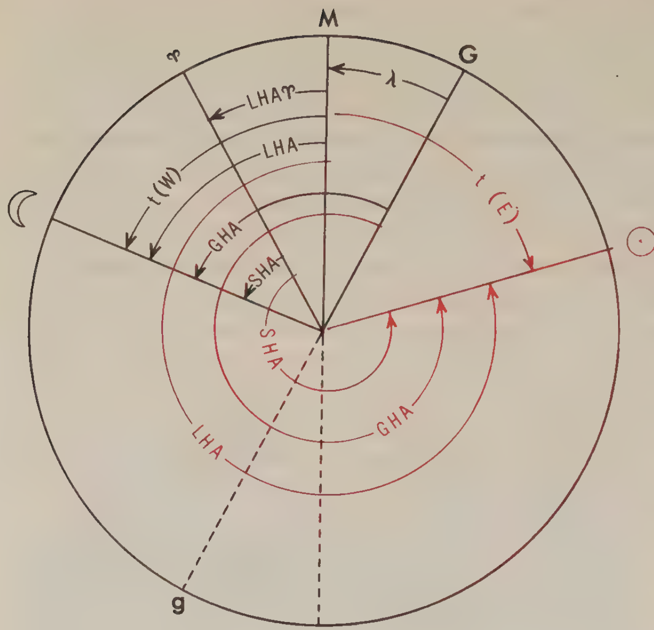

FIGURE 1427a.—Time diagram.

their hour circles. The hour angles themselves would be indicated by the angles, at the pole, between a celestial meridian and the hour circles. On a reduced scale, and without benefit of actual circles showing in the sky, such a view is available to a northern-hemisphere observer who looks at the north celestial pole (approximately at Polaris) and observes stars of high northerly declination, such as those of the big dipper and *Cassiopeia*, circle the sky.

A diagram based upon this concept, called a **time diagram** or **diagram on the plane of the celestial equator,** can be useful in visualizing the relationships of the various "longitude" terms of article 1426. Refer to figure 1427a. The circle represents the celestial equator. The parallels of declination are not of concern, and are omitted. By convention, the diagram is oriented so that the upper branch of the local celestial meridian is at the top, labeled M. The lower branch is shown as a broken line, labeled m. The observer in this case is at longitude 27° W. Therefore, the Greenwich meridian is 27° *east*, as shown. It is labeled G and g to indicate the upper and lower branches, respectively. The vernal equinox is 30° west of the meridian, as shown, and labeled ♈. The moon is 70° west of the celestial meridian, and the sun is 75° east of the celestial meridian. Various quantities are shown and labeled. To one who knows these relationships, a time diagram is often useful in visualizing conditions of a given situation, particularly when some quantities are to be found from others.

Example.—An observer is at longitude 104° W. GHA ♈ is 195°. The SHA of a star is 206°.

Required.—(1) LHA, (2) t, (3) LHA ♈.

Solution.—Draw the diagram, as shown in figure 1427b. From the diagram determine the required relationships: (1) LHA=GHA ♈+SHA−λ. (2) t=360°−LHA. (3) LHA ♈=GHA ♈−λ.

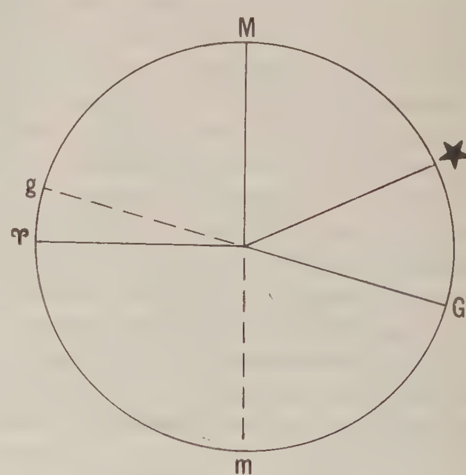

FIGURE 1427b.—Solution by time diagram.

Answers.—(1) LHA 297°, (2) t 63° E, (3) LHA ♈ 91°.

1428. Horizon system.—The celestial equator system of coordinates is not convenient for locating celestial bodies relative to an observer. For this purpose the horizon system is preferable. In this system, the **horizon** is the primary great circle analogous to the equator (fig. 1428a). The **zenith** (Z) is that point directly overhead

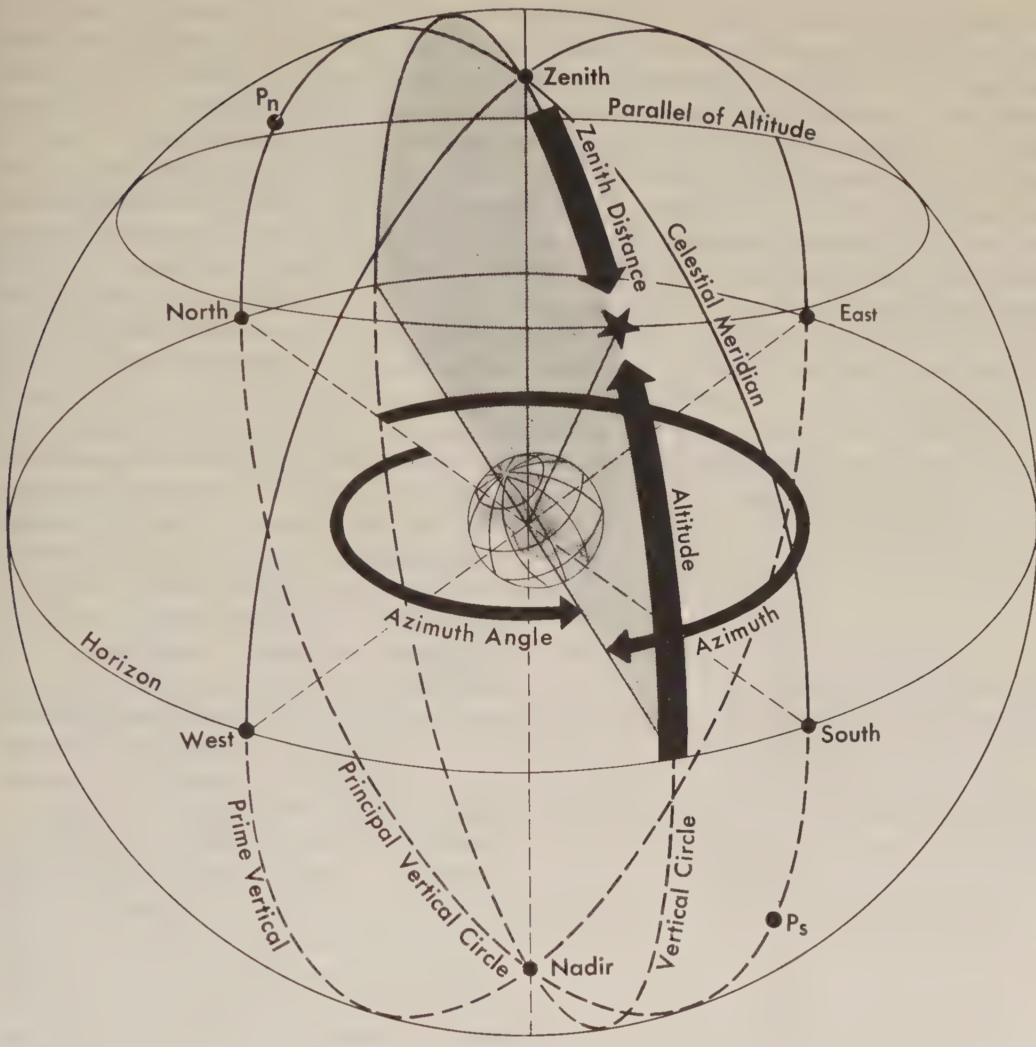

FIGURE 1428a.—The horizon system of coordinates.

(opposite to the direction of gravity). The **nadir** (**Na**) is 180° from the zenith. The zenith and nadir are the poles of the system. A circle parallel to the plane of the horizon is a **parallel of altitude** (sometimes called an **altitude circle** or **almucantar**). Angular distance above the horizon is **altitude** (**h**); angular distance from the zenith is **zenith distance** (**z**). Great circles through the zenith and nadir, and therefore perpendicular to the horizon, are **vertical circles.** The vertical circle through the east and west points of the horizon is the **prime vertical circle,** or, as usually stated, the **prime vertical** (**PV**). The vertical circle through the north and south points of the horizon is the **principal vertical circle.** It is also the celestial meridian (art. 1426).

The angular difference between north and any other horizontal direction (the bearing) is called **azimuth** (**Zn**) when referred to a celestial body. Azimuth, like bearing, is measured clockwise around the horizon from 000° at north through 360°. It is usually expressed in three figures. Sometimes it is convenient to express direction in terms of **azimuth angle** (**Z**) which is usually measured from the direction of the elevated pole (north or south to agree with the latitude), through 180°, but occasionally from the *nearer* north or south point, through 90°. Azimuth angle is labeled to avoid

ambiguity. It is given a prefix, N or S, to indicate the origin of measurement, and a suffix, E or W, to indicate the direction of measurement. By means of these labels azimuth angle can be converted to azimuth. Thus, N 37° W means that the given direction is found by starting at north and measuring 37° in a westerly direction, or 360°−37°=323°. Similarly S 164° W is 164° west of south, or 180°+164°=344°. In converting from azimuth to azimuth angle, one must know the name (N or S) of the latitude if the 180° system is used. Thus, Zn 068° is equal to N 68° E in north latitude, and S 112° E in south latitude. If the 90° system is used, it could be N 68° E only, since this system is without ambiguity except at east and west. In either the 90° or 180° system the suffix agrees with meridian angle, for if a body is east by meridian angle, it is also east by azimuth angle. If LHA is less than 180°, the body is west of the meridian, and hence has an azimuth of more than 180°. Thus, *both* LHA and Zn cannot be either less or greater than 180°.

At rising or setting, a body is not on the prime vertical unless its declination is zero. The arc of the horizon between the prime vertical and the body is its **amplitude** (**A**). This is given the prefix E (east) if the body is rising and W (west) if setting. It is given the suffix N if the body rises or sets north of the prime vertical (which it does if it has northerly declination) and S if it rises or sets south of the prime vertical (having southerly declination). Interconversion of amplitude and azimuth is similar to that of azimuth angle and azimuth. Thus, if A=E 15° S, the body is 15° south of east, or 90°+15°=105°. For any given body, the numerical value of amplitude would be the same at rising and setting if the declination did not change. Amplitudes to a declination range of 24° are given in table 27. A correction to convert the observed value when the body is on the apparent horizon to the corresponding value it would have if the body were on the celestial horizon (tab. 27) is given in table 28.

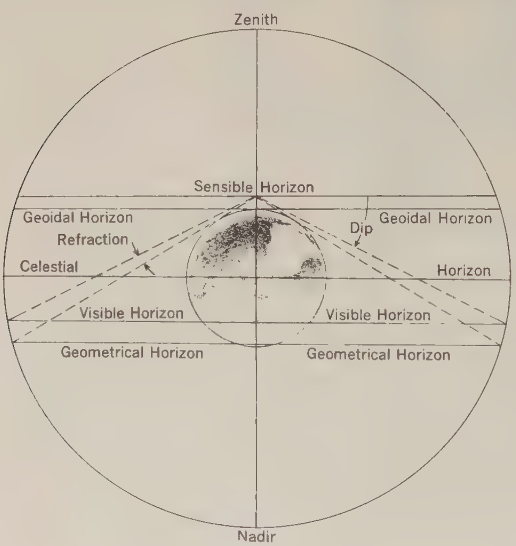

FIGURE 1428b.—The horizons.

The horizon system of coordinates is based upon the **celestial horizon** (sometimes called **rational horizon**). This is a great circle (of the celestial sphere) midway between the zenith and nadir. Its plane passes through the center of the earth, and is perpendicular to the zenith-nadir line (fig. 1428b). At the infinite distance of the celestial sphere this is considered identical with the **sensible horizon,** one having a plane parallel to that of the celestial horizon, but through the eye of the observer. At heights of eye used in marine navigation, the sensible horizon may be considered identical with **geoidal horizon,** the plane of which is parallel to that of the sensible horizon, but through the point on the **geoid** (the sea-level surface of the earth) vertically below the observer. Only the sun and moon are near enough to the earth that the difference of altitude measured from the celestial and sensible horizons has practical significance to the navigator. None of these horizons is marked by a line visible to an observer. In practice, the marine navigator usually measures altitude from the **visible horizon** and converts his readings to the corresponding value from the sensible horizon by means of dip (art. 1606). The visible horizon is the line where earth and sky appear to meet. Over land it is a somewhat irregular line, but at sea this line appears as a circle. It is

approximately a small circle of the celestial sphere differing from the sensible horizon because of height of the observer's eye above the surface, and atmospheric refraction. The **geometrical horizon** is below the visible horizon by the amount of terrestrial refraction. A straight line from the eye of the observer tangent to the earth leads to the geometrical horizon. Occasionally the expression *geometrical horizon* is used as the equivalent of *celestial horizon.*

Altitude measured from the celestial horizon is the complement of zenith distance. Celestial bodies *below* the celestial horizon have **negative altitude,** or a zenith distance of more than 90°. In this case, $z=90°-(-h)=90°+h$, when h is measured downward or negatively from the celestial horizon. Because of dip a body may have slight negative altitude and still be above the visible horizon.

1429. Ecliptic system.—The ecliptic system is based upon the **ecliptic** as the primary great circle, analogous to the equator. The points 90° from the ecliptic are the north and south **ecliptic poles.** The series of great circles through these poles, analogous to meridians, are **circles of latitude.** The circles parallel to the plane of the ecliptic, analogous to parallels on the earth, are **parallels of latitude** or **circles of longitude.** Angular distance north or south of the ecliptic, analogous to latitude, is **celestial latitude. Celestial longitude** is measured *eastward* along the ecliptic through 360°, starting at the vernal equinox. This system of coordinates is of interest chiefly to astronomers.

1430. Galactic system.—Another system of interest primarily to astronomers is based upon a great circle called the **galactic equator,** considered to be in the plane of the galaxy. The north and south **galactic poles** are 90° from the galactic equator. **Galactic latitude** is measured north and south from the galactic equator. **Galactic longitude** is measured eastward from a point on the galactic equator at about SHA 84°24′, declination 28°55′ S in 1950.

1431. Summary of coordinate systems.—The four systems of celestial coordinates are analogous to each other and to the terrestrial system, although each has distinctions such as differences in directions, units, and limits of measurement. The following table indicates the analogous term or terms under each system. For differences, see the description of each system, given earlier in the chapter, or appendix E.

Earth	Celestial Equator	Horizon	Ecliptic	Galactic
equator	celestial equator	horizon	ecliptic	galactic equator
poles	celestial poles	zenith, nadir	ecliptic poles	galactic poles
meridians	hour circles, celestial meridians	vertical circles	circles of latitude	
prime meridian	hour circle ♈, Greenwich celestial meridian, local celestial meridian	principal vertical circle, prime vertical circle	circle of latitude through ♈	great circle through galactic poles and intersection of galactic equator at about SHA 84°24′, declination 28°55′ S (1950)
parallels	parallels of declination	parallels of altitude	parallels of latitude	
latitude	declination	altitude	celestial latitude	galactic latitude
colatitude	polar distance	zenith distance	celestial colatitude	galactic colatitude
longitude	SHA, RA, GHA, LHA, t	azimuth, azimuth angle, amplitude	celestial longitude	galactic longitude

1432. Diagram on the plane of the celestial meridian.—From a point outside the celestial sphere (if this were possible) and over the celestial equator, at such a distance that the view would be orthographic, the great circle appearing as the outer limit would be a celestial meridian. Other celestial meridians would appear as ellipses. The celestial equator would appear as a diameter 90° from the poles, and parallels of declina-

tion as straight lines parallel to the equator. The view would be similar to the orthographic view of the earth, as shown in figure 319b.

A number of useful relationships can be demonstrated by drawing a **diagram on the plane of the celestial meridian** showing this orthographic view. Arcs of circles can be substituted for the ellipses without destroying the basic relationships. Refer to figure 1432a. In the lower diagram the circle represents the celestial meridian, QQ' the celestial equator, Pn and Ps the north and south celestial poles, respectively. If a star has a declination of 30° N, an angle of 30° can be measured from the celestial equator, as

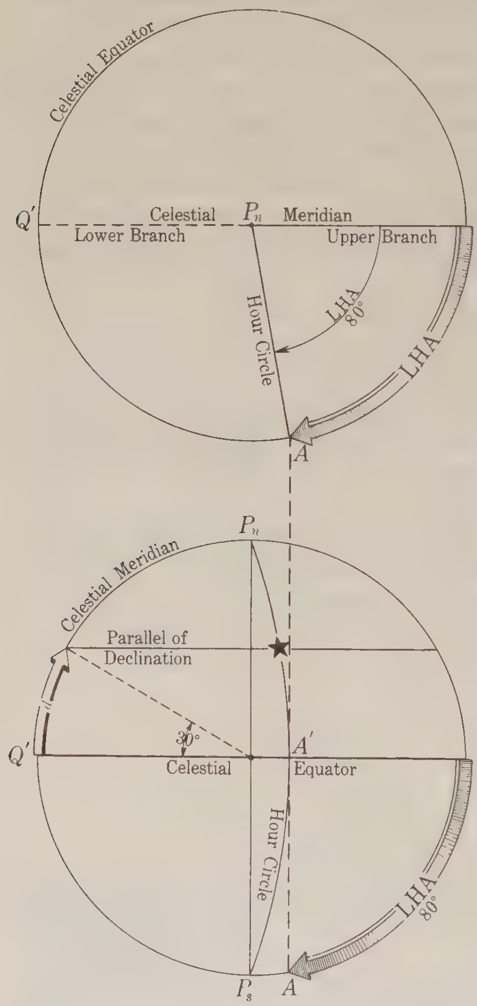

FIGURE 1432a.—Measurement of celestial equator system of coordinates.

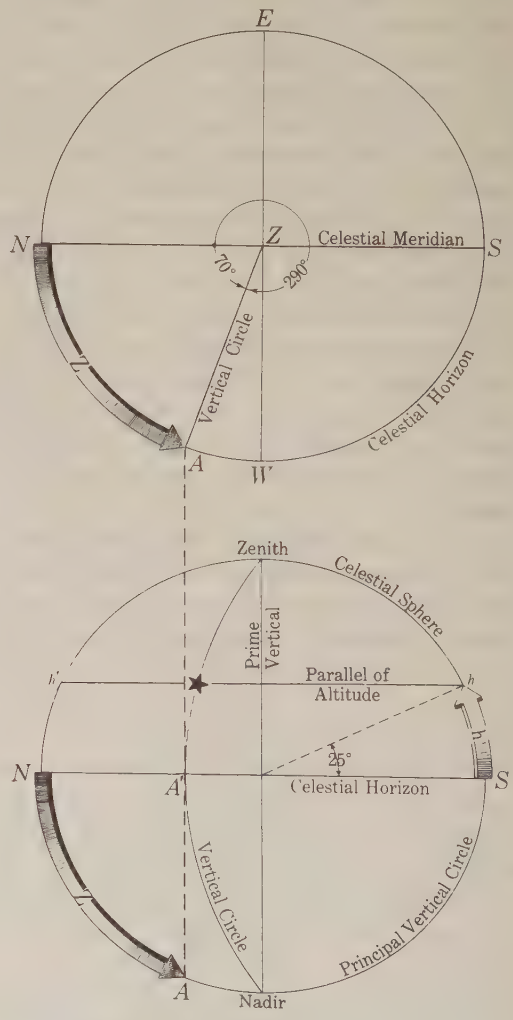

FIGURE 1432b.—Measurement of horizon system of coordinates.

shown. It could be measured either to the right or left, and would have been toward the south pole if the declination had been south. The parallel of declination is a line through this point and parallel to the celestial equator. The star is somewhere on this line (actually a circle viewed on edge).

To locate the hour circle, draw the upper diagram so that Pn is directly above Pn of the lower figure (in line with the polar axis Pn Ps), and the circle is of the same diameter as that of the lower figure. This is the plan view, looking down on the celestial sphere from the top. The circle is the celestial equator. Since the view is from above

the *north* celestial pole, west is clockwise. The diameter QQ' is the celestial meridian shown as a circle in the lower diagram. If the *right* half is considered the upper branch, local hour angle is measured clockwise from this line to the hour circle, as shown. In this case the LHA is 80°. The intersection of the hour circle and celestial equator, point A, can be projected down to the lower diagram (point A') by a straight line parallel to the polar axis. The elliptical hour circle can be represented approximately by an arc of a circle through A', Pn, Ps. The center of this circle is somewhere along the celestial equator line QQ', extended if necessary. It is usually found by trial and error. The intersection of the hour circle and parallel of declination locates the star.

Since the upper diagram serves only to locate point A' in the lower diagram, the two can be combined. That is, the LHA arc can be drawn in the lower diagram, as shown, and point A projected *upward* to A'. In practice, the upper diagram is not drawn, being shown here for illustrative purposes only.

In this example the star is on that half of the sphere toward the observer, or the *western* part. If LHA had been greater than 180°, the body would have been on the *eastern* or "back" side.

From the east or west point over the celestial horizon, the orthographic view of the horizon system of coordinates would be similar to that of the celestial equator system from a point over the celestial equator (fig. 1432a), since the celestial meridian is also the principal vertical circle. The horizon would appear as a diameter, parallels of altitude as straight lines parallel to the horizon, the zenith and nadir as poles 90° from the horizon, and vertical circles as ellipses through the zenith and nadir, except for the principal vertical circle, which would appear as a circle, and the prime vertical, which would appear as a diameter perpendicular to the horizon.

A celestial body can be located by altitude and azimuth in a manner similar to that used with the celestial equator system. If the altitude is 25°, this angle is measured from the horizon toward the zenith and the parallel of altitude is drawn as a straight line parallel to the horizon, as shown at hh' in the lower diagram of figure 1432b. The plan view from above the zenith is shown in the upper diagram. If north is taken at the left, as shown, azimuths are measured clockwise from this point. In the figure the azimuth is 290° and the azimuth angle is N 70° W. The vertical circle is located by measuring either arc. Point A thus located can be projected vertically downward to A' on the horizon of the lower diagram, and the vertical circle represented approximately by the arc of a circle through A' and the zenith and nadir. The center of this circle is on NS, extended if necessary. The body is at the intersection of the parallel of altitude and the vertical circle. Since the upper diagram serves only to locate A' on the lower diagram, the two can be combined, point A located on the lower diagram and projected upward to A', as shown. Since the body of the example has an azimuth greater than 180°, it is on the western or "front" side of the diagram.

Since the celestial meridian appears the same in both the celestial equator and horizon systems, the two diagrams can be combined and, if properly oriented, a body can be located by one set of coordinates, and the coordinates of the other system can be determined by measurement.

Refer to figure 1432c, in which the black lines represent the celestial equator system, and the red lines the horizon system. By convention, the zenith is shown at the top and the north point of the horizon at the left. The west point on the horizon is at the center, and the east point directly behind it. In the figure the latitude is 37° N. Therefore, the zenith is 37° north of the celestial equator. Since the zenith is established at the top of the diagram, the equator can be found by measuring an arc of 37° toward the south, along the celestial meridian. If the declination is 30° N and the LHA is 80°, the body can be located as shown by the black lines, and described above.

The altitude and azimuth can be determined by the reverse process to that described above. Draw a line *hh′* through the body and parallel to the horizon, *NS*. The altitude, 25°, is found by measurement, as shown. Draw the arc of a circle through the body and the zenith and nadir. From *A′*, the intersection of this arc with the horizon, draw a vertical line intersecting the circle at *A*. The azimuth, N 70° W, is found by measurement, as shown. The prefix N is applied to agree with the latitude. The body is left (*north*) of *ZNa*, the prime vertical circle. The suffix *W* applies because the LHA, 80°, shows that the body is west of the meridian.

If altitude and azimuth are given, the body is located by means of the red lines. The parallel of declination is then drawn parallel to *QQ′*, the celestial equator, and the declination determined by measurement. Point *L′* is located by drawing the arc of a circle through *Pn*, the star, and *Ps*. From *L′* a line is drawn perpendicular to *QQ′*, locating *L*. The meridian angle is then found by measurement. The declination is known to be north because the body is between the celestial equator and the north celestial pole. The meridian angle is west to agree with the azimuth, and hence LHA is numerically the same.

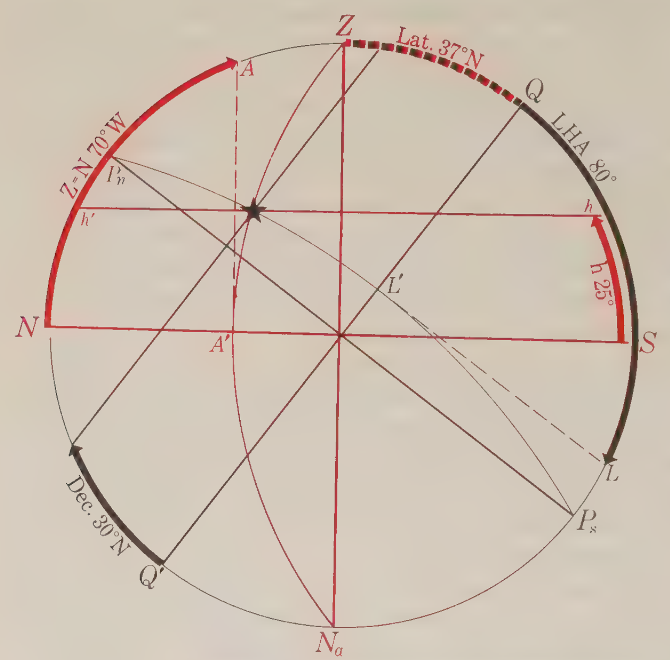

FIGURE 1432c.—Diagram on the plane of the celestial meridan.

Since *QQ′* and *PnPs* are perpendicular, and *ZNa* and *NS* are also perpendicular, arc *NPn* is equal to arc *ZQ*. That is, *the altitude of the elevated pole is equal to the declination of the zenith, which is equal to the latitude.* This relationship is the basis of the method of determining latitude by an observation of Polaris (art. 2105).

The diagram on the plane of the celestial meridian is useful in approximating a number of relationships. Consider figure 1432d. The latitude of the observer (*NPn* or *ZQ*) is 45° N. The declination of the sun (*Q4*) is 20° N. Neglecting the change in declination for one day, note the following: At sunrise, position 1, the sun is on the horizon (*NS*), at the "back" of the diagram. Its altitude, h, is 0°. Its azimuth angle, Z, is the arc *NA*, N 63° E. This is prefixed N to agree with the latitude and suffixed E to agree with the meridian angle of the sun at sunrise. Hence, Zn=0°+63°=063°. The amplitude, A, is the arc *ZA*, E 27° N. The meridian angle, t, is the arc *QL*, 110° E. The suffix E is applied because the sun is east of the meridian at rising. The LHA is 360°−110°=250°.

As the sun moves upward along its parallel of declination, its altitude increases. It reaches position 2 at about 0600, when t=90° E. At position 3 it is on the prime vertical, *ZNa*. Its azimuth angle, Z, is N 90° E, and Zn=090°. The altitude is *Nh′* or *Sh*, 27°.

Moving on up its parallel of declination, it arrives at position 4 on the celestial meridian about noon—when t and LHA are both 0°, by definition. On the celestial meridian a body's azimuth is 000° or 180°. In this case it is 180° because the body is south of the zenith. The maximum altitude occurs at meridian transit, in this case

the arc $S4$, 65°. The zenith distance, z, is the arc $Z4$, 25°. A body is not in the zenith at meridian transit unless its declination is numerically, and by name, the same as the latitude.

Continuing on, the sun moves downward along the "front" or western side of the diagram. At position 3 it is again on the prime vertical. The altitude is the same as when previously on the prime vertical, and the azimuth angle is numerically the same, but now measured toward the west. The azimuth is 270°. The sun reaches position 2 six hours after meridian transit, and sets at position 1, when the azimuth angle is numerically the same as at sunrise, but westerly, and Zn=360°−63°=297°. The amplitude is W 27° N.

After sunset the sun continues on downward along its parallel of declination until it reaches position 5, on the lower branch of the celestial meridian, about midnight. Its negative altitude, arc $N5$, is now greatest, 25°, and its azimuth is 000°. At this point it starts back up along the "back" of the diagram, arriving at position 1 at the next sunrise, to start another cycle.

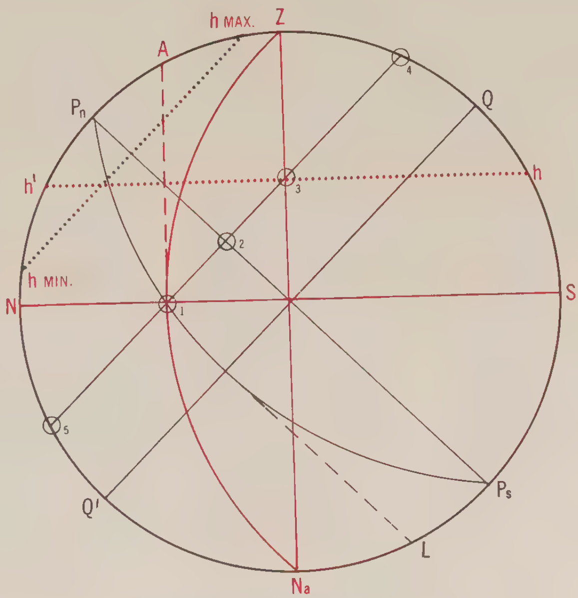

FIGURE 1432d.—A diagram on the plane of the celestial meridian for lat. 45° N.

Half the cycle is from the crossing of the 90° hour circle (the $PnPs$ line, position 2) to the upper branch of the celestial meridian (position 4) and back to the $PnPs$ line (position 2). When the declination and latitude have the **same name** (both north or both south), more than half the parallel of declination (position 1 to 4 to 1) is above the horizon, and the body is above the horizon more than half the time, crossing the 90° hour circle above the horizon. It rises and sets on the same side of the prime vertical as the elevated pole. If the declination is of the same name but numerically smaller than the latitude, the body crosses the prime vertical above the horizon. If the declination and latitude have the same name and are numerically equal, the body is in the zenith at upper transit. If the declination is of the same name but numerically *greater* than the latitude, the body crosses the upper branch of the celestial meridian between the zenith and elevated pole, and does not cross the prime vertical. If the declination is of the same name as the latitude and complementary to it (d+L=90°), the body is on the horizon at lower transit, and does not set. If the declination is of the same name as the latitude and numerically *greater* than the colatitude, the body is above the horizon during its entire daily cycle, and has maximum and minimum altitudes, as shown by the black dotted line in figure 1432d.

If the declination is 0° at any latitude, the body is above the horizon half the time, following the celestial equator QQ', and rising and setting on the prime vertical. If the declination is of **contrary name** (one north and the other south), the body is above the horizon less than half the time, and crosses the 90° hour circle below the horizon. It rises and sets on the opposite side of the prime vertical from the elevated pole. If the declination is of contrary name and numerically smaller than the latitude, the body

crosses the prime vertical below the horizon. This is the situation with the sun in winter, when days are short. If the declination is of contrary name and numerically equal to the latitude, the body is in the nadir at lower transit. If the declination is of contrary name and complementary to the latitude, the body is on the horizon at upper transit. If the declination is of contrary name and numerically greater than the colatitude, the body does not rise.

All of these relationships, and those that follow, can be derived by means of a diagram on the plane of the celestial meridian. They are modified slightly by atmospheric refraction, height of eye, semidiameter, parallax, changes in declination, and apparent speed of the body along its diurnal circle.

It is customary to keep the same orientation in south latitude, as shown in figure 1432e. In this illustration the latitude is 45° S, and the declination of the body is 15° N. Since *Ps* is the elevated pole, it is shown above the southern horizon, with both *SPs* and *ZQ* equal to the latitude, 45°. The body rises at position 1, on the opposite side of the prime vertical from the elevated pole; moves upward along its parallel of declination to position 2, on the upper branch of the celestial meridian, bearing north; and then downward along the "front" of the diagram to position 1, where it sets; remaining above the horizon for less than half the time because declination and latitude are of contrary name. The azimuth at rising is arc *NA*, the amplitude *ZA*, and the azimuth angle *SA*. The altitude circle at meridian transit is shown at *hh′*.

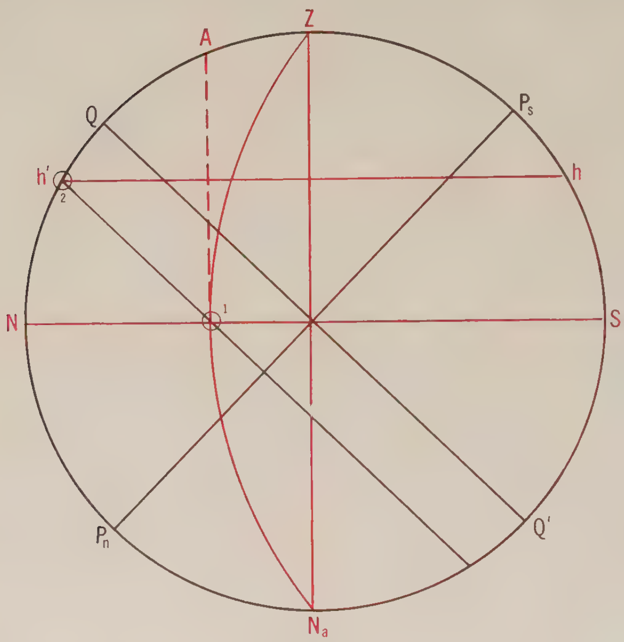

FIGURE 1432e.—A diagram on the plane of the celestial meridian for lat. 45° S.

A diagram on the plane of the celestial meridian can be used to demonstrate the effect of a change in latitude. As the latitude increases, the celestial equator becomes more nearly parallel to the horizon. The colatitude becomes smaller, increasing the number of circumpolar bodies and those which neither rise nor set, and also increasing the difference in the length of the days between summer and winter. At the poles (fig. 1416b), celestial bodies circle the sky, parallel to the horizon. At the equator (fig. 1416a) the 90° hour circle coincides with the horizon. Bodies rise and set vertically; and are above the horizon half the time. At rising and setting the amplitude is equal to the declination. At meridian transit the altitude is equal to the codeclination. As the latitude changes name, the same-contrary name relationship with declination reverses. This accounts for the fact that one hemisphere has winter while the other is having summer.

The error arising from showing the hour circles and vertical circles as arcs of circles instead of ellipses increases with increased declination or altitude. More accurate results can be obtained by measurement of azimuth on the parallel of altitude instead of the horizon, and of hour angle on the parallel of declination instead

of the celestial equator. Refer to figure 1432f. The vertical circle shown is for a body having an azimuth angle of S 60° W. The arc of a circle is shown in black, and the ellipse in red. The black arc is obtained by measurement around the horizon, locating A' by means of A, as previously described. The intersection of this arc with the altitude circle at 60° places the body at M. If a semicircle is drawn with the altitude circle as a diameter, and the azimuth angle measured around this, to B, a perpendicular to the hour circle locates the body at M', on the ellipse. By this method the altitude circle, rather than the horizon, is, in effect, rotated through 90° for the measurement. This refinement is seldom used because actual values are usually found mathematically, the diagram on the plane of the meridian being used primarily to indicate relationships.

With experience, one may mentally visualize the diagram on the plane of the celestial meridian without making an actual drawing. Devices with two sets of spherical coordinates, on either the orthographic (art. 319) or stereographic (art. 318) projection, pivoted at the center, have been produced commercially to provide a mechanical diagram on the plane of the celestial meridian. However, since the diagram's principal use is to illustrate certain relationships, such a device is not a necessary part of the navigator's equipment.

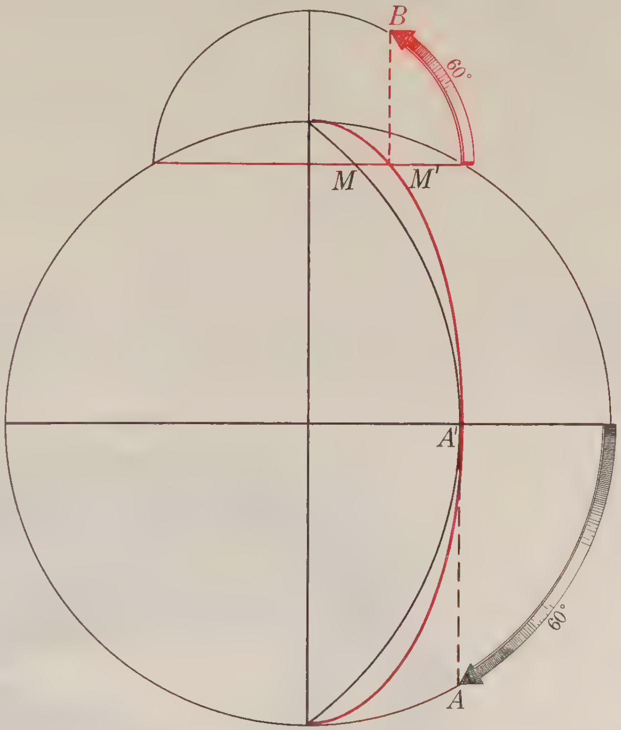

FIGURE 1432f.—Locating a point on an ellipse of a diagram on the plane of the celestial meridian.

1433. The navigational triangle.—A triangle formed by arcs of great circles of a sphere is called a **spherical triangle.** A spherical triangle on the celestial sphere is called a **celestial triangle.** The spherical triangle of particular significance to navigators is called the **navigational triangle.** It is formed by arcs of a celestial meridian, an hour circle, and a vertical circle. Its vertices are the elevated pole, the zenith, and a point on the celestial sphere (usually a celestial body). The terrestrial counterpart is also called a navigational triangle, being formed by arcs of two meridians and the great circle connecting two places on the earth, one on each meridian. The vertices are the two places and a pole. In great-circle sailing these places are the point of departure and the destination. In celestial navigation they are the **assumed position** (**AP**) of the observer and the **geographical position** (**GP**) of the body (the place having the body in its zenith). The GP of the sun is sometimes called the **subsolar point,** that of the moon the **sublunar point,** that of a satellite (either natural or artificial) the **subsatellite point,** and that of a star its **substellar** or **subastral point.** When used to solve a celestial observation, either the celestial or terrestrial triangle may be called the **astronomical triangle.**

The navigational triangle is shown in figure 1433a on a diagram on the plane of the celestial meridian, labeled as in article 1432, but with the hour circle and vertical

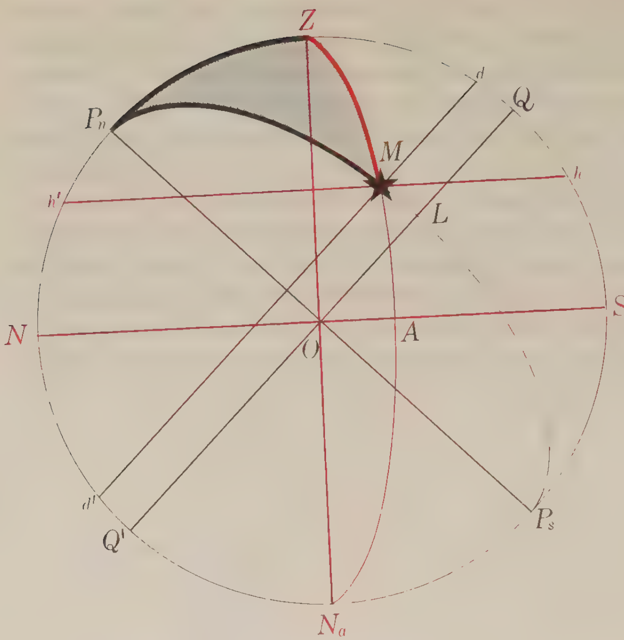

FIGURE 1433a.—The navigational triangle.

circle properly shown as ellipses. The earth is at the center, *O*. The star is at *M*, *dd'* is its parallel of declination, and *hh'* its altitude circle.

In the figure, arc *QZ* of the celestial meridian is the latitude of the observer, and *PnZ*, one side of the triangle, is the **colatitude.** Arc *AM* of the vertical circle is the altitude of the body, and side *ZM* of the triangle is the zenith distance, or **coaltitude.** Arc *LM* of the hour circle is the declination of the body, and side *PnM* of the triangle is the polar distance, or **codeclination.**

The angle at the elevated pole, *ZPnM*, having the hour circle and the celestial meridian as sides, is the meridian angle, t. The angle at the zenith, *PnZM*, having the vertical circle and that arc of the celestial meridian which includes the elevated pole as sides, is the azimuth angle. The angle at the celestial body, *ZMPn*, having the hour circle and the vertical circle as sides, is

FIGURE 1433b.—The navigational triangle in perspective.

the **parallactic angle** (X) (sometimes called the **position angle**), which is not generally used by the navigator.

A number of problems involving the navigational triangle are encountered by the navigator, either directly or indirectly. Of these, the most common are:

1. Given latitude, declination, and meridian angle, to find altitude and azimuth angle. This is used in the reduction of a celestial observation, to establish a line of position (ch. XX).
2. Given latitude, altitude, and azimuth angle, to find declination and meridian angle. This is used to identify an unknown celestial body (ch. XXII).
3. Given meridian angle, declination, and altitude, to find azimuth angle. This may be used to find azimuth when the altitude is known (ch. XX).
4. Given the latitude of two places on the earth and the difference of longitude between them, to find the initial great-circle course and the great-circle distance (ch. VIII). This involves the same parts of the triangle as in 1, above, but in the terrestrial triangle, and hence defined differently.

Both celestial and terrestrial navigational triangles are shown in perspective in figure 1433b.

Problems

1427. *Given.*—An observer is at longitude 77°E. The sun is 60° east of the meridian. GHA ♈ is 37°.

Required.—(1) LHA of the sun.

(2) GHA of the sun.

(3) SHA of the sun.

(4) Approximate time at the local meridian.

Answers.—(1) LHA 300°, (2) GHA 223°, (3) SHA 186°, (4) T 0800.

1428a. *Required.*—Convert Z to Zn in the following:

(1) N 174° E	(4) S 39° E
(2) S 1° E	(5) N 106° W
(3) S 90° W	(6) N 90° W

Answers.—(1) Zn 174°, (2) Zn 179°, (3) Zn 270°, (4) Zn 141°, (5) Zn 254°, (6) Zn 270°.

1428b. *Required.*—Convert Zn to Z in the following, using the 180° system:

Zn	*Lat.*	*Zn*	*Lat.*
(1) 214°	N	(4) 333°	S
(2) 163°	S	(5) 206°	N
(3) 007°	N	(6) 206°	S

Answers.—(1) Z N 146° W, (2) Z S 17° E, (3) Z N 7° E, (4) Z S 153° W, (5) Z N 154° W, (6) Z S 26° W.

1428c. *Required.*—Convert Zn to Z in the following, using the 90° system:

(1) 051°	(3) 251°
(2) 151°	(4) 351°

Answers.—(1) Z N 51° E, (2) Z S 29° E, (3) Z S 71° W, (4) Z N 9° W.

1428d. *Given.*—The following amplitudes:

A	*Lat.*	*A*	*Lat.*
(a) W 24° N	N	(c) E 55° S	N
(b) E 18° N	S	(d) W 4° S	S

Required.—(1) Zn, (2) Z (180° system), (3) Z (90° system).

Answers.—(1) (a) Zn 294°, (b) Zn 072°, (c) Zn 145°, (d) Zn 266°; (2) (a) Z N 66° W, (b) Z S 108° E, (c) Z N 145° E, (d) Z S 86° W; (3) (a) Z N 66° W, (b) Z N 72° E, (c) Z S 35° E, (d) Z S 86° W.

1428e. *Given.*—The following azimuth angles at rising and setting:

(1) N 80° E	(3) S 110° E
(2) N 95° W	(4) S 90° W

Required.—Amplitude.

Answers.—(1) A E 10° N, (2) A W 5° S, (3) A E 20° N, (4) A 0°.

Solve the following problems by diagrams on the plane of the celestial meridian:

1432a. *Given.*—L 32° N, t 71° W, d 27° N.

Required.—Altitude and azimuth.

Answers.—h 28°, Zn 288°.

1432b. *Given.*—L 17° S, t 64° E, d 28° S.

Required.—Altitude and azimuth.

Answers.—h 28°, Zn 115°.

1432c. *Given.*—L 59° N, h 27°, Zn 052°.

Required.—Declination and meridian angle.

Answers.—d 41° N, t 111° E.

1432d. *Given.*—L 31° N, declination of sun 18° S.

Required.—(1) Azimuth at sunrise, (2) maximum altitude, (3) altitude when the azimuth is 234°, (4) azimuth angle when the altitude in the afternoon is 10°, (5) amplitude at sunset.

Answers.—(1) Zn 111°, (2) h 41°, (3) h 18°, (4) Z N 118° W, (5) A W 21° S.

1432e. *Given.*—The declination of the star Dubhe is approximately 62° N. When observed at lower transit, its altitude is 43°.

Required.—(1) Latitude of the observer, (2) azimuth at upper transit.

Answers.—(1) L 71° N, (2) Zn 180°.

1432f. *Required.*—For an observer at latitude 39° N, find for the sun at summer and winter solstices, respectively: (1) LHA at sunrise, (2) LHA when on the prime vertical during the morning, (3) maximum altitude, (4) LHA at sunset, (5) length of daylight if the sun moves 15° per hour.

Answers.—

	Summer	*Winter*
(1) LHA	248°	292°
(2) LHA	304°	236° (below horizon)
(3) h	74°	28°
(4) LHA	112°	68°
(5) T	14^h56^m	9^h04^m

1432g. *Given.*—L 83° N, sun's declination 4° S.

Required.—(1) LHA at sunrise, (2) maximum altitude, (3) LHA at sunset, (4) length of daylight (sun moving 15° per hour).

Answers.—(1) LHA 305°, (2) max h 3°, (3) LHA 55°, (4) T 7^h20^m.

CHAPTER XV

INSTRUMENTS FOR CELESTIAL NAVIGATION

1501. The marine sextant is a hand-held instrument for measuring the angle between the lines of sight to two points by bringing into coincidence at the eye of the observer the direct ray from one point, and a double-reflected ray from the other, the measured angle being twice the angle between the reflecting surfaces. Its principal use is to measure the altitudes of celestial bodies above the visible sea horizon. Sometimes it is turned on its side and used for measuring the *difference* in bearing of two terrestrial objects. Because of its great value for determining position at sea, the sextant has been a symbol of navigation for more than 200 years. The quality of his instrument, the care he gives it, and the skill with which he makes observations are to the navigator matters of professional pride.

The name "sextant" is from the Latin *sextans*, "the sixth part." The arc of early marine sextants is approximately the sixth part of a circle, but because of the optical principle involved (art. 1502), the instrument measures angles of 120°. Most modern instruments measure something more than this.

1502. Principle of operation.—When a ray of light is reflected from a plane surface, the **angle of reflection** is equal to the **angle of incidence** (fig. 1502a). When the reflecting

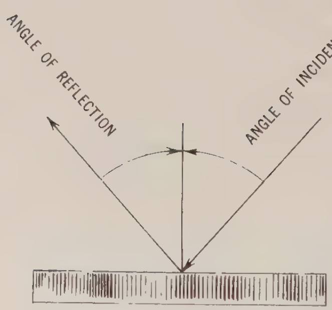

FIGURE 1502a.—Angle of reflection equals angle of incidence.

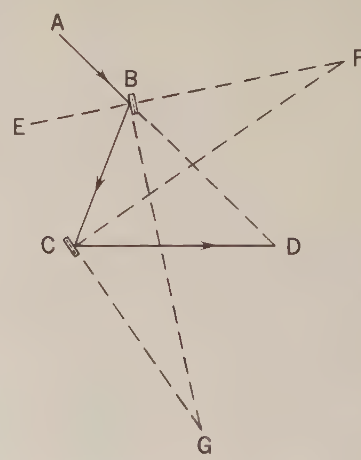

FIGURE 1502b.—Optical principle of the marine sextant.

surface is rotated toward or away from the incident ray, each angle is changed by the amount of rotation, so that the total angle between the incident and reflected rays is altered by twice the change in the reflecting surface. With the sextant, the ray of light is reflected by two mirrors; one movable and the other fixed. The angle between the first and last directions is twice the angle between the mirrors.

In figure 1502b, AB is a ray of light from a celestial body. The index mirror of the sextant is at B, the horizon glass at C, and the eye of the observer at D. Construction lines EF and CF are perpendicular to the index mirror and horizon glass, respectively, and lines BG and CG are parallel to these mirrors. Therefore, angles

BFC and *BGC* are equal because their sides are mutually perpendicular (art. O27). Angle *BGC* is the inclination of the two reflecting surfaces. The ray of light *AB* is reflected at mirror *B*, proceeds to mirror *C*, where it is again reflected, and then continues on to the eye of the observer at *D*. Since the angle of reflection is equal to the angle of incidence,

$$ABE=EBC, \text{ and } ABC=2EBC$$
$$BCF=FCD, \text{ and } BCD=2BCF.$$

Since an exterior angle of a triangle equals the sum of the two nonadjacent interior angles (art. O28),

$$ABC=BDC+BCD, \text{ and } EBC=BFC+BCF.$$

Transposing,

$$BDC=ABC-BCD, \text{ and } BFC=EBC-BCF.$$

Substituting $2EBC$ for *ABC*, and $2BCF$ for *BCD* in the first of these equations,

$$BDC=2EBC-2BCF, \text{ or } BDC=2(EBC-BCF).$$

Since

$$BFC=EBC-BCF, \text{ and } BFC=BGC,$$

therefore

$$BDC=2BFC=2BGC.$$

That is, *BDC*, the angle between the first and last directions of the ray of light, is equal to $2BGC$, twice the angle of inclination of the reflecting surfaces. Angle *BDC* is the altitude of the celestial body.

1503. Micrometer drum sextant.—A modern marine sextant, called a **micrometer drum sextant,** is shown in figure 1503a. In most marine sextants, the **frame.** *A*, is

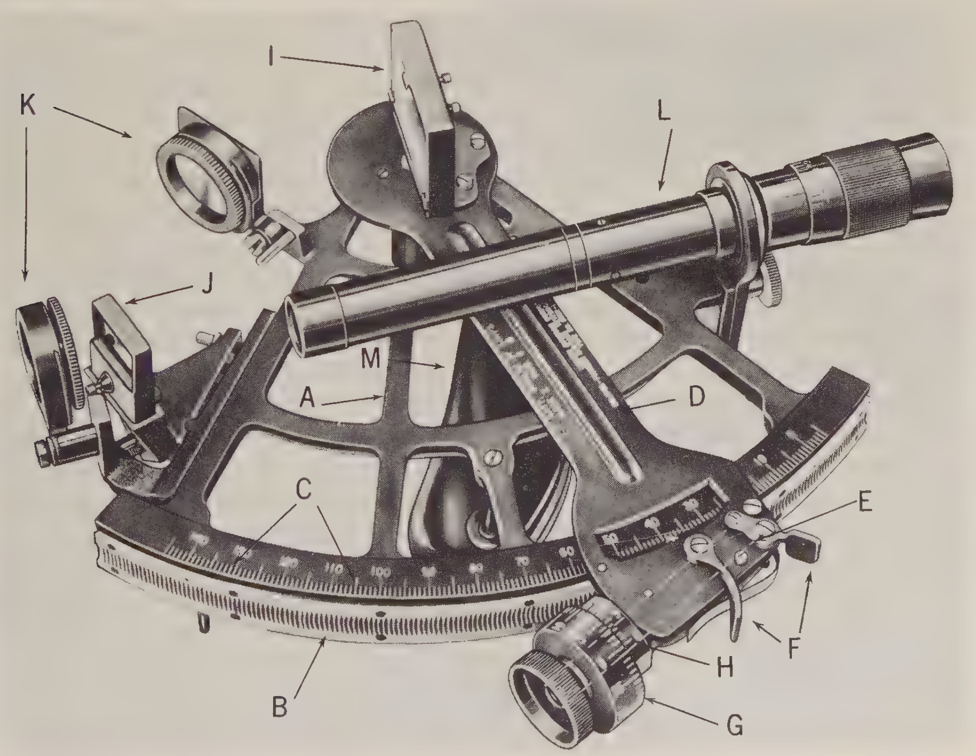

FIGURE 1503a.—U. S. Navy standard micrometer drum sextant.

made of brass or aluminum. There are several variations of the design of the frame, nearly all conforming generally to that shown. The **limb,** *B*, is cut on its outer edge with teeth, each representing one degree of altitude. The altitude graduations, *C*, along the limb, are called the **arc.** Some sextants have an arc marked in a strip of brass, silver, or platinum inlaid in the limb.

The **index arm,** *D*, is a movable bar of the same material as the frame. It is pivoted about the center of curvature of the limb. The **tangent screw,** *E*, is mounted perpendicularly on the end of the index arm, where it engages the teeth of the limb. Because the index arm can be moved through the length of the arc by rotating the tangent screw, this is sometimes called an "endless tangent screw," in contrast with the limited-range device on older instruments. The **release,** *F*, is a spring-actuated clamp which keeps the tangent screw engaged with the teeth of the limb. By applying pressure on the legs of the release, one can disengage the tangent screw. The index arm can then be moved rapidly along the limb. Mounted on the end of the tangent screw is a **micrometer drum,** *G*, which is graduated in minutes of altitude. One complete turn of the drum moves the index arm one degree of altitude along the arc. Adjacent to the micrometer drum and fixed on the index arm is a **vernier,** *H*, which aids in reading fractions of a minute. The vernier shown is graduated into ten parts, permitting readings to six seconds. Other sextants (generally of European manufacture) have verniers graduated into only six parts, permitting readings to ten seconds. The most expensive sextant in common use has no vernier, and readings more precise than one minute can only be estimated.

The **index mirror,** *I*, is a piece of silvered plate glass mounted on the index arm, perpendicular to the plane of the instrument, with the center of the reflecting surface directly over the pivot of the index arm. The **horizon glass,** *J*, is a piece of plate glass silvered on its half nearer the frame. It is mounted on the frame, perpendicular to the plane of the sextant. The index mirror and horizon glass are mounted so that their surfaces are parallel when the micrometer drum is set at 0°, if the instrument is in perfect adjustment. **Shade glasses,** *K*, of varying or variable darkness, are mounted on the frame of the sextant in front of the index mirror and horizon glass. They can be moved into the line of sight at will, to reduce the intensity of light reaching the eye of the observer. Older sextants have two sets of shade glasses, as shown in figure 1504. Many modern sextants are fitted with a single Polaroid **filter** of variable darkness in place of each set of shade glasses, as shown in figure 1503a.

The **telescope,** *L*, screws into an adjustable collar in line with the horizon glass, and should then be parallel to the plane of the instrument. Most modern sextants are provided with only one telescope, but some are equipped with two or more. When only one telescope is provided, it is of the "erect image type," either such as shown or one with a wider "object glass" (far end of telescope), which generally is shorter in length and gives a greater field of view. The second telescope, if provided, is of the "inverting type." The inverting telescope, having one lens less than the erect type, absorbs less light, but at the expense of producing an inverted image. A small colored glass cap is usually provided, to be placed over the "eyepiece" (near end of telescope) to reduce the glare. With this in place, shade glasses are generally not needed. A "peep sight" may be provided. It is a clear tube which serves to direct the line of sight of the observer when no telescope is used.

The telescope shown in figure 1503a is fitted with a "spiral focusing mechanism." Other sextants substitute a "draw" for this mechanism. The draw is fitted inside the telescope tube without threads and is slid in or out as necessary to focus the instrument.

The spiral focusing mechanism is easily adjusted each time the sextant is used, but on the draw type, the navigator should mark the draw to indicate the correct extension for his eyes.

The **handle,** *M*, of most sextants is made of wood or plastic. Sextants are designed to be held in the right hand. Some are equipped with a small light on the index arm to assist in reading altitudes. The batteries for this light are fitted inside a recess in the sextant handle.

Figure 1503b shows a sextant with a silver arc inserted in the limb, a micrometer drum graduated oppositely to the one in figure 1503a, a vernier graduated into six parts, a shorter telescope with a wider object glass than that in figure 1503a, a telescope draw substituted for a spiral focusing mechanism, and a light fitted on the index arm.

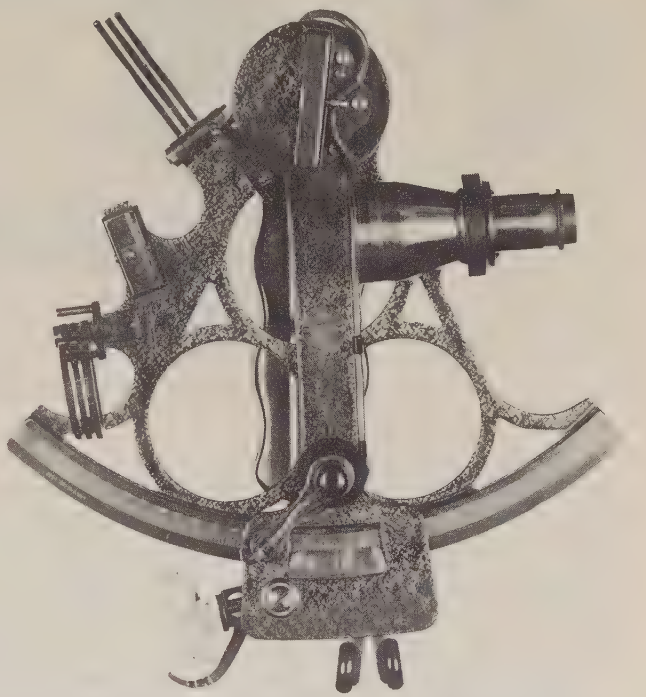

FIGURE 1503b.—A micrometer drum sextant used in the merchant marine.

1504. Vernier sextant.—Nearly all marine sextants of recent manufacture are of the type described in article 1503. At least two older-type sextants are still in use. These differ from the micrometer drum sextant principally in the manner in which the final reading is made. They are called **vernier sextants.**

The **clamp screw vernier sextant** is the older of the two. In place of the modern "release," a **clamp screw** is fitted on the underside of the index arm. To move the index arm, one loosens the clamp screw, releasing the arm. When the arm is placed at the approximate altitude of the body being observed, the clamp screw is tightened. Fixed to the clamp screw and engaged with the index arm is a long tangent screw. When this screw is turned, the index arm moves slowly, permitting accurate setting. Movement of the index arm (by the tangent screw) is limited to the length of the screw (several degrees of arc). Before an altitude is measured, this screw should be set to the approximate mid-point of its range. The final reading is made on a vernier set in the index arm below the arc. A small microscope or magnifying glass fitted to the index arm is used in making the final reading. Figure 1504 shows a clamp screw vernier sextant.

The **endless tangent screw vernier sextant** is identical with the micrometer drum sextant, except that it has no drum, and the fine reading is made by a vernier along the arc, as with the clamp screw vernier sextant. The release is the same as on the micrometer drum sextant and teeth are cut into the underside of the limb which engage with the endless tangent screw. The vernier itself is explained in article 1506.

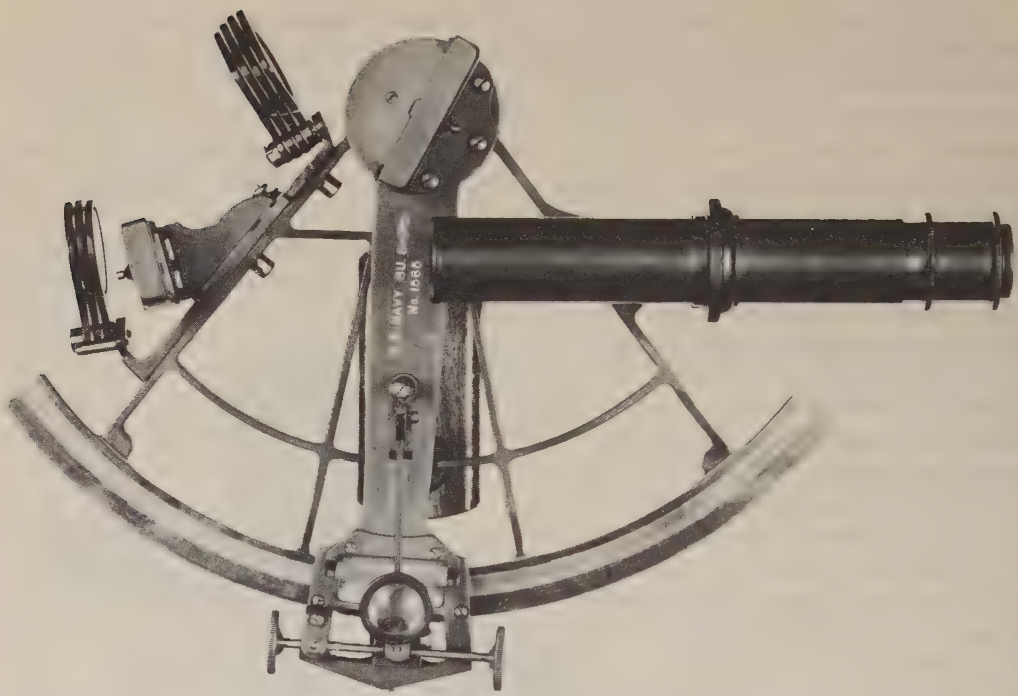

FIGURE 1504.—A clamp screw vernier sextant.

1505. Use of the sextant.—When the *sun* is observed, the sextant is held vertically in the right hand, and the line of sight is directed at the point on the horizon directly below the body. Suitable shade glasses are moved into the line of sight, and the index arm is moved outward from near the 0° point until the reflected image of the sun appears in the horizon glass, near the direct view of the horizon. The sextant is then tilted slightly to the right and left to check its perpendicularity. As the sextant is tilted, the image of the sun appears to move in an arc, and the observer may have to change slightly the direction in which he is facing, to prevent the image from moving out of the horizon glass. When the sun appears at the *bottom* of its apparent arc resulting from this **swinging the arc,** or **rocking the sextant,** the sextant is vertical, and in the correct position for making the observation. If the sextant is tilted, too *great* an angle will be measured. When the sextant is vertical, and the observer is facing directly toward the sun, its reflected image appears at the center of the horizon glass, half on the silvered part, and half on the clear part. The index arm is then moved slowly until the sun appears to be resting exactly on the horizon, which is tangent to the **lower limb.** Occasionally, the sun image is brought *below* the horizon, and the **upper limb** observed. It is good practice to make several observations, moving the limb away from the horizon, alternately above and below it, between readings. Practice is needed to determine the appearance at tangency, which occurs at only one point, to avoid the common error of beginners of bringing the image down too far (too little for an upper-limb observation). Some navigators get more accurate observations by letting the body contact the horizon by its own apparent motion, bringing it slightly below the horizon if rising, and above if setting. At the instant the horizon is tangent to the disk, the time is noted. The **sextant altitude** is the uncorrected reading of the sextant. Figure 1505a illustrates the major steps in making an observation of the sun.

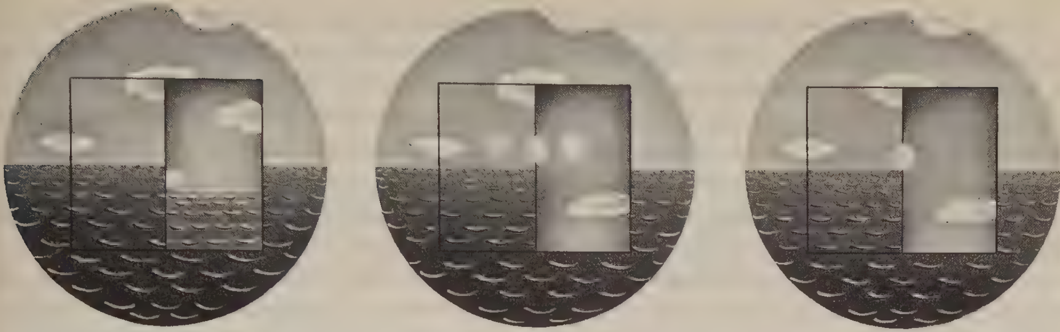

FIGURE 1505a.—*Left*, view through telescope with index arm set near zero. *Center*, "swinging the arc" after the sun has been brought close to the horizon. *Right*, sun at the instant of tangency.

At the left, the index arm has been moved a short distance from 0°. In the center, it has been clamped with the sun in the approximate position for a reading, and the sextant is being rocked. At the right, the sun is in the correct position for a reading.

When the *moon* is observed, the procedure is the same as for the sun, except that shade glasses are usually not required. The upper limb of the moon is observed more often than that of the sun, because of the phases of the moon. When the terminator (art. 1423) is nearly vertical, care should be exercised in selecting the limb that is illuminated, if an inaccurate reading is to be avoided. Sights of the moon are best made during daylight hours, or during that part of twilight in which the moon is least luminous. During the night, false horizons nearly always appear below the moon, due to illumination of the water by moonlight.

When a *star* or *planet* is observed, three methods of making the initial approximation of the altitude are in common use. In the most common, the index arm and micrometer drum are set on zero and the line of sight is directed at the body to be observed. Then, while keeping the reflected image of the body in the mirrored half of the horizon glass, the index arm is slowly swung *out* and the frame of the sextant is rotated *down*. The reflected image of the body is kept in the mirror until the horizon appears in the clear part of the horizon glass.

When there is little contrast between brightness of the sky and the body, this procedure is difficult, for if the body is "lost" while it is being brought down, it may not be recovered without starting again at the beginning of the procedure. An alternative method sometimes used consists of holding the sextant upside down in the left hand, directing the line of sight at the body, and slowly moving the index arm out until the horizon appears in the horizon glass. This is illustrated in figure 1505b. After contact is made, the sextant is inverted and the sight taken in the usual manner.

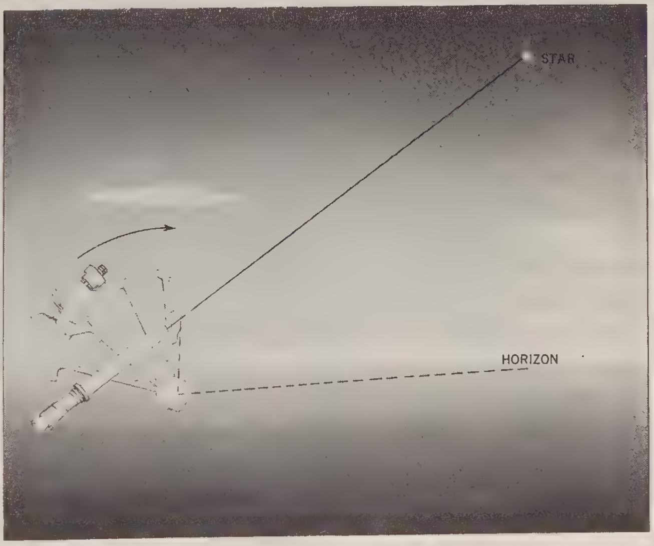

FIGURE 1505b.—Method of bringing horizon "up" to body.

A third method consists of determining in advance the approximate altitude and azimuth of the body by a **star finder** such as H.O. 2102–D (art. 2210). The sextant is set at the indicated altitude, and the observer faces in the direction indicated by the azimuth. After a short search, during which the index arm is moved backward and forward a few degrees, and the azimuth in which the observer faces is changed a little to each side, the image of the body should appear in the horizon glass. The best method to use for any observation is that which produces the desired result with the least effort. It is largely a matter of personal preference.

Measurement of the altitude of a star or planet differs from that of the sun or moon in that the *center* of a star or planet, rather than a limb, is brought into coincidence with the horizon. Figure 1505c shows the reflected image of a star as it should appear at the time of observation. Because of this difference, and the limited time usually available for observation during twilight, the method of letting a star or planet intersect the horizon by its own motion is little used. As with the sun and moon, however, the navigator should not forget to swing the arc to establish perpendicularity of the sextant.

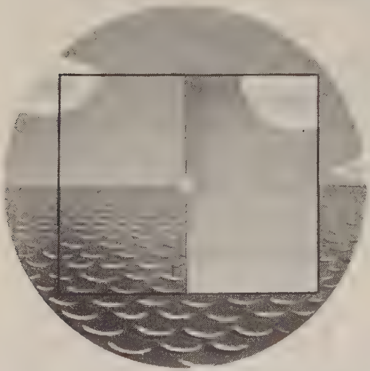

FIGURE 1505c.—Correct position of planet or star at moment of observation.

Occasionally, fog, haze, or other ships may obscure the horizon directly below a body which the navigator wishes to observe. If the arc of the sextant is sufficiently long, a **back sight** might be obtained, using the opposite point of the horizon as the reference. The observer faces *away* from the body and observes the *supplement* of the altitude. If the sun or moon is observed in this manner, what appears in the horizon glass to be the lower limb is in fact the upper limb. In the case of the sun, it is usually preferable to observe what appears to be the upper limb. The arc that appears when rocking the sextant for a back sight is inverted; that is, the *highest* point indicates the position of perpendicularity.

If more than one telescope is furnished with the sextant, the erecting telescope is used to observe the sun. Generally, the inverting telescope will produce the best results when observing the stars, although some navigators prefer not to use any telescope, thus obtaining a wider field of view. The collar into which the sextant telescope fits may be adjusted in or out in relation to the frame. When moved in, more of the mirrored half of the horizon glass is visible to the navigator, and a star or planet is more easily observed when the sky is relatively bright. Near the darker limit of twilight, the telescope can be moved out, giving a broader view of the clear half of the glass, and making the less distinct horizon more easily discernible. If both eyes are kept open until the last moments of an observation, eye strain will be lessened. But in making the final measurement, the nonsighting eye should be closed to permit full ocular concentration. Practice will permit observations to be made quickly, reducing inaccuracy due to eye fatigue. If several observations are made in succession, with a short rest between them, the best results should be obtained. With experience, the observer should be able to "call his shots," identifying the better ones.

When an altitude is being measured, it is desirable to have an assistant note the time, so that simultaneous values of time and altitude will be available. He should be given a warning "stand-by" when the measurement is nearly completed, and a "mark" at the moment a reading is made. He should be instructed to read the three hands in order of their rapidity of motion; the second hand first, then the minute hand, and

finally the hour hand. If it is sufficiently dark that a light is needed to make the reading, the assistant should read both the time, and then the altitude, *behind* the observer and facing away from him, to avoid impairment of the observer's eye adaption to sky and horizon lighting conditions.

If an assistant is not available to time the observations, the observer holds the watch in the palm of his left hand, leaving his fingers free to manipulate the tangent screw of the sextant. After making the observation, he quickly shifts his view to the watch, and notes the positions of the second, minute, and hour hands, respectively. The delay between completing the altitude observation and noting the time should not be more than one or two seconds. The average time should be determined by having someone measure it for several observations, or by counting the half seconds (learning to count with the half-second beats of a chronometer). This interval can then be subtracted from the observed time of each sight.

1506. Reading the sextant.—The reading of a micrometer drum sextant is made in three steps. The degrees are read by noting the position of the arrow on the index arm in relation to the arc. The minutes are read by noting the position of the zero on the vernier with relation to the graduations on the micrometer drum. The fraction of a minute is read by noting which mark on the vernier most nearly coincides with one of the graduations on the micrometer drum. This is similar to reading the time by means of the hour, minute, and second hands of a watch. In both, the relationship of one part of the reading to the others should be kept in mind. Thus, if the hour hand of a watch were *about* on "4," one would know that the time was about four o'clock. But if the minute hand were on "58," one would know that the time was 0358 (or 1558), not 0458 (or 1658). Similarly, if the arc indicated a reading of

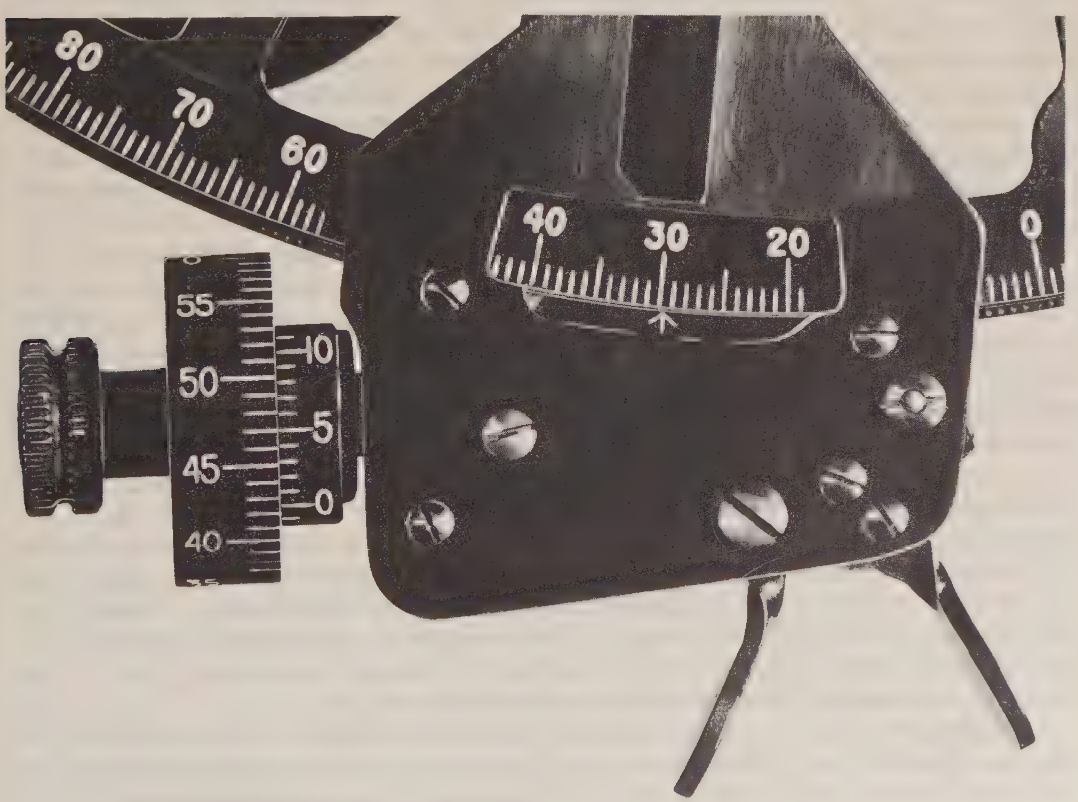

FIGURE 1506a.—Micrometer drum sextant set at 29°42′.5.

FIGURE 1506b.—Vernier sextant set at 29°42′30″.

about 40°, and 58′ on the micrometer drum were opposite zero on the vernier, one would know that the reading was 39°58′, not 40°58′. Similarly, any doubt as to the correct minute can be removed by noting the fraction of a minute from the position of the vernier. In figure 1506a the reading is 29°42′.5. The arrow on the index mark is between 29° and 30°, the zero on the vernier is between 42′ and 43′, and the "0′.5" graduation on the vernier coincides with one of the graduations on the micrometer drum.

The principle of reading a vernier type sextant is the same, but the reading is made in two steps. Figure 1506b shows a typical altitude setting on this type sextant. Each degree on the arc of this sextant is graduated into three parts, permitting an initial reading by the reference mark on the index arm to the nearest full 20 minutes of arc. In this illustration the reference mark lies between 29°40′ and 30°00′, indicating a reading between these values. The reading for the fraction of 20′ is made by means of the vernier, which is engraved on the index arm and has the small reference mark as its zero graduation. On this vernier, 40 graduations coincide with 39 graduations on the arc. Each graduation on the vernier is equivalent to $\frac{1}{40}$ of one graduation (20′) on the arc, or 0′.5 (30″). In the illustration, the vernier graduation representing $2\frac{1}{2}$ minutes (2′30″) most nearly coincides with one of the graduations on the arc. Therefore, the reading is 29°42′30″, or 29°42′.5, as before. When a vernier of this type is used, any doubt as to which mark on the vernier coincides with a graduation on the arc can usually be resolved by noting the position of the vernier mark on each side of the one that seems to be in coincidence.

Negative readings (as in determining index correction, art. 1603), are made in the same manner as positive readings, the various parts being added algebraically (art. O6). Thus, if the three parts of a micrometer drum reading are (−)1°, 56′, and 0′.3, the total reading is (−)1°+56′+0′.3=(−)3′.7.

1507. Developing observational skill.—A well-constructed marine sextant is capable of measuring angles with an instrument error not exceeding 0.'1. Lines of position from altitudes of this accuracy would not be in error by more than about 200 yards. However, there are various sources of error, other than instrumental, in altitudes measured by sextant. One of the principal sources is the observer himself. There is probably no single part of his work that the navigator regards with the same degree of professional pride as his ability to make good celestial observations. Probably none of his other tasks requires the same degree of skill.

The first fix a student navigator obtains by his observation of celestial bodies is likely to be disappointing. Most navigators require a great amount of practice to develop the skill needed to make good observations. But practice alone is not sufficient, for if a mistake is repeated many times, it will be difficult to eradicate. Early in his career a navigator would do well to establish good observational technique—and continue to develop it during the remainder of his days as navigator. Many good pointers can be obtained from experienced navigators, but it should be remembered that each develops his own technique, and a practice that proves highly successful for one observer may not help another. Also, an experienced navigator is not necessarily a good observer, although he may consider himself such. Navigators have a natural tendency to judge the accuracy of their observations by the size of the figure formed when the lines of position are plotted. Although this is some indication, it is an imperfect one, because it does not indicate the errors of individual observations, and may not reflect constant errors. Also, it is a compound of a number of errors, some of which are not subject to control by the navigator.

When a student first begins to use the sextant, he can eliminate gross errors of principle in its use, and gain some ability in making observations, by accepting the coaching of an experienced navigator. By watching the novice make observations, the experienced navigator can observe a tendency to hold the instrument incorrectly, swing the arc improperly, or make other mistakes. When a celestial body is near the celestial meridian, the experienced navigator might make an observation and quickly transfer the sextant to the inexperienced one, who can see how the sight should appear. The two might make simultaneous observations and compare results. At first it is well to select bodies of low altitude, if they are available.

This procedure is helpful in detecting gross mistakes, but since the observations of the experienced navigator are not without error, this method is not suitable for final polishing of technique. For this purpose, observations should be compared with a more exact standard. Lines of position from celestial observations can be compared with good positions obtained by electronics or by piloting, if near a shore. Although this is good practice and provides a means of checking one's skill from time to time, it does not provide the large number of comparisons in a short time needed if technique is to be perfected.

This can sometimes be accomplished when a vessel is at anchor, or at a pier, if a stretch of open horizon is available. In advance, the altitude of a celestial body which will be over the open horizon at a time favorable for observation is computed at intervals of perhaps eight minutes (change in hour angle of 2°). If the body will be near the meridian, a smaller interval should be used. The altitude is determined for the position of the vessel, and all sextant altitude corrections (ch. XVI) are applied with reversed sign. These altitudes are then plotted versus time on cross-section paper, to a large scale, and a curve drawn through the points. At the selected time, a large number of observations are made at short intervals, allowing only enough time between observations for resting the eyes and arms. These observations are then plotted on the cross-section paper and compared with the curve.

An analysis of the results should be instructive. Erratic results indicate poor observational conditions or the need for practice and more care in making observations. If the measured altitudes are consistently too great, the sextant may not be rocked properly, the condition of tangency of the lower limb of the sun or moon may not be judged accurately, a false horizon in the water may have been used, subnormal refraction (dip) might be present, the eye might be higher above water than estimated, time might be in error, the index correction may have been determined incorrectly, the sextant might be out of adjustment, an error may have been made in the computation, the horizontal (vertical) may be tilted slightly by nearby mountains, etc. If the measured altitudes are consistently too low, the condition of tangency of the upper limb of the sun or moon may not be judged accurately, a low cloud may have been used as the horizon, abnormal refraction (dip) might be present, height of eye might be lower than estimated, time might be in error, the index error may have been determined incorrectly, the sextant might be out of adjustment, an error may have been made in the computation, the waves or swell at the horizon might be higher than at the ship, the horizontal (vertical) may be tilted slightly, a planet or bright star may have been placed "tangent" to the horizon rather than centered on the horizon, etc.

A single test of this type, while instructive, may not be conclusive. Several tests should be made with different celestial bodies, at various altitudes, under various conditions of weather and sea, and at different places. Generally, it is possible and desirable to correct any errors being made in the technique of observation, but occasionally a **personal error** (sometimes called **personal equation**) will persist. This might be different for the sun and moon than for planets and stars, and might vary with degree of fatigue of the observer, and other factors. For this reason, a personal error should be applied with caution. However, if a relatively constant personal error persists, and experience indicates that observations are improved by applying a correction to remove its effect, better results might be obtained by this procedure than by attempting to eliminate it from one's observations.

When lines of position of great reliability are desired, even an experienced navigator can usually improve his results by averaging to reduce random error (art. 2904). A number of observations, preferably not less than ten, are made in quick succession. These can then be plotted versus time, on cross-section paper, and a curve faired through the points. Unless the body is near the celestial meridian, this curve should be very nearly a straight line. *Any* point on the curve can be used as the observation, using the time and altitude indicated by the point. It is best to use a point near the middle of the line, to avoid possible errors in its slope.

The slope can be determined by means of H.O. Pub. No. 214, using Δt, which is the change of altitude relative to change in meridian angle (time). Meridian angle changes at the rate of $1'$ in 4^s. Therefore, the change in altitude, in minutes of arc per second of time, is equal to Δt (expressed as minutes of arc) divided by 4^s, or $\frac{\Delta t'}{4^s}$. Thus, if Δt is 0.66, the altitude changes $\frac{0'.66}{4^s}=0'.165$ per second, or $15'\times 0'.66=9'.9$ per minute of time, increasing if the body is rising, and decreasing if it is setting. This rate may be altered by motion of the ship, the amount being the distance traveled in one minute, multiplied by the natural cosine of the relative azimuth of the body. Thus, if the speed is 15 knots, the ship moves 0.25 mile per minute. If the body is 30° on the bow, the altitude changes $0.25\times 0.86603=0'.2$ per minute due to motion of the ship, in addition to its own apparent motion due to rotation of the earth. If the body is forward of the beam, the effect of the ship's motion is to *increase* the altitude; if abaft the beam, to decrease it. The total effect is the algebraic sum of the separate effects due to

rotation of the earth and motion of the vessel, since rate *at the vessel* is desired. Rapid change of Δt indicates a curved rate line. If a large number of observations is made, the slope of the line should be apparent from the plotted points.

A somewhat simpler variation is generally available if observations are made at equal intervals, unless the body is near the meridian. It is based upon the assumption that the change in altitude should be equal for equal intervals of time. A number of observations might be made by having an assistant give a warning "stand-by" and then a "mark" at equal intervals of time, as every ten or 20 seconds. Perhaps a better procedure is to make the observations at equal altitude increments. After the first observation, the altitude is changed by a set amount according to its rate of change, as 5′. The setting is *increased* if the body is rising, and *decreased* if it is setting. The body is then permitted to cross the horizon by its own motion, and at the instant of doing so, the time is noted. If time intervals are constant, the *mid time* and the *average altitude* are used as the observation. If altitude increments are constant, the *average time* and *mid altitude* are used. An uneven number of observations simplifies the finding of the mid value, but with ten observations the finding of the average value is easier.

If only a small number of observations is available, as three, it is usually preferable to solve all observations and plot the resulting lines of position, adjusting them to a common time. The *average* position of the line might be used, but it is generally better practice to use the middle line (or a line midway between the two middle ones if there are an even number).

In this discussion of averaging, it has been assumed that all observations are considered of nearly equal value. Any observation considered unreliable, either in the judgment of the observer or as a result of a plot, should be rejected in finding an average.

1508. Care of the sextant.—The modern marine sextant is a well-built, precision instrument capable of rendering many years of reliable service, with minimum attention. However, its usefulness can easily be impaired by careless handling or neglect. If it is ever dropped, it may never again provide reliable information. If this occurs, the instrument should be taken to an expert for careful testing and inspection.

When not in use, a sextant should invariably be kept in its case and properly stowed. The sextant case should be a well-constructed hardwood box fitted on its exterior with a lock, a handle, and two hooks, preferably the type having safety catches. The interior of the case should be fitted with blocks in which the handle or legs, or both, are placed when the sextant is stowed. Some sextant cases are fitted with catches which clamp over the handle when the sextant is stowed, and some are fitted with felt-lined blocks on the inside of the cover, to clamp down on the extreme ends of the arc when the case is closed. The case should be so constructed that it can be closed with the shade glasses and index arm in nearly any normal position, and preferably with the telescope in place. The last is particularly valuable to the navigator on an overcast day when only one opportunity to observe the sun may present itself, and the sight may have to be taken quickly.

The case itself should be securely stowed in a convenient place away from excessive heat, dampness, and vibration. A shelf with built-up sides into which the case fits snugly is a good stowage place. The practice of leaving the sextant in its case on a chart room settee is a bad one, and the instrument should *never* be left unattended on the chart table.

To remove the sextant from its case, grasp the frame firmly with the left hand, making sure that no pressure is applied to the index arm, and lift the instrument from the box. Then take the sextant in the right hand, by its handle, leaving the left hand

free to make any adjustments necessary before taking a sight. The instrument should never be held by its limb, index arm, or telescope.

Next to careless handling, the greatest enemy of the sextant is moisture. The mirrors, especially, and the arc should be wiped dry after each use. A new sheet of plain lens paper is best to use for this purpose, and linen second best. Over a period of time, however, linen collects dust, which may contain abrasives that will scratch the surface of the mirrors. For this reason, linen, if it is used, should be kept in a small bag to protect it from dust in the air. Chamois leather and silk are particularly likely to collect abrasive dusts from the air and they should not be used to clean the mirrors or telescope lenses. Should the mirrors become particularly dirty, they can be cleaned with a small amount of alcohol, applied with a clean piece of lens paper. The arc can be cleaned, when necessary, with ammonia, but never with a polishing compound. In cleaning or drying the mirrors and arc, care should be taken that excessive pressure is not applied to any part of the instrument.

A small bag of silica gel kept in the sextant case will help in keeping the air in the case free from moisture, and will help to preserve the mirrors. Occasionally, the silica gel should be heated in an oven to remove the adsorbed moisture.

The tangent screw and the teeth on the side of the limb should be kept clean and lightly oiled, using the oil provided with the sextant. It is good practice to set occasionally the index arm of an endless tangent screw at one extremity of the limb and then to rotate the tangent screw over the length of the arc. This will clean the teeth and spread the oil through them. At any time that the sextant is to be stowed for a long period, the arc should be protected with a thin coat of petroleum jelly.

If the mirrors need resilvering, they are best taken to an instrument shop where a professional job can be done. However, on rare occasions it may be necessary to resilver the mirrors of a sextant at sea. In anticipation of this possibility, the navigator should obtain the necessary materials in advance, as makeshift substitutes cannot be relied upon to do the job adequately. The required materials are xylene (available in most pharmacies), dilute nitric acid (optional), alcohol, cotton, tin foil about 0.005 inch thick, a small amount of mercury, a clean blotter, and some tissue paper. Do not substitute aluminum foil commonly used in packaging candy and cigarettes.

First, remove the protective coating with alcohol (or better, acetone) from the back of the mirror to be resilvered, and clean the glass with xylene or acid. If the old silvering is difficult to remove, soak it in water. Place the blotter on a flat surface and turn up and seal the edges to form a tray. This will serve to contain the mercury if the vessel should roll during the operation. Using cotton, clean and smooth out both sides of a piece of tin foil slightly larger than the glass to be silvered, first with alcohol and then with xylene (do not use acid). Make certain that no lint adheres to the foil, and place it on the blotter. Clean the mercury by squeezing it through cheese cloth, and apply a drop to the foil. Carefully spread it over the surface with a finger, making sure that none of the mercury gets under the foil. Add a few more drops of mercury until the entire surface of the foil is covered and tacky. The mercury combines with some of the tin to form an amalgam. Place the chemically cleaned glass on a piece of clean tissue paper with the side to be silvered face down. Then place the glass and the paper on the amalgam. Apply slight pressure to the glass and withdraw the tissue paper. Following this, grasp the edge of the tin foil and lift it and the mirror from the blotter. Invert the glass and the tin foil and place in an inclined position, silvered side up. Any mercury remaining on the blotter is no longer pure and should be disposed of. Five or six hours later any loose foil may be scraped from the sides of the mirror, and the following day a coat of commercial varnish or lacquer should be applied to the silvered

surface. Should the mirrored half of the horizon glass require silvering, the clear half may be protected by a strip of cellulose or adhesive tape.

1509. Sextant adjustments.—There are at least seven sources of error in the marine sextant, three nonadjustable by the navigator, and four adjustable.

The **nonadjustable errors** are: "prismatic error," "graduation error," and "centering error."

The **prismatic error** is present if the two faces of the shade glasses and mirrors are not parallel. Error due to lack of parallelism in the shade glasses may be called **shade error.** Shade error in the shade glasses near the index mirror can be determined by comparison of an angle measured when a shade glass is in the line of sight with the same angle measured when the glass is not in the line of sight. In this manner, the error for each shade glass can be determined and recorded. If shade glasses are used in combination, their combined error should be determined separately. If additional shading is needed for the observations, use the colored telescope eyepiece cover. This does not introduce an error because direct and reflected rays are traveling together when they reach it, and are therefore affected equally by any lack of parallelism of its two sides.

Lack of parallelism of the two faces of the index mirror can be detected by carefully measuring a series of angles; then removing the index mirror, inverting it, and replacing it; and then measuring the same angles again. Half the difference is the prismatic error. After the index mirror has been inverted, it should be checked carefully for perpendicularity to the frame of the sextant, as explained below.

Lack of parallelism of the two faces of the horizon glass will appear as part of the index error, and so need not have separate attention. The same is true of prismatic error in the shade glasses located near the horizon glass, but unless index error is determined with the shade glasses in place, the measured index error will not be the correct value for the combined error.

Graduation errors occur in the arc, micrometer drum, and vernier of a sextant which is improperly cut or incorrectly calibrated. Normally, the navigator cannot determine whether the arc of a sextant is improperly cut, but the principle of the vernier makes it possible to determine the existence of graduation errors in the micrometer drum or vernier and is a useful guide in detecting a poorly made instrument. The first and last markings on any vernier should align perfectly with one less graduation on the adjacent micrometer drum. In figure 1503a, the vernier is graduated in ten units. When the zero point is aligned with any graduation on the micrometer drum, the "ten" graduation should be in perfect alignment with a micrometer graduation nine units greater than the one in line with zero on the vernier. In figure 1503b, the vernier is graduated in six units and should align perfectly with any two graduations five units apart on the micrometer.

Centering error results if the index arm is not pivoted at the exact center of curvature of the arc. It can be determined by measuring known angles, after the adjustable errors have been removed. Horizontal angles can be used by determining the accurate value by careful measurement with a theodolite (art. 4004). Several readings by both theodolite and sextant should minimize errors. An alternative method is to measure angles between the lines of sight to stars, comparing the measured angles with computed values. To minimize refraction errors, one should select stars at about the same altitude, and avoid stars near the horizon.

The same shade glasses, if any, used for determining or eliminating index error should be used for measuring centering error. The errors determined in this manner include any error due to faulty graduation, and prismatic error of the index mirror,

unless corrections are applied for these errors. However, since all vary with the angle measured, they need not be separated. Usually, it is preferable to make a single correction table for all three errors, called **instrument error.** Customarily, such a table is determined by the manufacturer and attached to the inside cover of the sextant case. The sign of the error is reversed, so that the values given are for **instrument correction (I).**

The **adjustable errors** in the sextant are those related to *perpendicularity* of (1) the frame and the index mirror, and (2) the frame and the horizon glass, and *parallelism* of (3) the index mirror and horizon glass to each other at zero setting, and of (4) the telescope to the frame. Each of these errors, if it exists, can be removed from the sextant by careful adjustment. In making these adjustments, *never tighten one adjusting screw without first loosening the other screw which bears on the same surface.* The adjustments should be made in the order indicated.

The first adjustment is for **perpendicularity of the index mirror** to the frame of the sextant. To test for perpendicularity, place the index arm at about 35° on the arc,

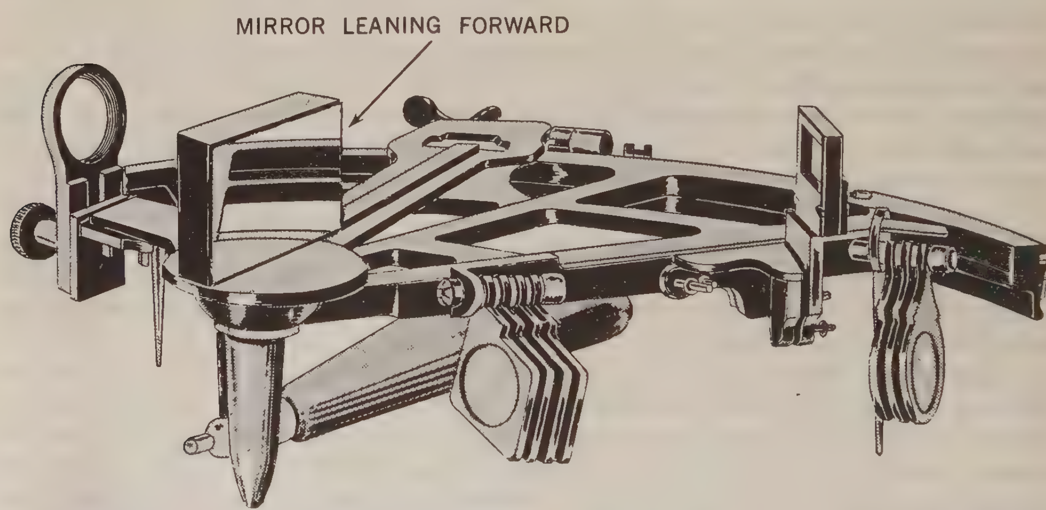

FIGURE 1509a.—Testing the perpendicularity of the index mirror. Here the mirror is not perpendicular.

and hold the sextant on its side, with the index mirror "up" and toward the eye. Observe the direct and reflected views of the sextant arc, as illustrated in figure 1509a. If the two views do not appear to be joined in a straight line, the index mirror is not perpendicular. If the reflected image is above the direct view, the mirror is inclined forward. If the reflected image is below the direct view, the mirror is inclined backward. An alternative and sometimes more satisfactory method of determining perpendicularity involves the use of two small vanes, or similar objects, of exactly the same height. Figure 1509b illustrates this method. Again the index arm is set at about 35°. The vanes are placed upright on the extremities of the limb, in such a way that the observer can, by placing his eye near the index mirror, see the direct view of one vane and the reflected image of the other. The tops of the objects are then observed for alignment. The use of vanes permits observation in the plane of adjustment, rather than at an angle. Adjustment is made by means of two screws at the back of the index mirror.

The second adjustment is for **perpendicularity of the horizon glass** to the frame of the sextant. An error resulting from the horizon glass not being perpendicular is

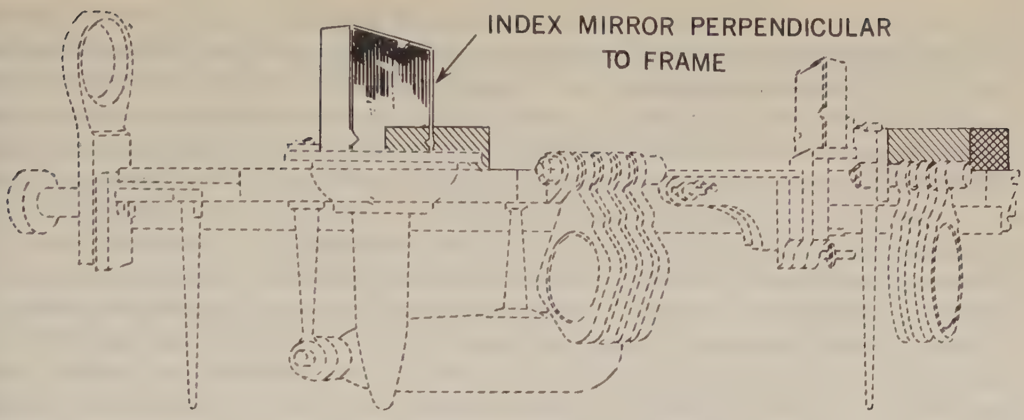

FIGURE 1509b.—Alternative method of testing the perpendicularity of the index mirror. Here the mirror is perpendicular.

called **side error.** To test for perpendicularity, set the index arm at zero and direct the line of sight at a star. Then rotate the tangent screw back and forth so that the reflected image passes alternately above and below the direct view. If, in changing from one position to the other, the reflected image passes directly over the star as seen without reflection, no side error exists, but if it passes to one side, the horizon glass is not perpendicular to the frame of the sextant. Figure 1509c illustrates observations without side error (left) and with side error (right). Whether the sextant reads zero when the true and reflected images are in coincidence is immaterial in this test. An alternative method is to observe a vertical line, such as one edge of the mast of another vessel (or the sextant can be held on its side and the horizon used). If the direct and reflected portions do not form a continuous line, the horizon glass is not perpendicular to the frame of the sextant. A third method is to hold the sextant vertical, as in observing the altitude of a celestial body, and bring the reflected image of the horizon into coincidence with the direct view, so that it appears as a continuous line across the horizon glass. Then tilt the sextant right or left. If the horizon still appears continuous, the horizon glass is perpendicular to the frame, but if the reflected portion appears above or below that part seen direct, the glass is not perpendicular. Adjustment is made by means of two screws near the base of the horizon glass.

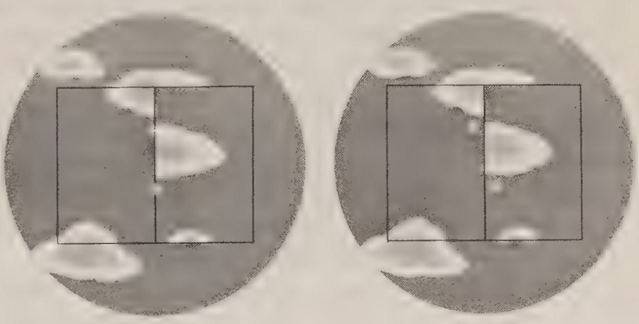

FIGURE 1509c.—Testing the perpendicularity of the horizon glass. *Left*, side error does not exist. *Right*, side error does exist.

The third adjustment is to make the **index mirror and horizon glass parallel** when the index arm is set exactly at zero. The error which results when the two are not parallel is the principal cause of **index error,** the total error remaining after the four adjustments have been made. Index error should be determined each time the sextant is used and need not be removed if its value is known accurately. To make the test for parallelism of the mirrors, set the instrument at zero, and direct the line of sight at the horizon or a star. Side error having been eliminated, the direct view and reflected image of the horizon appear as a continuous line, or the star as a single point,

if the two mirrors are parallel. If the mirrors are not parallel, the horizon appears broken at the edge of the mirrored part of the horizon glass, one part being higher than the other. The reflected image of a star appears above or below the star seen without reflection. If the star appears as a single point, move the tangent screw a small amount to be sure both direct view and reflected image are in the range of vision. The sun can be used by noting the reading when the reflected image is tangent to the sun as seen direct, first above it and then below. These should be numerically equal but of opposite sign (one positive and the other negative). To avoid variations in refraction, do not use low altitudes; or turn the sextant on its side and use the two sides of the sun. Adjustment is made by two screws near the base of the horizon glass. If the error is not to be removed, turn the tangent screw until direct view and reflected image of the horizon or a star are in coincidence. The reading of the sextant is the index error. It is positive if the reading is "on the arc" (positive angle), and negative if "off the arc" (negative angle). In the case of the sun it is *half* the numerical difference (algebraic sum) of the readings, positive or negative to agree with the larger reading. **Index correction (IC)** is numerically the same as index error, but of opposite sign. Since both the second and third adjustments involve the position of the horizon glass, it is good practice to recheck for side error after index error has been eliminated. Index error should always be checked after adjustment for side error.

The fourth adjustment is to make the **telescope parallel** to the frame of the sextant. If the line of sight through the telescope is not parallel to the plane of the instrument, an **error of collimation** will result, and altitudes will be measured as greater than their actual values. To check for parallelism of the telescope, insert it in its collar, and observe two stars 90° or more apart, bringing the reflected image of one into coincidence with the direct view of the other, near either the right or left edge of the field of view (the upper or lower edge if the sextant is horizontal). Then tilt the sextant so that the stars appear near the opposite edge. If they remain in coincidence, the telescope is parallel to the frame, but if they separate, it is not. An alternative method is to place the telescope in its collar and then lay the sextant on a flat table. Sight along the frame of the sextant and have an assistant place a mark on the opposite bulkhead, in line with the frame. Place another mark above the first at a distance equal to the distance from the center of the telescope to the frame. This second line should be in the center of the field of view of the telescope if the telescope is parallel to the frame. Adjustment for nonparallelism is made to the collar, by means of the two screws provided for this purpose.

Determination of any of the errors should be based upon a series of observations, rather than a single one. This is particularly true in the case of index error, which should be determined by approaching coincidence from opposite directions (up and down) on alternate readings. If adjustments are made carefully, and the sextant is given proper handling, it should remain in adjustment over a long period of time. Unless the navigator has reason to question the accuracy of the adjustments, they need not be checked at intervals of less than several months, except in the case of index error, which has the greatest effect on accuracy of readings, and should be checked each time the sextant is used. If the horizon is used for determining index error, this check should be made *before* evening twilight observations, and *after* morning twilight observations, while the horizon is sharp and distinct. If a star is used, the index error should be determined *after* evening observations and *before* morning sights are taken. During the day, it should be checked both before and after observations.

Frequent manipulation of the adjusting screws should be avoided, as it may cause excessive wear. Except in the case of index error, slight lack of adjustment has little

effect on the results, and should be ignored. If adjustments are needed at frequent intervals, the sextant is not receiving proper care, or has worn parts which should be replaced at a navigation instrument shop. If index error is not constant, it should not be removed, but index correction should be determined before or after every observation and applied to the readings, until the sextant can be repaired. A small variable error might well be accepted, but should be watched to see that it does not become unduly large.

1510. Selection of a sextant.—For satisfactory results a sextant should be selected carefully. For accurate work the radius of the arc should be about 7½ inches or more. The instrument should be light, but strongly built. The various moving parts should fit snugly, but move freely without binding or gritting. If the index arm is either too loose or too tight at either end of the arc, the pivot may not be perpendicular to the frame of the sextant. The telescope should be easy to insert or remove from its holder, and to focus.

The use to be made of a sextant should be considered in its selection. For ordinary use in measuring altitudes of celestial bodies, an arc of 90° or slightly more is sufficient. A longer arc is desirable if back sights are to be made, or if horizontal angles are to be measured. If use of the sextant is to be limited to horizontal angles, less accuracy is required. The arc can be of smaller radius, and small nonadjustable errors are unimportant.

If practicable, a sextant should be examined by an expert, and tested for non-adjustable errors before acceptance.

1511. Octants, quintants, and quadrants.—Originally, the term "sextant" was applied to the navigator's double-reflecting, altitude-measuring instrument only if its arc was 60° in length—a sixth of a circle—permitting measurement of angles from 0° to 120°. In modern usage the term is applied to all navigational altitude-measuring instruments, regardless of angular range or principles of operation, although some are octants (angular range 90°), some quintants (144°), some quadrants (180°), and many have an intermediate range.

1512. The artificial horizon.—Measurement of altitude requires a horizontal reference. In the case of the marine sextant this is commonly provided by the visible sea horizon. If this is not clearly visible, reliable altitudes cannot be measured unless a different horizontal reference is available. Such a reference is commonly called an **artificial horizon.** If it is attached to, or part of, the sextant, altitudes can be measured at sea, on land, or in the air, whenever celestial bodies are available for observations. On land, where the visible horizon is not a reliable indication of the horizontal, an external artificial horizon can be devised.

Any horizontal reflecting surface will serve the purpose. A pan of mercury, heavy oil, molasses, or other viscous liquid sheltered from the wind is perhaps simplest. A piece of plate glass fitting snugly across the top of the container is usually the best shelter. If there is any reasonable doubt as to the parallelism of the two sides of the glass, two readings should be made with the glass turned 180° in azimuth between readings, and the average value taken. The pan and liquid should be clean, as foreign material on the surface of the liquid is likely to distort the image and introduce an error in the reading.

To use an external artificial horizon, the observer stands or sits in such a position that the celestial body to be observed is reflected in the liquid, and is also visible by direct view. By means of the sextant, the double-reflected image is brought into coincidence with the image appearing in the liquid. In the case of the sun or moon the *bottom* of the double-reflected image is brought into coincidence with the *top* of the

image in the liquid, if a lower-limb observation is desired. For an upper-limb observation, the opposite sides are brought into coincidence. If one image is made to cover the other, the observation is of the *center* of the body.

When the observation has been made, apply the index correction and any other instrumental correction, as well as any correction for personal error. Then take *half* the remaining angle and apply all other corrections except dip (height of eye) correction, since this is not applicable. If the *center* of the sun or moon is observed, omit, also, the correction for semidiameter. Chapter XVI explains the various corrections and their applications.

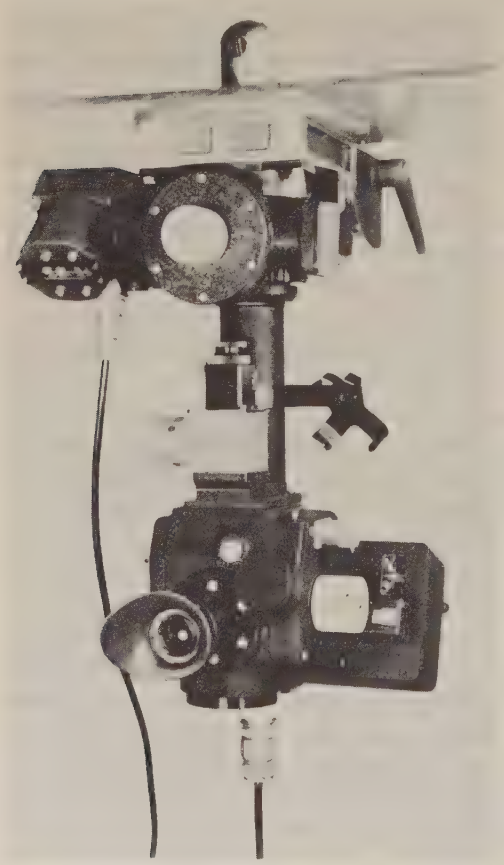

FIGURE 1513a.—Modern periscopic sextant.

A commercial artificial horizon consisting of a metal tray, mercury, cover of two sloping glass sides held in a metal frame, metal bottle to hold the mercury when not in use, and a funnel for pouring, was at one time a familiar part of a navigator's equipment, but the modern navigator might experience difficulty in locating such a device.

1513. Artificial-horizon sextants.—Shortly after the marine sextant was invented (art. 124), an attempt was made to extend its use to periods of darkness. This was done by providing a spirit level attachment. The observer brought the double-reflected image of the celestial body being observed into coincidence with the bubble of the spirit level. Such devices have been made available from time to time, and are still being manufactured. However, they have never come into general use, and are of questionable value.

Charles A. Lindbergh's historic solo flight across the North Atlantic in 1927 demonstrated the practicability of long over-water flights. The development of a suitable instrument for observing altitudes of celestial bodies during darkness and when the horizon was obscured by clouds or haze became a virtual requirement. Various forms of artificial horizon have been used, including a bubble, gyroscope, and pendulum. Of these, the bubble has been most widely used. Figure 1513a illustrates a modern periscopic sextant permitting observation with only a small tube protruding through the top of the airplane. Figure 1513b shows the optical principle of a different type aircraft sextant.

With an artificial horizon of the bubble or pendulum type, considerable skill is needed to make an observation. The image of the horizontal reference (a circle or horizontal line) and the celestial body both appear in the field of view, and both may seem unsteady. An observation is made by matching the two near the center of the field of view. The appearance at coincidence depends upon the instrument. Some bubbles appear dark and are placed on a level with the body. Others have a clear center and are placed over the body. One pendulum type has a horizontal line that is customarily

placed directly across the body, although a limb observation can be made if desired. Bubbles can be regulated in size, and the instructions provided with the instrument should be followed. In general, the bubble diameter should be about one-sixth to one-fourth the size of the field of view. This is about three to four times the size of the sun or full moon as seen through the eyepiece. A very small bubble should be avoided because it tends to lag sextant movements so much that it is unreliable as a horizontal reference.

A considerable amount of practice is needed to develop skill in making reliable observations with an artificial-horizon sextant, even on land or other steady platform. At sea or in the air the motions of the craft greatly increase the difficulty of observation. In addition to compounding the difficulty of making coincidence, the craft motion introduces a sometimes large and rapidly varying **acceleration error.** That is, motions of the craft produce an acceleration on the pendulum or the liquid of the bubble chamber, causing false indication of the horizontal. In smooth air the accelerations tend to follow a cycle of about one to two minutes in length. They are largely eliminated by use of an averaging device. In making an observation, the observer attempts to maintain coincidence continuously over a period, usually two minutes. The *average* altitude, generally indicated on a dial or drum, is used with the *mid* time of observation. Thus, perhaps 60 individual observations, or a continuously integrated altitude, are available to smooth out errors of individual observations.

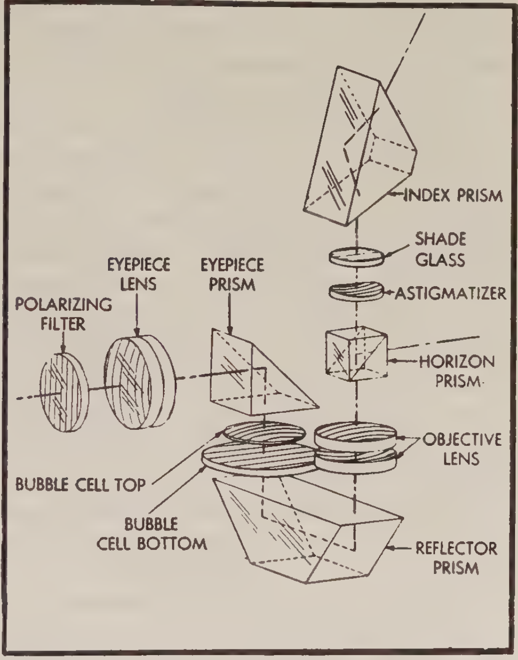

FIGURE 1513b.—Optical principle of a typical bubble sextant.

On land or other steady platform a skillful observer using a two-minute averaging bubble or pendulum sextant can measure altitudes to an accuracy of perhaps 2′ (two miles). This, of course, refers to the accuracy of measurement only, and does not include additional errors such as abnormal refraction, deflection of the vertical, computational and plotting errors, etc. In steady flight through smooth air the error of a two-minute observation is increased to perhaps five to ten miles. At sea, conditions are different. In a glassy sea with virtually no roll or pitch, results should approach those on land. However, with even a slight, gentle roll the accelerations to which a vessel is subjected are quite complex, as indicated by the difficulty one not accustomed to the sea has in getting his "sea legs" during the early part of a voyage. If the vessel is yawing, a large Coriolis error (art. 1611) may be introduced. Under these conditions observational errors of 10–15 miles are not unreasonable. With a moderate sea, errors of 30 miles or more are common. In a heavy sea, any useful observations are virtually impossible to obtain. Single altitude observations in a moderate sea can be in error by a matter of *degrees.*

Because of the difficulty of observing, and the large acceleration errors encountered aboard a vessel, bubble and pendulum type sextants have very limited use at sea. A submarine on war patrol, surfacing only during darkness, may have use for such an instrument. A large number of observations on a reasonably calm night can produce

results of some value. However, even under these conditions some navigators report better results with a marine sextant and dark-adapted eyes. In pack ice a ship generally provides a reasonably steady platform. When the horizon is obscured by ice or haze, polar navigators can sometimes obtain better results with an artificial-horizon sextant than with a marine sextant. Some artificial-horizon sextants have provision for making observations with the natural horizon as a reference, but since this is a secondary usage, results are not generally as satisfactory as by marine sextant. Because of their more complicated optical systems, and the need for providing a horizontal reference, artificial-horizon sextants are generally much more costly to manufacture than marine sextants. Designed for use in the air, they serve a useful purpose there, but for ordinary use aboard ship they have little to recommend them.

Altitudes observed by artificial-horizon sextant are subject to the same errors as those observed by marine sextant, except that dip (height of eye) correction does not apply. Also, when the center of the sun or moon is observed, no correction for semidiameter should be made. Chapter XVI explains the various sextant altitude corrections and their applications.

Adjustment of an artificial-horizon sextant should not be attempted by other than an instrument man qualified to handle the particular type instrument involved. An exception is the adjustment of the size of the bubble. Also, with some instruments an easily movable index permits elimination or reduction of index error. This error can best be determined in an instrument shop equipped with a collimator. If one is not available, the error can be determined by comparing the average of a number of observations made at a known point on land with the computed values. A precomputed curve of altitude versus time is useful for this purpose. Altitude corrections equal to the errors but with reversed sign should be applied to computed altitudes. With normal usage, the index error should not change. In most artificial-horizon sextants there is no index error.

The care and operation of various types of instruments vary considerably. The instruction booklet provided with each instrument should serve as the guide. Information on certain artificial-horizon sextants, and a general guide to artificial-horizon sextant observation, is given in H.O. Pub. No. 216, *Air Navigation*, and other texts.

1514. The marine chronometer is a timepiece having a nearly constant rate. It is used aboard ship to provide accurate time, primarily for timing celestial observations for lines of position, and secondarily for setting the ship's other timepieces. It differs from a watch principally in that it contains a variable lever device to maintain even pressure on the mainspring, and a special balance designed to compensate for temperature variations. A ship in which celestial navigation is used carries one or more chonometers.

A chronometer is set approximately to Greenwich mean time (GMT) and is not reset until the instrument is overhauled and cleaned, usually at three-year intervals. Resetting might disturb the rate. Instead, the difference between GMT and **chronometer time** (C) is carefully determined, and applied as a correction to all chronometer readings. This difference, called **chronometer error** (CE), is "fast" (F) if chronometer time is later than GMT, and "slow" (S) if earlier. The amount by which chronometer error changes in one day is called **chronometer rate,** or sometimes **daily rate,** considered "gaining" or "losing" as the chronometer is running faster or slower than the correct rate. An erratic rate indicates a defective instrument, or need for overhaul. The methods of determining and applying chronometer error and chronometer rate are explained in chapter XIX.

A chronometer is mounted in gimbals in a box, which should be carefully stowed to protect the instrument from damage due to heavy rolling and pitching, vibration, temperature variations, and electrical and magnetic influences. Usually this is done by fitting the box snugly into a heavily padded case suitably located in the chart room of merchant ships, and below decks, near the center of motion, in U. S. Navy ships.

The principal maintenance requirement aboard ship is regular winding at about the same time each day. Aboard United States naval vessels this is customarily done at about 1130 each morning, and reported to the commanding officer at 1200. Aboard merchant ships it is usually wound at about 0800. Although a chronometer is designed to run for more than two days, daily winding helps insure a uniform rate, and constitutes a daily routine that decreases the possibility of letting the instrument run down. On the face of each chronometer is a small dial that indicates the number of hours before the chronometer will be run down. To wind the chronometer, gently turn the instrument on its side, and slide back the guard covering the keyhole. Insert the key and carefully wind in a counterclockwise direction. Seven half-turns should suffice. If a chronometer should run down, wait until GMT is nearly the same as the time indicated before winding. If the chronometer does not start after winding, move the case back and forth gently. Check the error and rate carefully.

At maximum intervals of about three years, a chronometer should be sent to a good chronometer repair shop for cleaning and overhaul. When transported by hand, a chronometer should be clamped in its gimbals and stowed in the large case provided. When shipped, it should be allowed to run down, and the balance secured by a cork before the chronometer is stored in the large case.

Detailed instructions for the care and handling of chronometers are available to U. S. Navy ships in the *Bureau of Ships Manual* and current directives.

1515. Watches.—In the interest of accuracy, a chronometer is not disturbed more than necessary. Celestial observations are timed and ship's clocks set by means of a **comparing watch.** This is a high-grade pocket watch which is set by comparison with a chronometer, and then carried to the place where accurate time is needed. For celestial navigation, a comparing watch should have a large sweep-second hand which can be set. A comparing watch used for timing celestial observations should preferably be set to Greenwich mean time, to avoid the necessity of applying a correction for each observation.

If the second hand cannot be set, the watch should be set to the nearest whole minute, being sure that the second hand is in synchronism with the minute hand, and the **watch error** (**WE**) determined. If a watch is to be used for other purposes than timing of celestial observations, it might preferably be set to zone time. A comparing watch should be set, or watch error determined, immediately before or after celestial observations are made, to avoid the necessity for determining and applying a correction for **watch rate,** and to eliminate a possible error due to an inaccurate or variable rate. If a watch set to GMT is used for timing celestial observations, care should be taken to avoid a possible error of 12 hours or 24 hours. The mental application of zone description to ship's time indicates the approximate GMT and the Greenwich date. The subject of time is discussed more fully in chapter XIX. A stop watch may also be used for celestial observations.

Watches rated to sidereal time (art. 1913) can be purchased, but these have limited use aboard ship.

1516. Other instruments.—The sextant, chronometer, and comparing watch (or stop watch) are the principal instruments of celestial navigation. The azimuth circle

for observing azimuths of celestial bodies is discussed in article 629. Plotting equipment is the same as that for dead reckoning (arts. 602–606). A flashlight might be needed for reading the sextant and the comparing watch. A pocket notebook is desirable for recording predicted positions of celestial bodies if a star finder is used, and for recording the observations. A workbook is desirable for solving celestial observations, so that a permanent record is available. Work forms are desirable, but should form part of the work book, and not be kept separately. These might be provided by rubber stamp, or by printing. In the latter case a looseleaf work book may be desirable to permit arrangement of the various papers in chronological order.

CHAPTER XVI

SEXTANT ALTITUDE CORRECTIONS

1601. Need for correction.—Altitudes of celestial bodies, obtained aboard ship for the purpose of establishing lines of position, are normally measured by a hand-held **sextant,** described in chapter XV. The uncorrected reading of a sextant after such an operation is called **sextant altitude (hs).** If the sextant is in proper adjustment, certain sources of error are eliminated, as explained in article 1509. There remains, however, a number of sources of error over which the observer has little or no control. For each of these he applies a correction. When all of these **sextant altitude corrections** have been applied, the value obtained is the altitude of the center of the celestial body above the celestial horizon, for an observer at the center of the earth. This value, called **observed altitude (Ho),** is compared with the **computed altitude (Hc)** to find the **altitude difference** (*a*) used in establishing a line of position, as explained in chapter XVII.

Articles 1602–1620 describe the various corrections. For highly accurate results, all of these are needed to the greatest accuracy obtainable. The needs of ordinary practical navigation, however, make no such exacting requirements, and in the course of his usual day's work at sea, the navigator has relatively few corrections to apply, from conveniently-arranged tables readily accessible to him. The detailed information in articles 1602–1620 is given to (1) provide the basis for a better understanding of the problem, (2) furnish the information needed for evaluation of results, and (3) provide a source of reference material beyond that given in the usual navigation text.

1602. Instrument correction (I) is the combined correction for nonadjustable errors (prismatic error, graduation error, and centering error) of the sextant, as explained in article 1509. Usually, this correction is determined by the manufacturer, and recorded on a card attached to the inside of the top of the sextant box. It varies with the angle, may be either positive or negative, and is applied to all angles measured by that instrument. For a well-made instrument, the maximum value is so small that this correction can be ignored for all except the most accurate work. Normally, instrument error of artificial-horizon sextants is so small, considering the precision to which angles can be measured by such instruments, that no correction is provided.

1603. Index correction (IC), due to lack of parallelism of the horizon glass and index mirror at zero reading, is discussed in article 1509. Until the adjustment is disturbed, the index correction remains constant for all angles, and is applicable to all angles measured by the instrument. It may be either positive or negative. Normally, artificial-horizon sextants do not have index corrections. Some navigators prefer to adjust their marine sextants so as to eliminate index correction. This is good practice *if* one remembers to check the value each time the sextant is used. Other navigators prefer to retain an index correction to serve as a reminder to check the values. Since dip (art. 1606) at any given height of eye is also a constant for all altitudes, the need for applying both IC and dip can be eliminated by adjusting the sextant so that IC is numerically equal to dip, but of opposite sign. Such a practice should not be used unless the observer has some positive system of reminding himself that the value should be checked each time the instrument is used, and changed if the height of eye changes. It is of little value if observations are not generally made from the same height of eye. If personal correction (art. 1604) is constant, it can also be combined with the index

correction. However, it is generally preferable to keep each of these corrections separate, to avoid possible error.

1604. Personal correction (**PC**) is numerically the same as personal error (art. 1507), but of opposite sign, either positive or negative. If experience indicates the need for such a correction, it should be made to altitudes of the bodies to which it applies. However, the observer should be sensitive to changes in its value. Unless the observer has sufficient evidence to be sure of the existence and relative constancy of a personal error, no correction should be applied. The possibility of combining this correction with dip is explained in article 1603.

1605. Tilt correction (**N**).—The altitude of a celestial body is the *vertical* angle above the horizon. The angular distance from the body to any point on the horizon other than that vertically below the body is greater than the altitude. Therefore, if the frame of a marine sextant is not held vertical during observation, the angle measured is too great, and a negative **tilt correction** is needed. Tables of this correction have been prepared, but they are generally not applicable because **tilt error** can be eliminated by rocking the sextant (art. 1505). If this is not done accurately, an error may remain, but the observer is not aware of it, and therefore does not know the size of the angle of tilt. A "ball recording" artificial-horizon sextant used to some extent during World War II measured the tilt angle, and a tilt correction table was provided with the sextant. Bubble sextants are kept vertical by centering the bubble. With an artificial horizon, there is no tilt error because the celestial body is aligned with its own image.

Tilt correction increases with greater angle of tilt. For the same angle it also increases with greater altitude of the body. There is difference of opinion as to whether the value continues to increase after an altitude of 45°, or whether it then begins to decrease. This question resolves itself into one of whether the axis of tilt is horizontal or in the line of sight to the body. Evidence seems to favor the line of sight axis, with the error being maximum at altitude 45°. The correction, if there is one, applies equally to all celestial bodies. In rough weather, when observation may be difficult, this error can be minimized by observing bodies that are not high in the sky.

1606. Dip (**D**) of the horizon is the angle by which the visible horizon (art. 1428) differs from the horizontal at the eye of the observer (the sensible horizon, art. 1428). Thus, it applies only when the visible horizon is used as a reference, and not when an artificial horizon, either internal or external to the sextant, is used. It applies to all celestial bodies. If the eye of the observer were at the surface of the earth, visible and sensible horizons would coincide, and there would be no dip. This is never the situation aboard ship, however, and at any height *above* the surface, the visible horizon is normally *below* the sensible horizon, as shown in figure 1428b. Normally, then, an altitude measured from the visible horizon is too *great*, and the correction is *negative*. It increases with greater height of the observer's eye. Because of this, it is sometimes called **height of eye correction.**

If there were no atmospheric refraction, dip would be the angle between the horizontal at the eye of the observer, and a straight line from this point tangent to the surface of the earth. In figure 1606a, the eye of the observer is at A, at some point above the surface of the earth. The line AB is the horizontal through A, and AC is the tangent through this point. Angle BAC is the dip at A, neglecting refraction. Since OA is perpendicular to AB, and OD is perpendicular to AC (art. O30), angle AOD is equal to angle BAC (art. O27). If r is the radius of the earth, and h is the height of the observer's eye above the surface, the cosine of angle AOD is $\frac{r}{r+h}$.

The line of sight to the horizon, however, passes through the lowest layers of the earth's atmosphere, where the density of the atmosphere normally decreases as

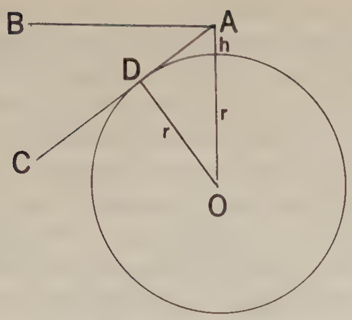

FIGURE 1606a.—Dip without refraction.

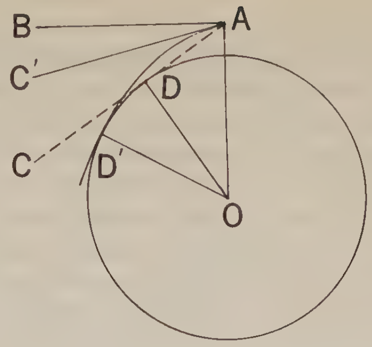

FIGURE 1606b.—Dip with refraction.

height above the surface increases. Consequently, the ray of light from the horizon to the observer's eye is bent by refraction. The result of this **terrestrial refraction** is to increase the distance to the horizon, which is at D' (fig. 1606b) instead of at D. This actual distance, under normal conditions, is given in table 8. Although the horizon is farther away than it would be if there were no refraction, it appears *higher*, for the eye of the observer does not detect the curvature of the line of sight. Therefore, the horizon *appears* to be at C' instead of at C. The dip shown in the tables is BAC'. The effect of refraction, $C'AC$, is shown exaggerated for purposes of illustration.

The amount by which refraction alters dip varies with changing atmospheric conditions. Even the *average* value has not been established with certainty, and several methods of computing dip have been proposed. The values given in the critical table on the inside front cover of the *Nautical Almanac* were computed by the equation

$$D=0.97\sqrt{h},$$

where D is the dip, in minutes of arc; and h is the height of eye of the observer, in feet. Part of this table is repeated on the page facing the inside back cover. The *Air Almanac* table was computed independently by a different method, to a precision of whole minutes. The minor discrepancies thus introduced are not important in practical navigation.

The values given in the table are satisfactory for practical navigation under most conditions. An investigation by the Carnegie Institution of Washington showed that of 5,000 measurements of dip at sea, no value differed from the tabulated value by more than 2′.5, except for one difference of 10′.6. Extreme values of more than 30′ have been reported, and even values of several *degrees* have been encountered in polar regions. Greatest variations from tabulated values can be expected in calm weather, with large differences between sea and air temperatures, particularly if mirage effects are present. Irregularities in the shape of the rising or setting sun may indicate abnormal conditions. Large variations may also be present shortly after passage of a squall line, when errors of as much as 15′ have been reported. When a temperature inversion is known to exist, the tabulated dip may be too small, numerically. The effect of sea-air temperature difference is discussed in greater detail in article 1607.

In the determination of height of eye, position on the ship should be considered, and also the condition of loading and trim. If an observation is made from a position differing from the usual place, the altered height of eye should not be overlooked. Momentary changes due to rolling and pitching can be neutralized, to a large extent, by making observations from a point on the center line of the vessel, at the axis of pitch. The possibility of combining dip and index corrections is discussed in article 1603.

Instruments and marine sextant attachments for measurement of dip have been devised, but are not generally available to the navigator. However, the sextant can

be used without special attachment if it has an arc of sufficient length. The method is to measure the "altitude" of the opposite horizon; that is, the angle (through the zenith) between the lines of sight to the horizon on reciprocal bearings. This is equal to 180° plus the sum of the dip in the two directions. If these can be considered equal, and under stable conditions the difference is probably not great, dip is equal to *half* the difference between 180° and the measured angle (corrected as necessary). However, direct measurement of an angle greater than 180° cannot be made with an ordinary sextant because the reflecting surfaces of the sextant mirrors would have an angle of more than 90° with respect to each other, and a ray of light could not be reflected from the index mirror to the surface of the horizon glass. Satisfactory results can sometimes be obtained by observing the altitude of a body first by facing toward it, in the usual manner, and then by facing 180° from it (a back sight, art. 1633). In the case of the sun or moon, the same limb should be observed in both directions. (It will appear as the opposite limb.) Instrument correction, index correction, and personal correction, as applicable, are applied, and the two altitudes added. The difference between this value and 180° is the sum of the dip in the two directions, if allowance is made for the change of altitude between observations. Unless the body is near the celestial meridian, this is best done by taking a direct sight, a back-sight, and another direct sight, with equal time intervals between observations. The average of the two direct sights is used.

Since variations from normal dip may be one of the principal sources of error in celestial observations, a method of determing dip at sea can be of considerable value. If such a method is not available, the observer should be alert to conditions affecting terrestrial refraction. *Any* observation taken within half an hour after passage of a squall line should be regarded as unreliable. If dip cannot be measured, the effects of abnormal conditions can be minimized by observing three bodies differing in azimuth by about 120° (or four bodies by 90°, five bodies by 72°, etc.). If the error is constant in all directions, its effect is to increase (or possibly to decrease) the size of the closed figure formed by the lines of position without altering the position of its center. Hence, the size of the figure is not necessarily an indication of the accuracy of the fix.

Recent evidence accumulated by the Office of Naval Research indicates that dip may fluctuate somewhat erratically over a range of at least several tenths of a minute, in addition to the slower changes associated with abnormal conditions. This may be caused by irregularities in the atmosphere, producing variations in the refraction. This effect cannot be removed either by measurement of dip or by observations of bodies equally spaced in azimuth, because the dip is likely to change between observations. Over a period of several minutes the variation from the mean value can probably be considered a random error (art. 2904) and therefore might be reduced by making a large number of observations of a single body, and plotting the results on cross-section paper in the manner explained in article 1507.

If land, another ship, or other obstruction is between the observer and his horizon, an altitude can be measured by using the water line of the obstruction as a horizontal reference, if its distance from the observer is known. In this case the dip is greater than that given in the almanacs. Table 22 gives the values to be used.

Further discussion of refraction is given in article 1613. When abnormal astronomical refraction occurs, abnormalities in terrestrial refraction can be expected.

1607. Sea-air temperature difference correction (S).—Under normal atmospheric conditions, the temperature and pressure both decrease at standard rates with increase in height above the surface. Accordingly, the *density* of the atmosphere also decreases at a standard rate, which is uniform over the height encountered aboard ship. The effect of refraction upon dip, as given in the tables, is based upon this standard rate.

Usually, the difference between standard and actual conditions is not great enough to introduce important errors in the assumption that standard conditions exist.

However, when there is a difference between sea and air temperatures at the surface, the air in contact with the sea is warmed or cooled by the sea water, upsetting the normal rate of decrease near the surface. The effect is greater as the temperature difference increases. It may extend only a few inches above the surface, or for hundreds of feet. Under extreme conditions, if the air is very much colder than the water, the surface may steam. The **frost smoke** rising from the water may obscure the horizon, and under the most severe conditions it may rise to such heights as to interfere with visibility. Celestial bodies can be seen, but altitudes cannot be measured with a marine sextant because of lack of a horizon.

Under less extreme conditions, the dip is altered, but observations may seem normal. If the water is warmer than the air, the horizon is depressed and dip is increased. Under these conditions the measured altitudes are too great. Therefore, as a correction to the *altitude*, the sea-air temperature difference correction is negative when the water is warmer than the air. When the air is warmer, the reverse is true, and the altitude correction is positive.

Various attempts have been made to establish a simple relationship between the sea-air temperature difference and the correction, but the results reported by different investigators differ considerably. This is due, in part, to difference of opinion as to the height and depth at which measurements should be made, difficulties in obtaining accurate readings near the surface, variations of temperature differences at the ship and along the line of sight to the horizon, and influence of the vessel on temperatures in its immediate vicinity. Wind, too, has a considerable effect. On a calm day, the lower portion of the atmosphere tends to form in layers, without mixing. If there is a strong, gusty wind, turbulence in the air minimizes the effect due to temperature difference. Actually, sea temperature serves only to indicate temperature at the surface, but temperature gradient in the water may be large, as in the air. Therefore, the ideal would seem to be the measurement of *air* temperature *at the surface*, and at some greater height, since it is the abnormal **lapse rate** (decrease of air temperature with height) that produces the change in normal terrestrial refraction.

Suggested factors based upon difference between temperature of the sea and air vary from about 0.′11 per degree Fahrenheit (0.′20 per degree Celsius) to 0.′21 per degree Fahrenheit (0.′37 per degree Celsius). The average of these is about 0.′16 per degree Fahrenheit (0.′28 per degree Celsius). Thus, the correction is about one-sixth of a minute per degree Fahrenheit, or one minute for each six degrees. The methods of measuring sea and air temperature are discussed in article 3712.

This correction applies to all bodies when the sea horizon is used. However, it should be used with caution, and only under conditions which indicate that better results will be obtained if it is used. Under normal conditions, it is not used. If abnormal conditions are suspected, observations are avoided or considered of questionable reliability; or the precautions indicated in article 1606 are used. If allowance for abnormal conditions is made by using an altered value of dip, as one obtained by measurement, the sea-air temperature difference correction is not used. That is, if allowance is made for abnormal dip, *either* the tabulated value of dip is altered *or* the sea-air temperature correction is applied, *but not both.*

1608. Wave height correction (W).—Corrections for dip are based upon the assumption of a calm sea. Waves disturb this condition, causing the surface to be alternately raised and lowered. At the horizon, the troughs of waves are usually not visible. Through binoculars, irregularities in the line forming the horizon can sometimes be seen, but observations are made from the *tops* or nearly the tops of the waves.

If it is assumed that the vessel is not raised and lowered by the waves, the line of sight to the horizon is *raised* by waves. Refer to figure 1608. The wavy line represents the surface of the sea, with the size of the waves exaggerated. The equivalent still water level is shown by the broken line. The line AB is the curved tangent to the still water level, representing the line of sight if there were no waves. The line AC represents the actual line of sight to the top of a wave. If the slight curvature of AB and AC is neglected, the tangent of the wave height correction (CAB) is $\frac{CB}{AB}$.

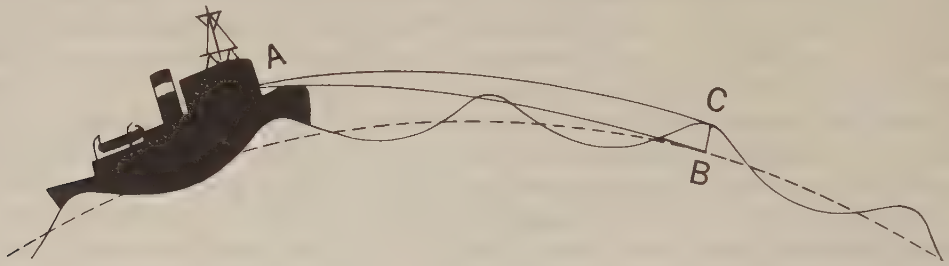

FIGURE 1608.—Effect of wave height on line of sight to horizon.

In this case, CB is approximately one-half the wave height, and AB is the distance to the horizon, both in feet. That is, AB is the value from table 8 multiplied by 6076.11549 . . . if nautical miles are used, or 5,280 if statute miles are used. The increased height of the sea decreases this distance slightly, but the decrease is too small to be a consideration except at low heights of eye or with very high waves. For waves two feet high, the correction is 0′.2 for a height of eye of seven feet. For waves six feet high, the correction is 0′.3 for a height of eye of 30 feet. For waves 20 feet high, the correction is 1′.3 for height of eye of 15 feet, 0′.9 for 30 feet, and 0′.7 for 50 feet. For waves 40 feet high, the correction is 2′.0 at 30 feet, and 1′.1 at 80 feet.

This correction is always positive, and applies to all celestial bodies, but only if the sea horizon is used as a reference. Normally, it is not applied because of the difficulty of determining (1) wave height at the horizon, and (2) height of eye above the equivalent calm level of the sea. Better practice is usually to estimate height of eye above the wave tops, allowing for motions of the vessel, and make no correction.

1609. Sea tilt correction (H).—The height of the sea at any place is affected by the density of the sea water, its temperature, and atmospheric pressure. Because of differences in these values, the height varies from place to place. This results in tilting of the surface of the sea, which is "downhill" from the ridge of high water to that of low water. The maximum tilt due to these causes is probably a little more than 1″.5. The wave caused by the tides also tilts the sea surface. However, on the open sea, tides are seldom more than about two and one-half feet high, and the distance from crest to trough is about 5,400 miles, or one-quarter of the great-circle distance around the earth. Under these conditions, the maximum tilting of the sea surface due to tides is about 0″.025. This may be increased somewhat by storm waves (art. 3311) or tsunamis (art. 3310). In confined waters, particularly in a funnel-shaped area where tides enter from the wide end and progress up a narrowing estuary, the error may be very much greater, possibly reaching a value of half a *minute*. The expression **tide correction** may be used instead of "sea tilt correction."

The correction is positive in the direction of high water and negative in the direction of low water. Between these directions it is equal approximately to the value in these directions multiplied by the cosine of the angle between the wave axis (the line perpendicular to the wave front) and the azimuth of the body. It applies equally to all bodies when the visible horizon is used as the reference. In practice it is not applied.

1610. Deflection of the vertical (V).—Usually, the direction of gravity is assumed to be normal (vertical) to the spheroidal surface of the earth. This assumption is not quite correct. Irregularities in density and height of the material making up the surface crust of the earth result in slight alterations of the direction of gravity. This **deflection of the vertical** is most apparent near high mountains bordering a deep sea (fig. 1610) where an extreme value of more than 1'.1 might be encountered. An experienced geodesist can predict the value with an average error of perhaps 50 percent

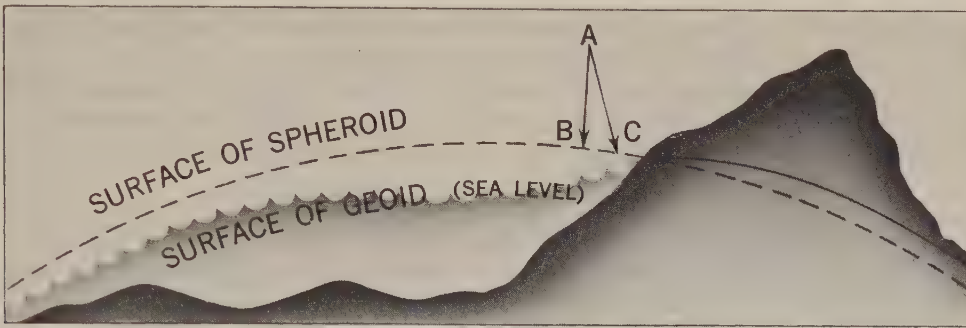

FIGURE 1610.—Deflection of the vertical. *AB* is normal to spheroid. *AC* is normal to geoid. Angle *BAC* is deflection of the vertical.

of the true value. On land, deflection of the vertical can be measured by carefully determining a highly accurate position by celestial observation, called an **astronomical position** (composed of **astronomical latitude** and **astronomical longitude**), and comparing this position with one determined by measurement (either by triangulation or trilateration) from a "known" position. Deflection of the vertical is always a relative value depending upon the position considered "known." A position expected to be relatively free from deflection is usually used as the starting point for a system of measurements, and is known as a **datum.** The **North American Datum of 1927,** used for surveying most of North America, is a station known as Meades Ranch, Kansas.

It has not been possible to measure deflection of the vertical by means of a single observation at sea, due largely to lack of a stable platform and the inability to extend triangulation or trilateration to ships at sea, with the required accuracy. However, this correction is of interest only when establishing a position relative to a fixed point on land, as when a shore-based electronic aid is used. For normal purposes of celestial navigation, it is not significant, for it is usually quite small. Moreover, it changes gradually from the position of the vessel to the destination, so that as land is approached, deflection of the vertical tends to approach the value on shore.

The shape of the earth, if surface irregularities (mountains, etc.) are neglected, is considered a **spheroid** if deflection of the vertical is neglected, and a **geoid** if that deflection is considered. The surface of the geoid is everywhere perpendicular to the direction of gravity. In general, the geoidal surface is *higher* than the spheroidal surface ashore, and *lower* at sea, as shown in figure 1610.

Normally, values of deflection of the vertical are not available to the navigator, and are not needed by him. In precise work, however, such values for a particular area might be furnished. The correction is negative in the direction toward which the zenith is deflected, and positive in the opposite direction. In any other direction it is equal approximately to the maximum deflection times the cosine of the angle between the given direction and the direction of maximum deflection, taking the sign of the nearest maximum deflection. It is applicable to all celestial bodies, whether the natural sea horizon or an artificial horizon is used.

1611. Coriolis correction (Z).—When a body is in motion over the surface of the earth, its motion *in space* is a combination of its motion relative to the earth, and the motion of the earth. Because of the rotation of the earth, principally, the path is a curved one. As a result, there is an apparent force causing deflection to the right in the northern hemisphere and to the left in the southern hemisphere. Because of this **Coriolis force,** ocean currents set in motion by wind flow in a direction to the right (northern hemisphere) of the direction in which the wind blows. Wind, too, is deflected. Instead of blowing directly from an area of high pressure to one of low pressure, and soon neutralizing the pressure difference, it moves toward one side. The result is the characteristic circulation around highs and lows.

The liquid of the bubble chamber of a bubble sextant, and a pendulum, are similarly affected, causing them to give a false indication of the vertical (or horizontal). The same is true of an artificial horizon. The equation for the deflection is

$$Z=2'.62\ S \sin L+0'.146\ S^2 \sin C \tan L-5'.25\ SC',$$

where Z is the Coriolis correction, S the speed over the surface of the earth in units of hundreds of knots, L the latitude, C the true course angle, and C′ the rate of change of true course angle in degrees per minute. The first term, $2'.62\ S \sin L$, corrects for motion along a great circle; the second term, $0'.146\ S^2 \sin C \tan L$, is an additional correction for the difference between motion along a rhumb line, and equivalent motion along a great circle; and the third term, $5'.25\ SC'$, is an additional correction for departures from the course, being negative (as shown) if the departure is right in the northern hemisphere or left in the southern hemisphere. Coriolis corrections (first term only) are given on the inside back cover of the *Air Almanac*.

Coriolis correction may be either positive or negative, and varies with speed and latitude. It applies to all bodies equally, and therefore can be applied to the altitude, the assumed position, or even as an adjustment to the plotted line of position or fix. If the AP or fix is adjusted, it is moved perpendicular to the course line, to the *right* in the northern hemisphere and to the *left* in the southern hemisphere, unless the third term is of such magnitude and sign as to make the entire correction negative, when it is applied in the opposite direction. If the correction is applied to the altitude, the value obtained by formula is multiplied by the sine of the *relative* azimuth. In the northern hemisphere, the resulting altitude correction is positive if the celestial body is on the starboard side, and negative if on the port side. In the southern hemisphere these signs are reversed. These signs assume that the value obtained by the formula is positive. If it is negative, all signs are reversed.

At ship speeds, the Coriolis correction is not large, unless the vessel is yawing considerably. For a ship steaming at 20 knots on a steady course of 090° at latitude 40°, the maximum Coriolis correction is 0′.3 for a celestial body which is abeam. Acceleration error due to rolling and pitching of the vessel is usually much greater than this, and is the principal reason why bubble or pendulum sextants are not often used aboard ship, as indicated in article 1513.

There is no Coriolis correction when the visible horizon is the horizontal reference.

1612. Acceleration correction (C).—If an artificial horizon-sextant with a bubble or pendulum is used, the liquid of the bubble chamber or the pendulum is affected by all accelerations of the instrument. The same is true of the free surface of the liquid of an artificial horizon. With high accelerations such as those due to rolling and pitching of a vessel, or changes of course or speed, the error can be very large. It is for this reason that such instruments are not customarily used aboard ship. Under normal conditions at sea the navigator does not have the information needed to compute the correction. The error is minimized by making observations at the center of roll

and pitch of the ship, or averaging the values taken at both ends of a roll or pitch. Observations should not be made during a turn or when the speed is being changed. Even with these precautions the error is usually unacceptably large except with an almost flat, calm sea. The effect on the level of the sea surface due to accelerations of the earth in its rotation or revolution is considered negligible.

The correction may be either positive or negative, and applies equally to all bodies observed with a bubble or pendulum sextant.

1613. Refraction (**R**).—Light, or other radiant energy, is assumed to travel in a straight line at uniform speed, if the medium in which it is traveling has uniform

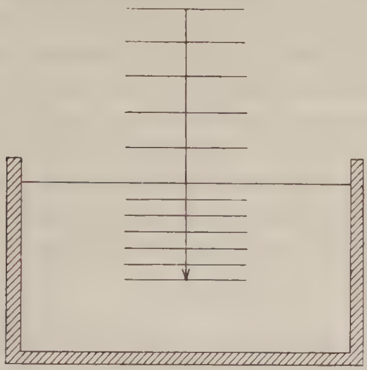

Figure 1613a.—No refraction occurs when light enters denser medium normal to the surface.

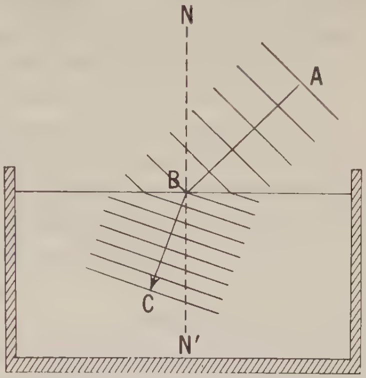

Figure 1613b.—A ray entering a denser medium at an oblique angle is bent toward the normal.

properties. But if light enters a medium of different properties, particularly if the density is different, the speed of light changes somewhat. Light from a single point source travels outward in all directions, in an expanding sphere. At great distances, a small part of the surface of this sphere can be considered flat, and light continuing to emanate from the source can be considered similar to a series of waves, in some respects resembling the ocean waves encountered at sea. If these light "waves" enter a more dense medium, as when they pass from air into water, the speed decreases. If the light is traveling in a direction perpendicular to the surface separating the two media (in this case vertically downward), all parts of each wave front enter the new medium at the same time, and so all parts change speed together, as shown in figure 1613a. But if the light enters the more dense medium at an oblique angle, as shown in figure 1613b, the change in speed occurs progressively along the wave front as the different parts enter the more dense medium. This results in a change in the direction of travel, as shown. This change in direction of motion is called **refraction.** If light enters a more dense medium, it is refracted *toward* the normal (NN'), as in figure 1613b. If it enters a less dense medium, it is refracted *away* from the normal, as light traveling in the opposite direction to that shown in figure 1613b.

The *amount* of the change in direction is directly proportional to the angle between the direction of travel and the normal (angle ABN in figure 1613b). The ratio of this angle to the similar angle after refraction takes place (angle CBN' in figure 1613b) is constant, so that as one increases, the other increases at the same *rate*. Hence, the *difference* between them (the change in direction) also increases at the same rate. Therefore, if the *incident* ray (AB) is nearly parallel to the surface at which refraction takes place, relatively large amounts of refraction occur.

The amount of refraction is also directly proportional to the relative speed of travel in the two media. Various substances are compared by means of a number called the

index of refraction (μ), which depends primarily upon the density of the substance. In figure 1613b, angle *ABN* is called the **angle of incidence** (ϕ) and angle *CBN′* the **angle of refraction** (θ). These are related by Snell's law, which states that *the sines of the angle of incidence and angle of refraction are inversely proportional to the indices of refraction of the substances in which they occur.* Thus, if μ_1 is the index of refraction of the substance in which ϕ occurs, and μ_2 is the index of refraction of the substance in which θ occurs

$$\frac{\sin \phi}{\sin \theta}=\frac{\mu_2}{\mu_1}.$$

If the index of refraction changes suddenly, as along the surface separating water and air (as shown in fig. 1613b), the change in direction is equally sudden. However, if a ray of light travels through a medium of gradually changing index of refraction, its path is curved, undergoing increased refraction as the index of refraction continues to change. This is the situation in the earth's atmosphere, which generally decreases in density with increased height. The gradual change of direction occurring there is called **atmospheric refraction.** The bending of a ray of light traveling from a point on or near the surface of the earth, to the eye of the observer, is called **terrestrial refraction.** This affects dip of the horizon, as discussed in article 1606. A ray of light entering the atmosphere from outside, as from a star, undergoes a similar bending called **astronomical refraction.**

The effect of astronomical refraction is to make a celestial body appear *higher* in the sky than it otherwise would, as shown in figure 1613c. If a body is in the zenith, its light is not refracted, except for a very slight amount when the various layers of the atmosphere are not exactly horizontal. As the zenith distance increases, the refraction becomes greater. At an altitude of 20° it is about 2′.6; at 10°, 5′.3; at 5°, 9′.9; and at the horizon, 34′.5. A table of refraction is given on the inside front cover and facing page of the *Nautical Almanac*, in the columns headed "Stars and Planets." As height above the surface of the earth increases, light from an outside source travels through less of the atmosphere, and refraction decreases. At shipboard heights the difference is negligible, but at aircraft heights the change is a consideration. Therefore, the table given on the inside back cover of the *Air Almanac* is a double-entry table.

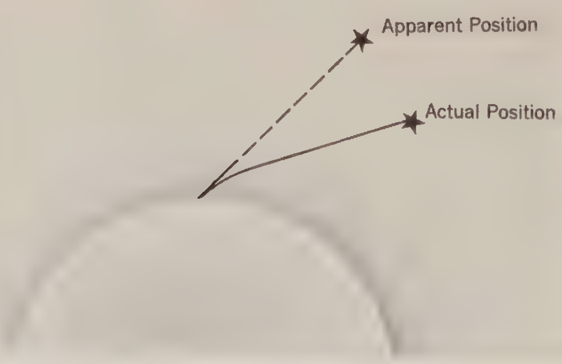

Figure 1613c.—Astronomical refraction.

The values given in the tables are for average conditions. This is called **mean refraction.** A considerable amount of research has been conducted to determine the mean values, the conditions under which values differ from the mean, and the amount of such differences. A number of different mean refraction tables have been produced. Values in the various tables differ slightly because of different assumptions, different methods of observation, and different observed results under apparently similar conditions. This last source of difference is due primarily to the fact that conditions could be determined at the position of the observer, but not at various points along the line traveled by the ray of light in passing through the atmosphere. Nevertheless, the various tables agree very well down to a minimum altitude of 2°. Below this, the refraction is erratic, and differences between values

in the various tables are not as important as differences between mean and instantaneous values. The values given in the almanac tables are in excellent agreement with those actually measured.

Because of their variability, refraction and dip (also affected by refraction) are the principal uncertainties in the accuracy of celestial observations of a careful observer. As a result of this uncertainty, navigators formerly avoided all observations below some arbitrary altitude, usually 15°. While this is still good practice if higher bodies are available, the growing knowledge of atmospheric refraction has increased the confidence with which navigators can use low-altitude sights. There is little reason for lack of confidence in sights as low as 5°. Below this, other available corrections should be applied (art. 1632). If altitudes below 2° are used, larger probable errors should be anticipated, even with the use of additional corrections. Generally, the error in tabulated refraction should not exceed two or three minutes, even at the horizon. However, a knowledge of conditions affecting refraction is helpful in determining the confidence to be placed in such observations. Since refraction elevates both the celestial body and the visible horizon, the error due to abnormal refraction is minimized if the visible horizon is used as a reference.

The atmosphere contains many irregularities which are erratic in their influence upon refraction. Normally, the navigator has not the information needed to correct for such conditions, but only to recognize their existence. As indicated in article 1606, observations made within half an hour after passage of a squall might be considerably in error. The passage of any front might have a similar effect. A temperature inversion (art. 3815) may upset normal refraction. Abnormal values may be expected when there is a large difference between the temperature of the sea and air. With an absence of wind, the air tends to form in layers. When this condition becomes extreme, mirage effects occur. Sometimes the rising or setting sun or moon appears distorted. Multiple horizons may appear, and other ships or islands may seem to float a short distance above the water. Under any such conditions large errors in refraction might be encountered.

Conditions causing abnormal refraction can be expected to occur with considerable frequency in the vicinity of the Grand Banks, along the west coast of Africa from Mogador to Cap Blanc and from the Congo to the Cape of Good Hope, in the Red Sea and the Persian Gulf, and over ice-free water in polar regions. Abnormal refraction may be encountered when offshore winds blow from high, snow-covered mountains to nearby tropical seas, as along the west coast of South America; where cold water from large rivers such as the Mississippi flows into warm sea water; when a strong current flows past a bay or coast, causing colder water to be drawn to the surface, as in the Bay of Rio de Janeiro and Santos, and along the Atlantic coast of Africa between Cape Palmas and Cape Three Points during the time of the southwest monsoon; and along the east coast of Africa in the vicinity of Capo Guardafui during the summer. In the temperate zones abnormal refraction is most common during the spring and summer.

Of the more systematic errors which affect refraction, two can be evaluated, and corrections applied. These are for air temperature (art. 1614) and atmospheric pressure (art. 1615). However, these corrections are based upon assumed standard *gradients* (changes) with height. Temperature gradients are known to vary with type of weather, time of day, season, etc., as well as in a more irregular manner. The various layers of the atmosphere are assumed to be horizontal to the surface, but this is not always the situation. When they tilt, refraction changes. No correction for this cause is available.

Humidity has a relatively slight effect on refraction. In completely dry air, astronomical refraction at the horizon (sometimes called **horizontal refraction**) is perhaps 0.′1 *greater* than the tabulated value. In very moist air, sometimes encountered in the tropics, the maximum refraction might possibly *decrease* by as much as 0.′2.

Wind speed is believed to have some effect upon refraction and dip. Apparently, refraction increases as wind speed becomes greater, the amount of change increasing in direct proportion to the *square* of the wind speed. At 20 knots the change is believed to be about 0.′1 at the horizon, and 0.″15 at altitude 2°. At 30 knots these values are approximately doubled.

Latitude has a slight effect upon refraction because of the decrease in the radius of the earth and the increase of gravity as latitude increases. Both radius and gravity affect density of the atmosphere, and hence refraction. Because of this, mean horizontal refraction is decreased about 0.′2 to 0.′3 at the equator, and increased about an equal amount at the poles. For normal altitudes the change is negligible.

Azimuth may have an effect at some locations. The reason for this is not entirely clear, but is believed to be due to a somewhat permanent tilt of certain atmospheric layers. A series of observations at a location in Germany indicated a difference of as much as 0.′5 between northerly and southerly observations of 0° altitude. At altitude 2° the difference was only 3″. The navigator normally does not have information required to apply such a correction, nor is it of navigational significance at normal altitudes. However, differences should be anticipated when the appearance of the horizon varies with azimuth, or large sea temperature differences exist within a few miles, as near the edge of the Gulf Stream. The same might be true near land, particularly in the tropics.

Dispersion of light of various colors results in light from blue stars being refracted more than light from red stars. At the horizon the maximum correction would be about 2″ for blue stars, and 8″ for red stars. At 5° the amount would be less than one-third these values.

Errors in the tables due to incorrect assumptions are probably too small to be of practical interest to the navigator. If increased knowledge indicates errors exist in the tables, corrected values will undoubtedly be provided.

Since refraction causes celestial bodies to appear elevated in the sky, they are above the horizon longer than they otherwise would be. The mean diameter of the sun and moon are each about 32′, and horizontal refraction is 34.′5. Therefore, the entire sun or moon is actually below the visible horizon when the lower limb appears tangent to the horizon. The effect of dip is to further increase the time above the horizon. Near the horizon the sun and moon appear flattened because of the rapid change of refraction with altitude, the lower limb being raised by refraction to a greater extent than the upper limb.

As a correction to sextant altitudes, refraction is negative because it causes the measured altitude to be too *great*. It *decreases* with increased altitude, and applies to all celestial bodies, regardless of sextant or horizon used.

1614. Air temperature correction (**T**).—The *Nautical Almanac* refraction table is based upon an air temperature of 50°F (10°C) at the surface of the earth. At other temperatures the refraction differs somewhat, becoming greater at lower temperatures, and less at higher temperatures. Table 23 provides the correction to be applied to the altitude to correct for this condition. If preferred, this correction can be applied with *reversed sign* to the refraction from the almanac, and a single refraction applied to the altitude. A combined correction for nonstandard air temperature and nonstandard atmospheric pressure (art. 1615) is given on page A4 of the *Nautical Almanac*. The correction for air temperature varies with the temperature of the air and the altitude of the celestial body, and applies to all celestial bodies, regardless of the method of observation. However, except for extreme temperatures or low altitudes, this correction is not usually applied unless results of unusual accuracy are desired.

1615. Atmospheric pressure correction (**B**).—The *Nautical Almanac* refraction table is based upon an atmospheric pressure of 29.83 inches of mercury (1010 millibars)

at sea level. At other pressures the refraction differs, becoming greater as pressure increases, and smaller as it decreases. Table 24 provides the correction to be applied to the altitude for this condition. A combined correction for nonstandard air temperature (art. 1614) and nonstandard atmospheric pressure is given on page A4 of the *Nautical Almanac*. If the correction is to be applied to the refraction, reverse the sign. This correction varies with atmospheric pressure and altitude of the celestial body, and is applicable to all celestial bodies, regardless of the method of observation. However, except for extreme pressures or low altitudes, this correction is not usually applied unless results of unusual accuracy are desired.

1616. Irradiation correction (**J**).—When a bright surface is adjacent to a darker one, an optical illusion takes place and the bright area appears to be larger than is actually the case. This is called **irradiation.** Thus, when the sky is considerably brighter than the water, the horizon appears slightly depressed. The apparent diameter of the sun is increased slightly by irradiation, and the bright stars appear to have a measurable diameter. Opinions differ on the need for a sextant altitude correction for irradiation. It is probable that during twilight there is insufficient contrast between sky and water to warrant the use of a correction. During the day a slight apparent depression of the horizon may occur. Altitudes of the lower limb of the sun should not be altered because the irradiation effect of sun and horizon are in the same direction and cancel out, approximately. The effect on the upper limb, however, is opposite to that on the horizon. The table of upper limb corrections of the sun given on the inside front cover and facing page of the *Nautical Almanac* includes an irradiation correction of (−) 1′.2, half for the apparent lowering of the horizon, and half for the apparent raising of the upper limb. No irradiation correction is given for bodies other than the sun. Thus, in terms of available corrections, irradiation is negative, is essentially constant, and applies only to the upper limb of the sun when the visible horizon is used as the reference. If an artificial horizon is used, it applies to either limb.

1617. Semidiameter (**SD**) of a celestial body is half the angle, at the observer's eye, subtended by the visible disk of the body. The position of the lower or upper limb of the sun or moon with respect to the visible horizon can be judged with greater precision than that of the center of the body. For this reason it is customary, when using a marine sextant and the visible horizon, to observe one of the limbs of these two bodies, and apply a correction for semidiameter. Normally, the lower limb is used if it is visible. In the case of a gibbous or crescent moon, however, only the upper limb may be available.

The semidiameter of the sun varies from a little less than 15′.8 early in July, when the earth is at its greatest distance from the sun, to nearly 16′.3 early in January, when the earth is nearest the sun. In the *Nautical Almanac* the semidiameter of the sun at GMT 12^h on the middle day of each page opening of the daily page section is given to the nearest 0′.1 at the bottom of the sun's GHA column. The altitude correction tables of the sun, given on the inside front cover and facing page, are divided into two parts, to be used during different periods of the year. The mean semidiameter of each period is included in the tables of both upper and lower limb corrections. The semidiameter each day is listed to the nearest 0″.01 in the *American Ephemeris and Nautical Almanac*. In the *Air Almanac* the semidiameter to the nearest whole minute (always 16′) is given near the lower right-hand corner of each odd-numbered daily page.

The moon undergoes a similar change in semidiameter as its distance from the earth varies. However, because of the greater eccentricity of the moon's orbit than that of earth, the variation in semidiameter is also greater, varying between about 14′.7 and 16′.8. The variation is more rapid, partly because of the greater spread of values, but principally because the moon completes its revolution in approximately

one month, while the earth makes one revolution per year. In the *Nautical Almanac*, semidiameter of the moon at 12^h each day is given to the nearest $0'.1$ at the bottom of the moon data columns. The correction for semidiameter of the moon is included in the corrections given on the inside back cover and facing page. In the *Air Almanac*, semidiameter is given to the nearest whole minute, being shown on the daily pages, immediately below the value for the sun. The semidiameter at intervals of half a day is given to the nearest $0''.01$ in the *American Ephemeris and Nautical Almanac.*

The navigational planets have small semidiameters. For Venus it varies between about $5''$ and $32''$; for Mars, $2''.7$ to $12''.6$; for Jupiter, $16''$ to $25''$; and for Saturn, $7''$ to $10''$. The value for any date is given in the *American Ephemeris and Nautical Almanac*, but not in the *Nautical Almanac* or *Air Almanac* because the apparent *centers* of these bodies are customarily observed.

Stars have no measurable semidiameter.

The computed altitude of a body refers to the *center* of that body, since the coordinates listed in the almanacs are for the center. If the *lower* limb is observed, the sextant altitude is *less* than the altitude of the center of the body, and hence the correction is *positive.* If the *upper* limb is observed, the correction is *negative.* The correction does not apply when the center of the body is observed, which is usually the case when an artificial-horizon sextant is used. With a marine sextant and either the natural or an artificial horizon, semidiameter is customarily applied to observations of the sun and moon, but not other celestial bodies.

1618. Phase correction (F).—Because of phase (art. 1423), the actual centers of planets and the moon may differ somewhat from the apparent centers. Average corrections for this difference are included in the additional corrections for Venus and Mars given on the inside front cover of the *Nautical Almanac.* They should be applied only when these bodies are observed during twilight. At other times the magnitude and even the sign of the correction might differ from those tabulated, because of a different relationship between the body and the horizon. The phase correction for navigational planets other than Venus and Mars is too small to be significant.

A phase correction may apply to observations of the moon if the apparent center of the body is observed, as with an artificial-horizon sextant. However, no provision is made for a correction in this case; the need for it can be avoided by observing one of the limbs of the body.

Phase correction does not apply to observations of the sun or stars.

1619. Augmentation (A).—As indicated in article 1617, semidiameter changes with distance of the celestial body from the observer, becoming greater as the distance decreases. The semidiameter given in the ephemeris and used in the almanacs is for a fictitious observer at the center of the earth. If the celestial body is on the actual observer's horizon, its distance is approximately the same as from the center of the earth; but if the body is in the zenith, its distance is less by about the radius of the earth (fig. 1412). Therefore, the semidiameter *increases* as the altitude becomes greater. This increase is called **augmentation.** For the moon, the augmentation from horizon to zenith is about $0'.3$ at the mean distance of the moon. At perigee it is about $2''$ greater, and at apogee about $2''$ less. Augmentation of the sun from horizon to zenith is about 1/24 of one second of arc. For planets it is correspondingly small, varying with the positions of the planets and the earth in their orbits. At any altitude the augmentation is equal to the sine of the altitude times the value at the zenith.

Augmentation increases the size of the semidiameter correction, whether positive or negative. It is included in the moon correction tables on the inside back cover and facing page of the *Nautical Almanac.* It is not included in the correction tables of other bodies or in the *Air Almanac* tables.

1620. Parallax (P) is the difference in apparent position of a point as viewed from two different places. If a finger is held upright at arm's length and the right and left eyes closed alternately, the finger appears to move right and left a short distance. Similarly, if one of the nearer stars were observed from the earth and from the sun, it would appear to change slightly with respect to the background of more distant stars. This is called **heliocentric parallax** or **stellar parallax.** The nearest star has a parallax of less than 1″. Even if the value were greater, no correction to sextant altitudes would be needed, for the difference would be reflected in the tabulated position of the body.

However, positions of celestial bodies are given relative to the *center* of the earth, while observations are made from its surface. The difference in apparent position from these two points is called **geocentric parallax.** If a body is in the zenith, at Z in figure 1620, there is virtually no parallax, for the line from the body to the center of the earth passes approximately through the observer at *A*. Suppose, however, the moon is at *M*. From *A* it appears to be along the line *AM*, while at the center of the earth it would appear to be along *OM*. The altitude at *A* would be the angle *SAM*, and that at *O* the angle *COM*. Angle *COM* is equal to angle *SBM* (art. O27), which is exterior to the triangle *ABM*, and hence equal to the sum of angles *SAM* and *AMO* (art. O28).

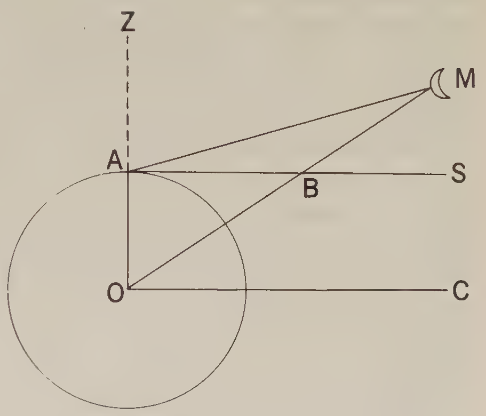

FIGURE 1620.—Geocentric parallax.

Since

$$\angle COM = \angle SBM = \angle SAM + \angle AMO,$$

then

$$\angle AMO = \angle COM - \angle SAM.$$

That is, the angle at the body between lines to the observer and the center of the earth is equal to the difference in altitude at the two places. Angle *AMO* is the geocentric parallax. Since it varies with altitude, it is sometimes called **parallax in altitude (P in A).** The maximum value for a visible body occurs when that body is on the horizon, at *S*. At this position the value is called **horizontal parallax (HP).**

The sine of horizontal parallax is equal to $\frac{r}{D}$, where r is the radius of the earth, and D the distance of the body from the center of the earth. Thus, the sine of the horizontal parallax is directly proportional to the radius of the earth, and inversely proportional to the distance of the body. Since the earth is an oblate spheroid, and not a sphere, the parallax varies slightly over different parts of the earth. The value at the equator, called **equatorial horizontal parallax,** is greatest, and the value at the poles, called **polar horizontal parallax,** is least. The difference is not enough to be of practical navigational significance. The parallax in altitude is equal almost exactly to the horizontal parallax times the cosine of the altitude (h). That is,

$$\text{P in A} = \text{HP} \cos h.$$

The moon, being nearest the earth, has the greatest parallax of any celestial body used for navigation. The equatorial horizontal parallax at mean distance is 57′02″.70. As the distance of the moon varies, so does the parallax, becoming greater as the moon

approaches closer to the earth, and less as it recedes, horizontal parallax varying several minutes each side of the value at mean distance. For the sun, mean equatorial horizontal parallax, called **solar parallax,** is 8″.80. Differences in position on the earth, and distance from the sun, have small effect, the maximum variation due to the latter being about 0″.15. Horizontal parallax of the planets varies considerably because of the large differences in their distances from the earth. For Venus the value varies between 5″ and 32″; for Mars, 3″ and 24″; for Jupiter, 1″ and 2″; and for Saturn, 0″.8 and 1″.0. The geocentric parallax of stars is too small to be measured, even by the most precise telescopes, since the value for the nearest star is only 0″.00003.

Daily values of horizontal parallax for the sun, moon, and planets are given in the *American Ephemeris and Nautical Almanac,* to a precision of 0″.01. In the *Nautical Almanac,* mean values for the sun are included in the two sun correction tables given on the inside front cover and facing page. Horizontal parallax of the moon is tabulated at intervals of one hour on the daily pages. This value is used to enter the lower part of the moon correction tables on the inside back cover and facing page. The additional corrections for Venus and Mars given on the inside front cover are partly for parallax. No correction is given for parallax of Jupiter and Saturn. The *Air Almanac,* giving values only to the nearest whole minute of arc, includes parallax corrections only for the moon. These values are given in the "Moon's P in A" column on the right-hand daily page.

Because of geocentric parallax, a body appears too *low* in the sky. Therefore, the correction is always positive. It applies regardless of the method of observation.

1621. Summary of corrections.—The essential information regarding the application of the various corrections may be tabulated as shown below. In the "Bodies" column, the symbols are: ⊙, sun; ☾, moon; P, planets; ☆, stars. In the "Sextants" column, M refers to a marine sextant with visible horizon, A refers to a marine sextant with artificial horizon, and B refers to an artificial-horizon sextant. The tabulation assumes that completely accurate results are desired and that corrections are to be made in the usual manner, where they are available. Some of the entries need qualification, which may be found in the preceding articles.

Correction	*Symbol*	*Sign*	*Increases with*	*Bodies*	*Sextants*	*Source*
Instrument	I	±	changing altitude	⊙, ☾, P, ☆	M, A, B	sextant box
Index	IC	±	constant	⊙, ☾, P, ☆	M, A, B	measurement
Personal	PC	±	constant	⊙, ☾, P, ☆	M, A, B	measurement
Tilt	N	—	greater tilt angle	⊙, ☾, P, ☆	M	computation
Dip	D	—	higher height of eye	⊙, ☾, P, ☆	M	almanacs
Sea-air temp. diff.	S	±	greater temp. diff.	⊙, ☾, P, ☆	M	computation
Wave height	W	+	higher waves	⊙, ☾, P, ☆	M	computation
Sea tilt	H	±	greater tilt of surface	⊙, ☾, P, ☆	M	computation
Deflection of vert.	V	±	position, azimuth	⊙, ☾, P, ☆	M, A, B	geodesist
Coriolis	Z	±	higher lat., greater speed	⊙, ☾, P, ☆	A, B	*Air Almanac*
Acceleration	C	±	greater acceleration	⊙, ☾, P, ☆	A, B	computation
Refraction	R	—	lower altitude	⊙, ☾, P, ☆	M, A, B	almanacs
Air temp.	T	±	greater diff. from 50° F	⊙, ☾, P, ☆	M, A, B	almanacs, table 23
Atmospheric pressure	B	±	greater diff. from 29.83 inches of mercury	⊙, ☾, P, ☆	M, A, B	*Nautical Almanac,* table 24
Irradiation	J	—	constant	⊙	M, A	*Nautical Almanac*
Semidiameter	SD	±	lesser dist. from earth	⊙, ☾	M, A	almanacs
Phase	F	±	phase	P	M, A, B	*Nautical Almanac*
Augmentation	A	±	higher altitude	☾	M, A	*Nautical Almanac*
Parallax	P	+	lower altitude	⊙, ☾, P	M, A, B	almanacs

These corrections can be considered to fall into five groups:

1. *Corrections for inaccuracies in reading.* Instrument correction, index correction*, personal correction, and tilt correction.

2. *Corrections for inaccuracies in reference level.* Dip*, sea-air temperature difference, wave height, sea tilt, deflection of the vertical, Coriolis, acceleration.

3. *Corrections for bending of ray of light from body.* Refraction*, air temperature, atmospheric pressure.

4. *Adjustment to equivalent reading at center of body.* Irradiation, semidiameter*, phase, augmentation.

5. *Adjustment to equivalent reading at center of earth.* Parallax*.

In the ordinary practice of seamen, extreme accuracy is not required, and only the principal correction of each group is applied (except that irradiation is applied for the upper limb of the sun, and augmentation for the moon). These principal corrections are indicated by asterisks. For low altitudes, additional corrections are applied, as indicated in article 1632.

1622. Order of applying corrections.—For purposes of ordinary navigation, sextant altitudes can be applied in any order desired, using sextant altitude for the entering argument whenever altitude is required. This practice is not strictly accurate, but for altitudes usually observed, the error thus introduced is too small to be of practical significance. When extreme accuracy is desired, however, or at low altitudes, where small changes in altitude result in significant changes in correction, the order of applying corrections is important. Corrections from the first two groups of article 1621 are applied to sextant altitude (hs) to obtain **rectified altitude (hr),** called "apparent altitude" by astronomers, which is then used as an entering argument for obtaining corrections of the third group. For strictest accuracy, all corrections of the first three groups and, in addition, irradiation and semidiameter, should be applied before augmentation, and all other corrections before parallax.

1623. Marine sextant corrections.—As shown in the tabulation of article 1621, all corrections except Coriolis and acceleration apply to marine sextant observations when the visible horizon is used. Of the five corrections ordinarily used, index correction can be eliminated by sextant adjustment (art. 1509), or it can be combined with dip in such manner as to eliminate both (art. 1603). Of the remaining three corrections, only refraction and parallax apply to planets; and only refraction applies to stars.

1624. Artificial-horizon corrections.—When an artificial horizon is used, index correction (and any others of the first group of article 1621) is first applied. The result is then divided by two. Other corrections are then applied to the result, as applicable, in the same manner as for observations using the visible horizon. The sun and full moon are normally observed by bringing the lower limb of one image tangent to the upper limb of the other image. The lower limb is observed if the image seen in the horizon mirror is *above* the image seen in the artificial horizon, unless an inverting telescope is used, when the opposite relationship holds. With a gibbous or crescent moon, judgment may be needed to establish the positions of the limbs. In some cases better results may be obtained by superimposing one image over the other, as with a planet or star. When this is done, the *center* of the body has been observed, and no correction is applied for semidiameter (or irradiation, phase, or augmentation). If the *lower* limb of the sun is observed, an irradiation correction of (+) 1′.2 may be applicable, if experience so indicates. There is no correction for dip (or sea-air temperature or wave height) when an artificial horizon is used.

1625. Artificial-horizon sextant corrections are the same as those for observations made by the use of the visible horizon, with two notable exceptions. First, there is

no correction for dip (or sea-air temperature difference or wave height), none for semidiameter (or irradiation, phase, or augmentation), and usually none for index correction (or instrument correction). Second, because of the lower accuracy normally obtainable by artificial-horizon sextant, corrections are normally made only to the nearest whole minute of arc. As a result of these differences, refraction is the only correction normally applied, except in the case of the moon, where parallax is also applied. Many air navigators, principal users of artificial-horizon sextants, avoid altitudes below 20° and accept the error introduced by refraction, so that no correction is needed. As flight altitudes increase, the error thus introduced becomes correspondingly smaller. However, at modern aircraft speeds, Coriolis correction is of increased importance.

1626. Corrections by *American Nautical Almanac*.—In the *Nautical Almanac*, certain corrections or parts of corrections are combined. Index correction, of course, is not included because this depends upon adjustment of the sextant. The various correction tables are as follows:

"*Sun*," on the inside front cover and facing page, gives mean refraction, mean semidiameter for each of two periods during the year, and mean solar parallax. Irradiation is also included in the upper limb corrections, given in separate columns from lower limb corrections. The table on the inside front cover, and repeated on the loose bookmark, is of the critical type, with altitude as the entering value. Thus, a tabulated correction applies to any value of altitude between that given half a line above it and that half a line below it. If an exact tabulated altitude is used to enter the table, the correction half a line *above* it should be used. In ordinary navigation, index correction, dip, and the correction from this table are needed for correcting marine sextant observations of the sun. For low altitudes or extremes of temperature or atmospheric pressure, a correction from the table on almanac page A4 (or tables 23 and 24 of this volume) should be applied.

"*Stars and planets*," on the inside front cover and repeated on the loose bookmark, gives mean refraction only, for the main tabulation. This is a critical type table, with altitude as the entering argument. The correction is always negative. In ordinary navigation, index correction, dip, and the correction from this table are the only ones needed for stars and the planets Jupiter and Saturn. For Venus and Mars, an additional correction for parallax and phase is given to the right of the main tabulation. The entering altitudes are limited to those occurring during twilight. If observations are made at other times, this additional correction should not be applied even though the altitude may fall within the tabulated range.

"*Dip*," on the inside front cover and repeated on the loose bookmark, is for dip of the horizon. An abbreviated dip table is also given on the page facing the inside back cover. The tables are of the critical type, and the entering argument is the height of the observer's eye, in feet, above the surface of the sea. The correction, always negative, applies to all observations made with the visible sea horizon as a reference.

"*Additional Correction Tables*" for *nonstandard conditions*, given on almanac page A4, provides an additional correction for nonstandard temperature and atmospheric pressure. The sign of each correction is indicated. Equivalent information is given, with increased range of entering values, in tables 23 and 24 of this volume.

"*Altitude Correction Tables—Moon*," on the inside back cover and facing page, gives mean refraction, semidiameter, augmentation, and parallax. The entering argument is altitude for the upper portion of the table, and altitude and horizontal parallax for the lower portion. The combined correction is always positive, but 30′ is to be subtracted from the altitude of the upper limb. In ordinary navigation, index correction, dip, and the correction from this table are needed in correcting marine sextant observations of the moon.

The various separate corrections available from the *Nautical Almanac* can be found as follows:

Dip. Dip table on inside front cover and repeated on loose bookmark, and on the page facing the inside back cover.

Refraction. Mean refraction from "Stars and Planets" table on inside front cover and repeated on loose bookmark, and on the facing page.

Irradiation. A value of (−) 1′.2 is included in the tables of corrections for the upper limb of the sun, given on the inside front cover and repeated on the loose bookmark, and on the facing page, to allow (−) 0′.6 for the upper limb and (−) 0′.6 for the horizon.

Semidiameter. For the sun, the semidiameter for the middle day of each page opening of this daily page section is given at the bottom of the sun GHA column. For the moon, semidiameter for each day is given at the bottom of the moon data columns. The values given are for GMT 1200 on the dates indicated.

Parallax. For the sun, parallax in altitude can be considered 0′.1 for altitudes 0° to 70°07′, and 0′.0 for higher altitudes, with negligible error. This is based upon the mean value of 8″.80. For the moon, horizontal parallax each hour is tabulated on the daily pages. Parallax in altitude is this value multiplied by the cosine of the altitude.

If artificial-horizon sextant altitudes of the sun or moon are corrected by *Nautical Almanac*, the upper and lower limb corrections can be found and the average computed.

1627. Corrections by *Air Almanac*.—In the *Air Almanac*, various corrections are given separately in critical type tables, to the nearest whole minute (nearest two or five minutes of refraction for low altitudes), as follows:

Dip. Outside back cover.

Refraction. Inside back cover. Aboard ship use the values for zero height. A special table for H.O. Pub. No. 218 is given on the page facing the inside back cover. A dome refraction table for use in aircraft is given on the same page.

Coriolis. Inside back cover, below the refraction table.

Air temperature. Inside back cover. This is shown, not as a separate correction, but as an adjustment to mean refraction. Instructions for use of the table are given on the inside back cover of the *Air Almanac*.

Semidiameter. For the sun and moon, on the right-hand daily page, below the moon's P in A. Values given are for GMT 1200. The value given for the sun is always 16′.

Parallax. For the moon, in the P in A table on the right-hand daily page. Horizontal parallax is the value for 0° altitude. Values given are for GMT 1200.

1628. Correcting altitudes of the sun.—In the normal practice of navigation, sun observations obtained by marine sextant with the visible horizon as reference are corrected as shown in the following examples:

Example 1.—On June 2, 1958, the lower limb of the sun is observed with a marine sextant having an IC of (−) 2′.0, from a height of eye of 38 feet. The hs is 51°28′.4.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac*.

Solution.—

(1)

	+ $\underline{\odot}$	−
IC		2′.0
D		6′.0
$\underline{\odot}$	15′.2	
sum	15′.2	8′.0
corr.		(+) 7′.2
hs		51°28′.4
Ho		51°35′.6

(2)

	+ $\underline{\odot}$	−
IC		2′
D		6′
R		1′
SD	16′	
sum	16′	9′
corr.		(+) 7′
hs		51°28′
Ho		51°35′

Example 2.—On June 2, 1958, the upper limb of the sun is observed with a marine sextant having an IC of (+) 1′.0, from a height of eye of 45 feet. The hs is 32°47′.9.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac.*

Solution.—

(1)

	+	☉̄	−
IC	1′.0		
D			6′.5
☉̄			18′.5
sum	1′.0		25′.0
corr.			(−) 24′.0
hs			32°47′.9
Ho			32°23′.9

(2)

	+	☉̄	−
IC	1′		
D			7′
R			2′
SD			16′
sum	1′		25′
corr.			(−) 24′
hs			32°48′
Ho			32°24′

A convenient work form is helpful in the solution. Once the form is prepared, the corrections can be entered in any order desired. The symbols ☉̲ and ☉̄ are used for the corrections from the sun table on the inside front cover of the *Nautical Almanac.* If additional corrections are used, they are included in the same manner as those shown. Observations by artificial horizon and by artificial-horizon sextant, and low-altitude observations and back sights, are discussed elsewhere in this chapter.

1629. Correcting altitudes of the moon.—Moon observations by marine sextant with the visible horizon as reference are normally corrected as shown in the following examples:

Example 1.—At about GMT 1100 on June 2, 1958, the lower limb of the moon is observed with a marine sextant having an IC of (+) 3′.2, from a height of eye of 32 feet. The hs is 18°04′.6.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac.*

Solution.—

(1)

	+	☾̲	−
IC	3′.2		
D			5′.5
☾	62′.5		
L	6′.7		
sum	72′.4		5′.5
corr.			(+)1°06′.9
hs			18°04′.6
Ho			19°11′.5

(2)

	+	☾̲	−
IC	3′		
D			6′
R			3′
SD	16′		
P	56′		
sum	75′		9′
corr.			(+)1°06′
hs			18°05′
Ho			19°11′

Example 2.—At about GMT 0900 on June 2, 1958, the upper limb of the moon is observed with a marine sextant having an IC of (−)1′.6, from a height of eye of 70 feet. The hs is 66°47′.3.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac.*

Solution.—

(1)

	+	☾̄	−
IC			1′.6
D			8′.1
☾	33′.0		
U	3′.8		
add'l			30′.0
sum	36′.8		39′.7
corr.			(−) 2′.9
hs			66°47′.3
Ho			66°44′.4

(2)

	+	☾̄	−
IC			2′
D			8′
R			—
SD			16′
P	23′		
sum	23′		26′
corr.			(−) 3′
hs			66°47′
Ho			66°44′

The typical work forms shown are useful in problems of this type. The symbol ☾ is used for the correction from the upper part of the moon correction table on the inside back cover, and facing page, of the *Nautical Almanac*. The symbols L and U are used for the corrections from the lower part of this table. Observations by artificial horizon, and by artificial-horizon sextant, and low-altitude observations and back sights, are discussed elsewhere in this chapter, as are additional corrections for use when unusual accuracy is desired.

1630. Correcting altitudes of planets.—When Venus and Mars are observed by marine sextant using the visible horizon as reference, sextant altitudes are normally corrected as shown in the following example:

Example.—On May 19, 1958, Venus is observed with a marine sextant having no IC, from a height of eye of 28 feet. The hs is 44°21′.3.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac*.

Solution.—

(1)

	+	V –
IC	—	—
D		5′.1
☆-P		1′.0
add'l	0′.2	
sum	0′.2	6′.1
corr.		(–) 5′.9
hs		44°21′.3
Ho		44°15′.4

(2)

	+	V –
IC	—	—
D		5′
R		1′
sum	—	6′
corr.		(–) 6′
hs		44°21′
Ho		44°15′

For Jupiter and Saturn, no additional correction is given. Correction of observations of these bodies is the same as corrections of star observations (art. 1631). Work forms are useful. The symbol ☆-P is used for the correction taken from the "Star-Planet" table on the inside front cover of the *Nautical Almanac*. If additional corrections are to be used, for results of unusual accuracy or low altitudes, they are included in the form in the same manner as those shown. Observations by artificial horizon and by artificial-horizon sextant, and low-altitude observations and back sights are discussed elsewhere in this chapter.

1631. Correcting altitudes of stars.—Star observations by marine sextant, using the visible horizon as reference, are normally corrected as shown in the following example:

Example.—Miaplacidus is observed with a marine sextant having an IC of (+) 1′.0, from a height of eye of 50 feet. The hs is 27°54′.0.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac*.

Solution.—

(1)

	+	☆ –
IC	1′.0	
D		6′.9
☆-P		1′.8
sum	1′.0	8′.7
corr.		(–) 7′.7
hs		27°54′.0
Ho		27°46′.3

(2)

	+	☆ –
IC	1′	
D		7′
R		2′
sum	1′	9′
corr.		(–) 8′
hs		27°54′
Ho		27°46′

Work forms for such problems are helpful. Additional corrections, used when unusual accuracy is desired, are included in the same manner as those shown. Observations by artificial horizon and by artificial-horizon sextant, and low-altitude observations and back sights, are discussed elsewhere in this chapter.

1632. Low altitudes are normally avoided because of large and variable refraction. But sometimes these are the only observations available. This is particularly true in polar regions, where the sun may be the only celestial body available, and may not reach an altitude of more than a few degrees over a considerable period. In lower latitudes the sun may appear briefly just before sunset or just after sunrise. Low-altitude observations can supply useful information if additional corrections are applied. Reliable lines of position can generally be obtained from low-altitude observations, but when conditions are abnormal, the errors introduced are generally larger than for higher altitudes, and the precautions of article 1613 should be particularly observed.

In correcting low-altitude observations, which for normal conditions can be defined as those less than 5°, first apply corrections from the first two groups of article 1621 to obtain rectified altitude (hr), called "apparent altitude" in the almanac. Normally, this includes only index correction and dip. Then apply the remaining corrections, using rectified altitude when an altitude is needed for entering correction tables. The corrections normally applied are mean refraction, air temperature, atmospheric pressure, semidiameter (as applicable), and parallax (for the sun and moon).

In practice, sextant altitudes are corrected in the usual manner, except that additional corrections are applied, and the process is divided into two parts. The use of rectified altitude for finding parallax introduces an error but this is too small (less than 0'.1) for practical consideration. If the *Nautical Almanac* is used, corrections for altitudes between the horizon and 10° are given in a noncritical type table on almanac page A3. The correction for a negative altitude can be obtained by extrapolation without introducing a significant error for values obtained at ship heights of eye. A combined temperature-atmospheric pressure correction can be obtained from the table on almanac page A4. This table is intended for use without interpolation between columns. Separate corrections can be obtained from tables 23 and 24 of the present volume, which provide interpolated values for greater accuracy. They also provide greater range of temperature and atmospheric pressure.

To correct a low altitude of the sun, then, apply index correction and dip to sextant altitude to find rectified altitude. Using this altitude as an entering value, find the following corrections and apply them to rectified altitude:

sun correction (☉̲ or ☉̄), from page A3 of the *Nautical Almanac;*

combined temperature-atmospheric pressure correction (TB), from page A4 of the *Nautical Almanac* (separate corrections for temperature (T) and atmospheric pressure (B) from tables 23 and 24, respectively, can be used *in place of* the combined correction).

If the *Air Almanac* is used, the mean refraction and air temperature corrections can be combined by using the factor on the inside back cover. A semidiameter correction of 16' is added if the lower limb is observed, and subtracted if the upper limb is observed. Since corrections are to whole minutes only, parallax is not used for the sun. In summary, apply index correction and dip to sextant altitude to find rectified altitude. Using this altitude as an entering value, where needed, apply the following corrections to rectified altitude:

refraction (adjusted for air temperature) (R), from inside back cover of *Air Almanac;*

atmospheric pressure (B), from table 24;

semidiameter (SD), 16' (add if lower limb, and subtract if upper limb).

Example 1.—On June 2, 1958, the lower limb of the sun is observed with a marine sextant having an IC of (+) 1'.8 from a height of eye of 45 feet. The hs is 1°24'.4, air temperature 88°F, and atmospheric pressure 29.78 inches.

Required.—Ho using (1) *Nautical Almanac*, (2) tables 23 and 24, and (3) *Air Almanac.*

Solution:

(1)

	+	$\underline{\odot}$	−
IC	1′.8		
D			6′.5
sum	1′.8		6′.5
corr.			(−) 4′.7
hs			1°24′.4
hr			1°19′.7
$\underline{\odot}$			6′.0
TB	2′.5		
sum	2′.5		6′.0
corr.			(−) 3′.5
hr			1°19′.7
Ho			1°16′.2

(2)

	+	$\underline{\odot}$	−
IC	1′.8		
D			6′.5
sum	1′.8		6′.5
corr.			(−) 4′.7
hs			1°24′.4
hr			1°19′.7
$\underline{\odot}$			6′.0
T	1′.5		
B	—		
sum	1′.5		6′.0
corr.			(−) 4′.5
hr			1°19′.7
Ho			1°15′.2

(3)

	+	$\underline{\odot}$	−
IC	2′		
D			7′
sum	2′		7′
corr.			(−) 5′
hs			1°24′
hr			1°19′
R			18′
B	—		
SD	16′		
sum	16′		18′
corr.			(−) 2′
hr			1°19′
Ho			1°17′

The larger intervals given in the *Air Almanac* refraction table may introduce additional error. In this example, the temperature is changed to Celsius (centigrade), giving a value of 31°. The factor at a height of 0 feet corresponding to this temperature is 0.9. With this and the rectified altitude, the combined refraction and air temperature correction is found to be as shown. Approximately the same result would have been obtained by correcting for mean refraction (without the factor) and temperature (from table 23) separately.

If the moment at which either limb is tangent to the horizon is noted, an observation of 0° altitude has been made without a sextant.

Example 2.—On June 2, 1958, the sun is observed at sunset as the upper limb drops below the horizon, from a height of eye of 38 feet. The air temperature is (−) 10°F, and atmospheric pressure 30.06 inches. Double extrapolation would be needed to solve this problem by the *Nautical Almanac*. A better solution is provided by means of tables 23 and 24.

Required.—Ho using (1) tables 23 and 24, and (2) *Air Almanac.*

Solution.—

(1)

	+	$\overline{\odot}$	−
IC	—		—

Corrections are applied algebraically. Therefore, for negative altitudes a negative correction is *numerically* added, and a positive correction is *numerically* subtracted.

To correct low altitudes of the moon, apply index correction and dip to sextant altitude to find rectified altitude. Using this altitude as an entering value, find the following corrections and apply them to rectified altitudes:

moon correction (☾), from inside back cover, and facing page, of *Nautical Almanac;*
lower or upper limb correction (L or U), from inside back cover, and facing page, of *Nautical Almanac;*
additional correction (add'l, (−) 30′, for upper limb observation only);
combined temperature-atmospheric pressure correction (TB), from page A4 of the *Nautical Almanac* (separate corrections for temperature (T) and atmospheric pressure (B) from tables 23 and 24, respectively, can be used in place of the combined correction).

If the *Air Almanac* is used, correct the rectified altitude by applying the following corrections:
refraction (adjusted for air temperature) (R), from inside back cover of *Air Almanac;*
atmospheric pressure (B), from table 24;
semidiameter, from right-hand daily page;
parallax, from right-hand daily page.

Example 3.—At GMT $17^h14^m27^s$ on June 2, 1958, the upper limb of the moon is observed with a marine sextant having no IC, from a height of eye of 33 feet. The hs is 2°35′.4, air temperature 63° F, and atmospheric pressure 29.81 inches.

Required.—Ho using (1) *Nautical Almanac*, (2) tables 23 and 24, and (3) *Air Almanac.*

Solution.—

(1)	+ ☾	−
IC	—	—
D		5′.6

A lower limb solution would be the same, except that an L correction would have been used from the *Nautical Almanac* and there would be no "add'l" correction, and in the *Air Almanac* solution the sign of the semidiameter correction would be reversed. The moon correction table on the inside back cover, and facing page, of the *Nautical Almanac* extends to a minimum altitude of 0°. The corrections for negative altitudes can be found by extrapolation.

To correct low altitudes of the planets Venus and Mars, apply index correction and dip to sextant altitude to find rectified altitude. Using this altitude as an entering value, find the following corrections and apply them to rectified altitude:

star-planet correction (☆-P), from page A3 of the *Nautical Almanac;*
additional correction (add'l), from page A2 of the *Nautical Almanac;*
combined temperature-atmospheric pressure correction (TB), from page A4 of the *Nautical Almanac* (separate corrections for temperature (T) and atmospheric pressure (B) from tables 23 and 24, respectively, can be used *in place of* the combined correction).

If the *Air Almanac* is used, correct the rectified altitude by applying the following corrections:

refraction (adjusted for air temperature) (R), from inside back cover of *Air Almanac;*
atmospheric pressure (B), from table 24.

Example 4.—On September 28, 1958, Mars is observed with a marine sextant having an IC of (+) 3′.5, from a height of eye of 17 feet. The hs is 4°02′.6, air temperature 2°F, and atmospheric pressure 29.67 inches.

Required.—Ho using (1) *Nautical Almanac*, (2) tables 23 and 24, and (3) *Air Almanac.*

Solution.—

The solution for Jupiter and Saturn, and for stars, is identical with that of example 4, except that the additional correction (phase and parallax) is omitted.

1633. Back sights.—An altitude measured by facing *away* from the celestial body being observed is called a **back sight.** It may be used when an obstruction, such as another vessel, obscures the horizon under the body; when that horizon is indistinct; or when observations are made in both directions, either to determine dip or to avoid error due to suspected abnormal dip. Such an observation is possible only when the arc of the sextant is sufficiently long to permit measurement of the angle, which is the supplement of the altitude. For such an observation of the sun or moon, the lower limb is observed when the image is brought below the horizon, appearing as a normal upper limb observation, and vice versa. To correct such an altitude, subtract it from 180° and reverse the sign of corrections of the first two groups of article 1621 (normally only index correction and dip).

Example.—On June 2, 1958, a back sight is taken of the lower limb of the sun, with a marine sextant having an IC of (−) 2′.0, from a height of eye of 24 feet. The measured sextant altitude is 118°41′.4.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac.*

Solution.—

(1)

Ho	61°41′	

1634. Correcting horizontal angles.—When a marine sextant is used to measure the horizontal angle between two objects, the result is not usually desired to a precision that makes correction necessary, unless the sextant has an unusually large index error. However, if precise results are desired, corrections of the first group only of article 1621 are applied. If a personal error exists, it is not likely to be the same as for altitudes. For measuring angles between two objects differing widely in altitude, as between two stars, it is not likely that results will be required to such precision that additional correction for the third, fourth, and fifth groups of article 1621 will be needed. If they are, the method of application can be determined from the principles of spherical trigonometry (app. O). In this case, the altitudes of both bodies will also be needed. Corrections for the second group of article 1621 are not applicable.

Problems

1624. At about GMT 0800 on June 2, 1958, the following bodies are observed with marine sextants having an IC of (+)2′.2, using an artificial horizon: sun (lower limb) hs 134°33′.9, moon (upper limb) hs 77°23′.4, Venus hs 98°04′.6, Schedar hs 43°24′.4.

Required.—Ho of each observation using (1) *Nautical Almanac*, and (2) *Air Almanac.*

Answers.—(1) Sun Ho 67°33′.6, moon Ho 39°11′.7, Venus Ho 49°02′.6, Schedar Ho 21°40′.9; (2) sun Ho 67°34′, moon Ho 39°12′, Venus Ho 49°03′, Schedar Ho 21°41′.

1625. At about GMT 0300 on June 2, 1958, the following bodies are observed with bubble sextants having no IC: sun hs 23°51′, moon hs 52°20′, Jupiter hs 63°18′, Eltanin hs 24°45′.

Required.—Ho of each observation using (1) *Nautical Almanac*, and (2) *Air Almanac.*

Answers.—(1) and (2) Sun Ho 23°49′, moon Ho 52°56′, Jupiter Ho 63°18′, Eltanin Ho 24°43′.

1628a. On June 2, 1958, the lower limb of the sun is observed with a marine sextant having an IC of (+)1′.8, from a height of eye of 34 feet. The hs is 41°34′.8.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac.*

Answers.—(1) Ho 41°45′.8; (2) Ho 41°46′.

1628b. On June 2, 1958, the upper limb of the sun is observed with a marine sextant having no IC, from a height of eye of 30 feet. The hs is 15°21′.7.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac.*

Answers.—(1) Ho 14°56′.0; (2) Ho 14°57′.

1628c. On June 2, 1958, the lower limb of the sun is observed with a marine sextant having an IC of (−)1′.3, from a height of eye of 43 feet. Another ship is between the observer and the horizon, at a distance of 1.4 miles from the observer. The water line of this ship is used as the horizontal reference. The hs is 25°18′.2.

Required.—Ho using table 22 and (1) *Nautical Almanac*, and (2) *Air Almanac*.

Answers.—(1) Ho 25°13.′0; (2) Ho 25°13′.

1629a. At about GMT 2100 on June 2, 1958, the lower limb of the moon is observed with a marine sextant having an IC of (−) 2.′5, from a height of eye of 55 feet. The hs is 47°35.′5.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac*.

Answers.—(1) Ho 48°20.′5; (2) Ho 48°22′.

1629b. At about GMT 2300 on June 2, 1958, the upper limb of the moon is observed with a marine sextant having an IC of (+)4.′0, from a height of eye of 12 feet. The hs is 22°58.′3.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac*.

Answers.—(1) Ho 23°34.′7; (2) Ho 23°35′.

1630a. On June 18, 1958, Mars is observed with a marine sextant having an IC of (+) 2.′2, from a height of eye of 60 feet. The hs is 34°11.′7.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac*.

Answers.—(1) Ho 34°05.′1; (2) Ho 34°05′.

1630b. Jupiter is observed with a marine sextant having an IC of (−)1.′0, from a height of eye of 27 feet. The hs is 11°23.′9.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac*.

Answers.—(1) Ho 11°13.′2; (2) Ho 11°13′.

1631. Alpheratz is observed with a marine sextant having no IC, from a height of eye of 42 feet. The hs is 38°20.′3.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac*.

Answers.—(1) Ho 38°12.′8; (2) Ho 38°13′.

1632a. On June 2, 1958, the lower limb of the sun is observed with a marine sextant having an IC of (−) 2.′3, from a height of eye of 24 feet. The hs is 2°04.′6, air temperature 65° F, and atmospheric pressure 30.81 inches.

Required.—Ho using (1) *Nautical Almanac*, (2) tables 23 and 24, and (3) *Air Almanac*.

Answers.—(1) Ho 1°55.′1; (2) Ho 1°55.′1; (3) Ho 1°56′.

1632b. On July 2, 1958, the sun is observed as the upper limb drops below the horizon at sunset, from a height of eye of 19 feet. The air temperature is 16° F, and atmospheric pressure 29.90 inches.

Required.—Ho using (1) *Nautical Almanac*, (2) tables 23 and 24, and (3) *Air Almanac*.

Answers.—(1) Ho (−)1°01.′4; (2) Ho (−)0°59.′2; (3) Ho (−)0°58′.

1632c. At GMT $6^h03^m29^s$ on June 2, 1958, the upper limb of the moon is observed with a marine sextant having an IC of (+)2.′6, from a height of eye of 35 feet. The hs is 1°12.′6, air temperature (−) 23° F, and atmospheric pressure 29.04 inches.

Required.—Ho using (1) tables 23 and 24, and (2) *Air Almanac*.

Answers.—(1) Ho 1°26.′1; (2) Ho 1°24′.

1632d. At GMT $12^h44^m01^s$ on June 2, 1958, the lower limb of the moon is observed with a marine sextant having an IC of (+)3.′2, from a height of eye of 22 feet. The hs is 0°24.′4, air temperature 40° F, and atmospheric pressure 29.94 inches.

Required.—Ho using (1) *Nautical Almanac*, (2) tables 23 and 24, and (3) *Air Almanac*.

Answers.—(1) Ho 1°07.′4; (2) Ho 1°07.′6; (3) Ho 1°04′.

1632e. On January 19, 1958, Venus is observed with a marine sextant having an IC of (−)0.′5, from a height of eye of 31 feet. The hs is 3°29.′8, air temperature 55° F, and atmospheric pressure 30.15 inches.

Required.—Ho using (1) *Nautical Almanac*, (2) tables 23 and 24, and (3) *Air Almanac*.

Answers.—(1) Ho 3°11′.3; (2) Ho 3°11′.1; (3) Ho 3°11′.

1632f. Saturn is observed with a marine sextant having an IC of (−) 2′.3, from a height of eye of 37 feet. The hs is 4°39′.2, air temperature 76° F, and atmospheric pressure 28.89 inches.

Required.—Ho using (1) *Nautical Almanac*, (2) tables 23 and 24, and (3) *Air Almanac*.

Answers.—(1) Ho 4°21′.4; (2) Ho 4°21′.1; (3) Ho 4°21′.

1632g. Gienah is observed with a marine sextant having no IC, from a height of eye of 44 feet. The hs is 2°46′.1, air temperature 35° F, and atmospheric pressure 29.92 inches.

Required.—Ho using (1) *Nautical Almanac*, (2) tables 23 and 24, and (3) *Air Almanac*.

Answers.—(1) Ho 2°23′.4; (2) Ho 2°23′.6; (3) Ho 2°21′.

1633. On June 2, 1958, a back sight is taken of the lower limb of the sun, with a marine sextant having an IC of (+) 1′.7, from a height of eye of 49 feet. The measured sextant altitude is 141°04′.9.

Required.—Ho using (1) *Nautical Almanac*, and (2) *Air Almanac*.

Answers.—(1) Ho 39°15′.0; (2) Ho 39°15′.

1634. The horizontal angle between two objects is measured with a marine sextant having an IC of (+) 4′.0. The measured angle is 85°14′.6.

Required.—Corrected angle.

Answer.—Corrected angle 85°18′.6.

CHAPTER XVII

LINES OF POSITION FROM CELESTIAL OBSERVATIONS

1701. Circles of equal altitude.—For every point on the earth there is a zenith (art. 1428) vertically overhead on the celestial sphere (art. 1403). Likewise, every point on the celestial sphere is vertically over *some* terrestrial point, called its **geographical position (GP)**. However, since the earth rotates on its axis, causing *apparent* rotation of the celestial sphere, the GP of any point on the celestial sphere is continually moving to the westward, at the rate of about 15° per hour. If a celestial body is changing its apparent position on the celestial sphere, this motion is added to that caused by rotation, so that the rates of motion of the GP's of various bodies differ slightly. Further, this motion may not be exactly westward, having a small northerly or southerly component as the body changes declination, due either to its own proper motion or precession of the equinoxes (art. 1419), or a combination of the two.

At any moment the declination of a celestial body is equal to the latitude of its GP. The Greenwich hour angle (GHA) of the body, if not greater than 180°, is equal to the longitude (west) of the GP. If the GHA is greater than 180°, its explement (art. O27) is equal to the longitude (east). Thus, if it is established that a body of known coordinates is in the zenith of an observer, the position of the observer is known. However, for the celestial bodies used in navigation, this condition rarely occurs for any individual observer, and is difficult to determine when it does occur.

More commonly, the altitude (art. 1428) is measured, and from this the zenith distance (art. 1428) can be determined. This value defines a circle on the earth, as shown in figure 1701a. Thus, if the observer is one mile from the GP, in *any* direction, he is 1′ from it, and his zenith is 1′ from the celestial body. Anywhere on a circle of one mile (1′) radius, with the GP as the center, the zenith distance is 1′. Similarly, if the zenith distance is 10°, the observer may be anywhere on a circle (assuming a spherical earth) of radius $10 \times 60 = 600$ miles, with the GP as the center. If the zenith distance is 30°, the radius is 1,800 miles; if 60°, the radius is 3,600 miles; and if 90° (body on the celestial horizon), the radius is 5,400 miles. This is a great circle dividing the earth into two hemispheres. Anywhere within that hemisphere having the GP as its center the celestial body is above the celestial horizon. Anywhere within the opposite hemisphere the body is below the celestial horizon.

These **circles of equal altitude** are **circles of position,** or circular **lines of position.** Two such circles for different celestial bodies, or for the same body at different times, may intersect at two points, as shown in figure 1701b. If these circles have radii equal to the zenith distances at the observer, the position of the observer is established at one of the two intersections. Normally, these intersections are separated by such great distances that no question arises as to which represents the position of the observer. However, uncertainty can be removed if additional altitude circles can be established by observation of other celestial bodies. It would be a rare coincidence for a third such circle to pass through both intersections of the first two. The third observation also serves as a check on the accuracy of the first two. The ambiguity might also be resolved by noting the azimuth of either or both of the bodies, for the azimuth should be in the same direction as the radius of the circle of position, measured at the intersection.

1702. Utilizing circles of equal altitude.—For most altitudes conveniently observed, the plotting of circles of equal altitude involves certain difficulties. Because of the long radii of such circles, a chart of very small scale would be needed, and virtually any chart distortion would introduce some error, unless an azimuthal projection (ch. III) centered upon the GP were used, an impractical procedure with a moving GP for each body. The appearance of two circles of equal altitude plotted on a Mercator chart is shown in figure 1702.

It has been suggested that the second difficulty, that of distortion, might be overcome by plotting directly on a sphere, using equipment designed for this purpose. While theoretically sound, this procedure does not overcome the first difficulty, that of scale, and has not proved practical. A variation of this has been the use of movable arcs, by which a small-scale model of one or more navigational triangles (art. 1433) is mechanically produced. The coordinates are carefully measured by means of sliding indices controlled by verniers or micrometers. Another variation has been a graphical solution based upon the drawing of a diagram according to any of various principles. Although a number of mechanical and graphical solutions have been devised, and some have proved practical (ch. XXI), none has been generally accepted as superior to the commonly used tabular methods of solution.

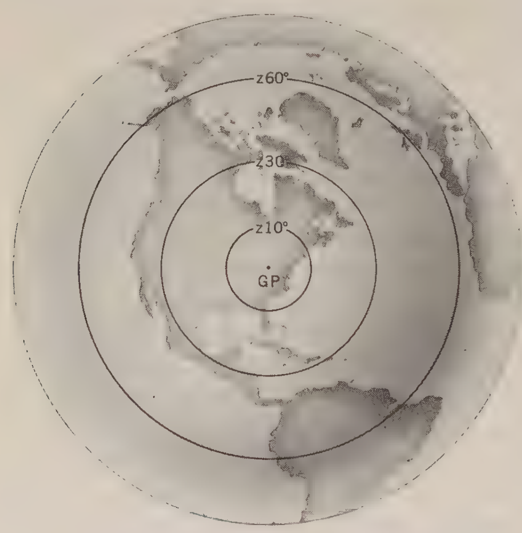

Figure 1701a.—Circles of equal altitude.

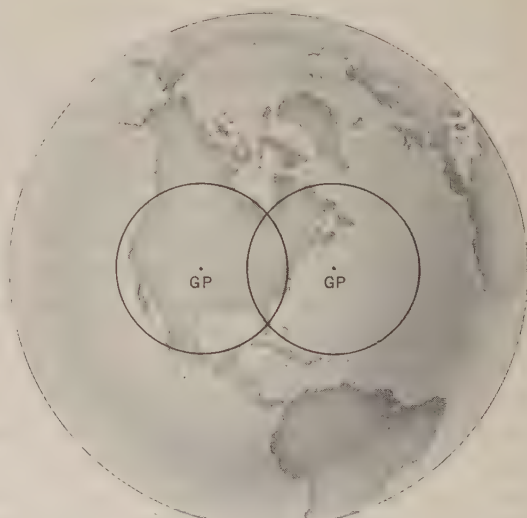

Figure 1701b.—Intersections of two circles of equal altitude.

However, as the altitude of a body increases, reducing the zenith distance, both distortion and scale difficulties decrease. Also, on a Mercator chart, they decrease as the GP approaches the equator. The observation of a celestial body near the zenith is difficult, but in the case of the sun no alternative may be available near noon in the tropics. Such a situation does provide an easy solution and may permit obtaining of a fix from two observations of the same body, with only a few minutes between observations. This solution is discussed further in article 2011.

1703. The line of position.—For zenith distances too great to plot conveniently, a line of position can be laid down in another manner.

The altitude of a celestial body may be measured. After appropriate corrections are applied, this is called **observed altitude (Ho)**. For the instant of observation, the altitude and azimuth at some convenient **assumed position (AP)** near the actual position of the observer are determined by calculation or equivalent process. The difference between this **computed altitude (Hc)** and Ho is the **altitude difference** (*a*), some-

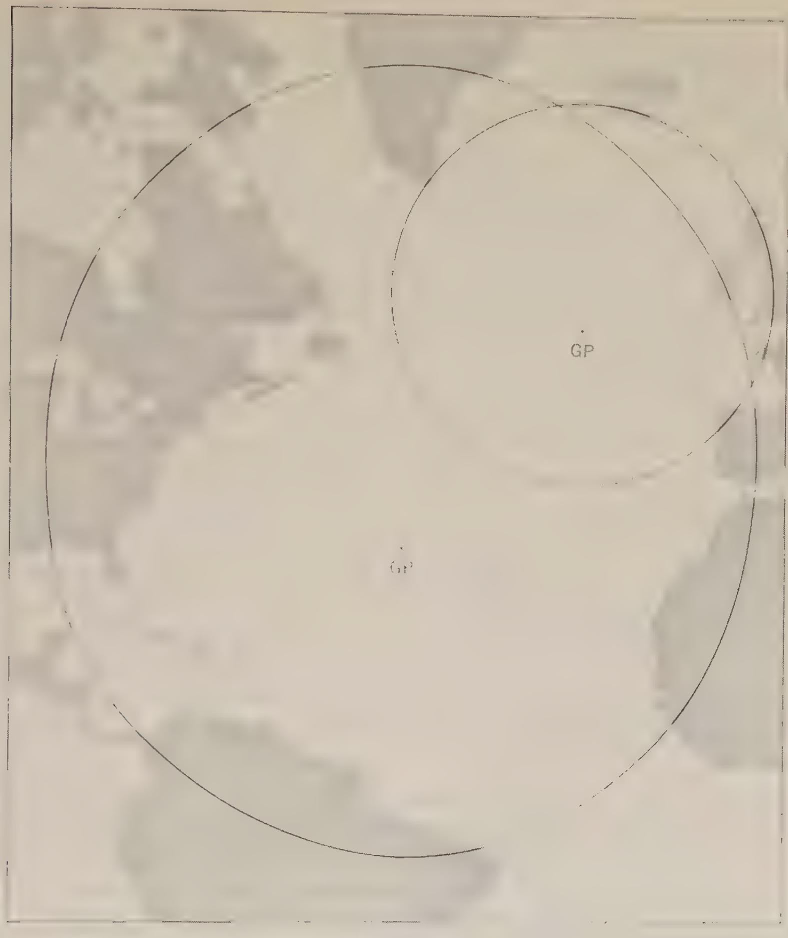

FIGURE 1702.—Circles of equal altitude on a Mercator chart.

times called **altitude intercept.** Since *a* is the difference in altitude at the assumed and actual positions, it is also the difference in zenith distance, and therefore the difference in radii of the circles of equal altitude at the two places. The position having the greater altitude is on the circle of smaller radius, and hence is closer to the GP of the body. In figure 1703a the AP is shown on the inner circle. Hence, Hc is greater than Ho.

The line of position can be plotted by using part of the information within the broken circle of figure 1703a, as shown in figure 1703b. First, the AP is plotted. The circle of equal altitude through this position is not needed, and is not plotted. From the AP the azimuth line is measured toward or away from the GP as appropriate, and the altitude difference is measured along this line. At the point thus located, a line is drawn perpendicular to the azimuth line. For several miles on each side of the azimuth line, this perpendicular can be considered part of the circle of position through the observer, as shown in figure 1703a. This perpendicular is the line of position. It is labeled with the time of observation above the line, and the name of the celestial body below the line, as shown in figure 1703b.

For neatness of plot the azimuth line should not be extended beyond the line of position or the AP, unless it is extended a short distance in the direction of the body, and the symbol of the body observed is shown to indicate whether a "toward" or

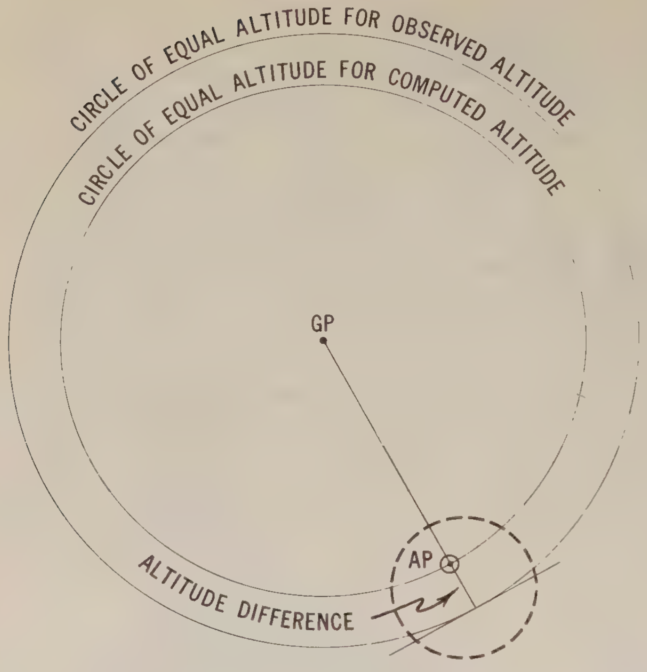

FIGURE 1703a.—The basis for the line of position from a celestial observation.

"away" observation. This method is used in the examples of H.O. Pub. No. 214. Some navigators omit the azimuth line, showing only the AP and line of position, and using a straightedge as a guide for the dividers in measuring the altitude difference. This is good practice, for it reduces the number of lines on the plotting sheet, and therefore minimizes the possibility of making an error. However, until one gains confidence in plotting lines of position, it is desirable to show the azimuth line.

For plotting a line of position from a celestial observation, then, only the assumed position, altitude difference (with an indication of which altitude is greater), and azimuth are needed.

The assumed position is chosen somewhat arbitrarily. It may be the dead reckoning position, an estimated position, or any arbitrarily chosen position nearby. Most commonly, however, the **assumed latitude** (*a*L) is taken as the *nearest* whole degree of latitude to the DR or EP; and the **assumed longitude** ($a\lambda$) is selected so that the local hour angle is a whole degree. The location of the line of position is independent of the location of the AP (within reasonable limits), assuming only that the altitude difference is measured from the AP used for determining Hc. That is, each AP has its own altitude difference, depending upon its distance from the line of position.

The altitude difference, the numerical difference between Hc and Ho, is customarily expressed in nautical miles (minutes of arc), and labeled **T** or **A** to indicate whether the line of position is **toward** or **away** from the GP, as measured from the AP:

Hc	37°51.′6	Hc	61°57.′3
Ho	37°43.′9	Ho	62°12.′7
a	7.7A	*a*	15.4T

The azimuth is customarily determined by computation or table at the time of determining Hc.

This method of plotting a line of position from a celestial observation was suggested by Marcq St.-Hilaire (art. 2108), and generally bears his name. It is used almost universally by modern navigators. The method is based upon knowledge of one point on the line, and the direction of the line. Another method of utilizing the same principle is to assume the latitude and compute the longitude at which the line of position crosses that parallel (the time sight method, art. 2106), or vice versa. When this method is used, the azimuth is customarily found separately, from a table or graph.

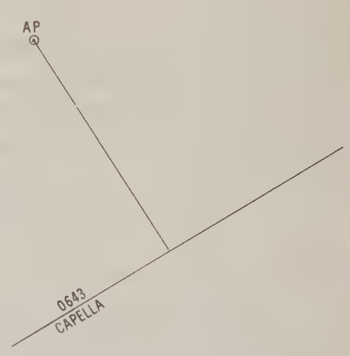

FIGURE 1703b.—A line of position from observation of the star Capella at 0643.

A third method is to compute two points on the line of position and draw a straight line through them. This line is a chord, rather than a tangent, of the circle of position, but in most cases the difference is negligible. This third method was that originally proposed by Captain Thomas H. Sumner (art. 131), and for this reason the resulting line of position is sometimes called a **Sumner line,** although the expression may be applied to any line of position resulting from celestial observation.

When celestial navigation is used, plotting is generally done on plotting sheets (art. 323) published by the U. S. Navy Hydrographic Office. These are less expensive than charts, and the absence of detail eliminates a possible source of confusion and error.

1704. Using lines of position from celestial observations.—Like any other line of position, one resulting from a celestial observation does not pinpoint the position of the craft, but may provide all the information needed to insure safety of the vessel. The selection of a celestial body and the time of observation to provide the desired information is based upon the fact that the line of position is perpendicular to the azimuth line. If the celestial body is on or near the celestial meridian, the line of position is a **latitude line,** indicating the latitude at the time of observation, sometimes called the **observed latitude.** Similarly, a body on or near the prime vertical provides a **longitude line,** indicating the **observed longitude.** One ahead or astern provides a **speed line,** since the line of position is perpendicular to the course, and hence is an indication of the speed made good since the last speed line or fix. Similarly, a body on the beam provides a **course line** which indicates to what extent the course is being made good. If the azimuth line is perpendicular to a coast line, shoal, or other hazard, the line of position indicates the distance of the vessel from the danger. Passage parallel to such a danger, or between two of them, might be made safely by means of a series of observations of a body on the beam during passage, without fixing the position of the vessel. This problem might be simplified by precomputing the sextant altitude at intervals during passage, and plotting this versus time on cross-section paper, so that sextant altitudes can be compared immediately with the values taken from the curve to determine any deviation from the desired track. In a perpendicular approach to a coast, the point at which landfall will be made can be predicted with considerable accuracy if a body having an azimuth parallel to the beach is observed.

During twilight, with clear skies, the selection of a celestial body to provide desired information is simply a matter of choosing the body with azimuth nearest that desired, remembering that bodies having azimuths differing by 180° should provide the same line of position. Observation of bodies in opposite directions provides a check, and a better one than two observations of the same body, or observations of two bodies having nearly the same azimuth, for any constant error in the observations, such as might be caused by abnormal dip, can be eliminated by observing bodies on opposite azimuths and using a line midway between the two plotted lines of position.

When a limited number of bodies is available for a considerable period, as during daylight, the best time to make an observation to obtain a line of position in a desired direction can be determined by means of an azimuth table or diagram, or an inspection table such as H.O. Pub. No. 214. The azimuth is located, and the corresponding meridian angle is recorded. The meridian angle can then be converted to GHA, and the time at which this GHA occurs can be determined from the almanac (art. 2104).

Lines of position can be used for determining an estimated position (art. 1705), or they can be advanced or retired (art. 1706) to obtain a fix (art. 1707) or running fix (art. 1708). If a single body is available for observation, increased accuracy can usually be obtained by making three or more observations, adjusting all lines to a common time (art. 1706), and using either the middle line, or the average position of all lines.

1705. Estimated position.—As indicated in chapter VIII, a **dead reckoning (DR) position** is determined by advancing a known position for courses and distances. In the absence of additional information, the DR position is the best estimate of the position of the vessel. However, the expression **estimated position (EP)** is generally applied to one determined by using additional but inconclusive information. If the effects of wind and current can be estimated, and these effects have not been considered in establishing the DR position, they can be applied separately to establish an EP. As each additional item of information is received, an improved estimate might be made.

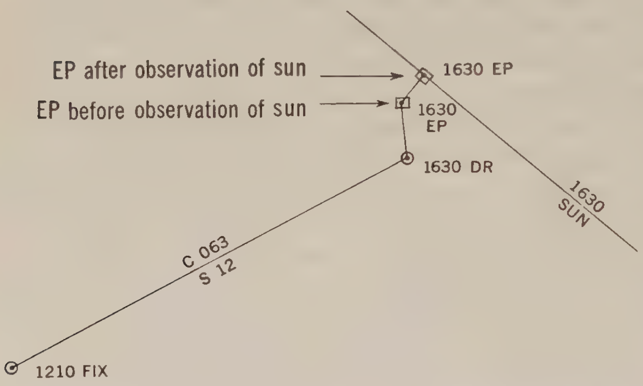

FIGURE 1705a.—Estimated positions before and after observation of the sun for a line of position, allowing for current.

A single line of position can be useful in establishing an estimated position. If an accurate line is obtained, the actual position is somewhere on this line. In the absence of better information, a perpendicular from the previous DR position or EP to the line of position establishes the new EP, as shown in figure 1705a. The foot of the perpendicular from the AP has no significance in this regard, since it is used only to locate the line of position.

The establishment of a good EP is dependent upon accurate interpretation of all information available. Generally, such ability can be acquired only by experience. If, in the judgment of the navigator or captain, the course has been made good, but the speed has been uncertain, the best estimate of the position might be at the intersection of the course line and the line of position, as shown in figure 1705b. If the speed since the last fix is considered accurate, but the course is considered uncertain, the EP might be at the intersection of the line of position and an arc centered on the previous fix and of radius equal to distance traveled, as shown in figure 1705c.

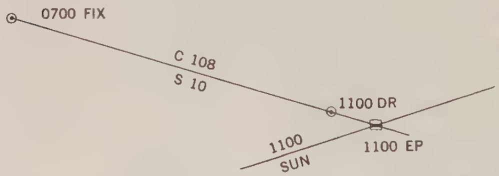

FIGURE 1705b.—An estimated position when the course and a line of position are considered accurate.

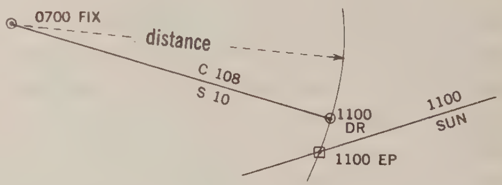

FIGURE 1705c.—An estimated position when the speed and a line of position are considered accurate.

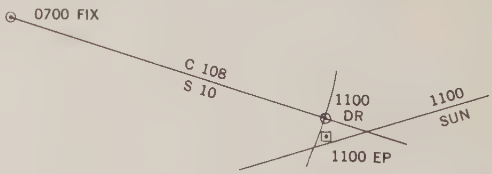

FIGURE 1705d.—An estimated position when a line of position is considered of first accuracy, speed of second accuracy, and course of third accuracy.

More often, neither course nor speed is known to be entirely accurate, but if one is considered more accurate than the other, the EP may be located accordingly. Even the line of position might properly be considered of questionable accuracy, and some estimate of its reliability established. Figure 1705d shows an EP that might be established by considering the line of position of greatest but incomplete accuracy, the speed of secondary accuracy, and the course as least accurate.

The expression **most probable position** (**MPP**) is sometimes used as the equivalent of *estimated position*. However, the former is of somewhat broader application, since it may apply equally well to establishment of the fix when more than two lines of position are available.

Further discussion of navigational accuracy is included in chapter XXIX.

1706. Advancing and retiring lines of position.—For a stationary observer, lines of position resulting from observations made at different times are equally applicable without adjustment. However, for a moving observer, as one aboard a vessel underway at sea, any line of position (except a course line) applies only to the position at the time of observation. If lines resulting from observations made at different times are to be utilized for determining position, they should be adjusted for the motion of the observer between observations.

A line of position resulting from observation of a celestial body can be advanced or retired in the same manner as other lines of position (ch. IX), by selecting any point associated with the line of position and running it forward or backward by dead reckoning, or by estimate. For most accurate results, the best estimate of course and speed made good (over the bottom) between the time of observation and the time to which the line is to be adjusted should be used. Any error in determining these values is reflected in the adjusted line of position. However, error in speed does not affect the accuracy of an adjusted course line, nor does error in course introduce an appreciable error in the accuracy of an adjusted speed line. The time label of an adjusted line of position includes both the time of observation and the time to which the line is adjusted.

As in the case of a line of position resulting from observation of the bearing of an identifiable, charted object (art. 904), the number of lines on the chart can be kept to a minimum, reducing the possibility of confusion, by adjusting the point from which the line is drawn. In the case of celestial navigation, this is the assumed position. This method applies equally well to all observations, and avoids some possible difficulty which might arise in advancing a line of position nearly parallel to the course line. When the AP is advanced or retired, the initial line of position need not be drawn unless it serves some useful purpose.

1707. The fix.—The common intersection of two or more lines of position constitutes a fix, regardless of the source of the position lines, provided only that the lines are based upon simultaneous observations. Celestial observations are seldom simultaneous because all sights of a group are customarily taken by a single observer, usually the navigator. If observations are made a few minutes apart (a **round of sights**), as during a twilight period, all lines are adjusted to a common time, and the position is considered a fix, rather than a running fix. Many navigators advance earlier lines to the time of the last observation, and consider the fix applicable at this time, as shown in figure 1707a. An alternative procedure, which is gaining in acceptance, is to *advance* earlier sights and *retire* later ones to an intermediate time, either the time of the mid observation or a convenient time during the period of observation, such as a whole, half, or quarter hour. This results in a more accurate and convenient time of the fix. In figure 1707b the lines of figure 1707a are adjusted to a common time at a whole hour. With any procedure, the time of the fix is the common time to which the lines of position are adjusted.

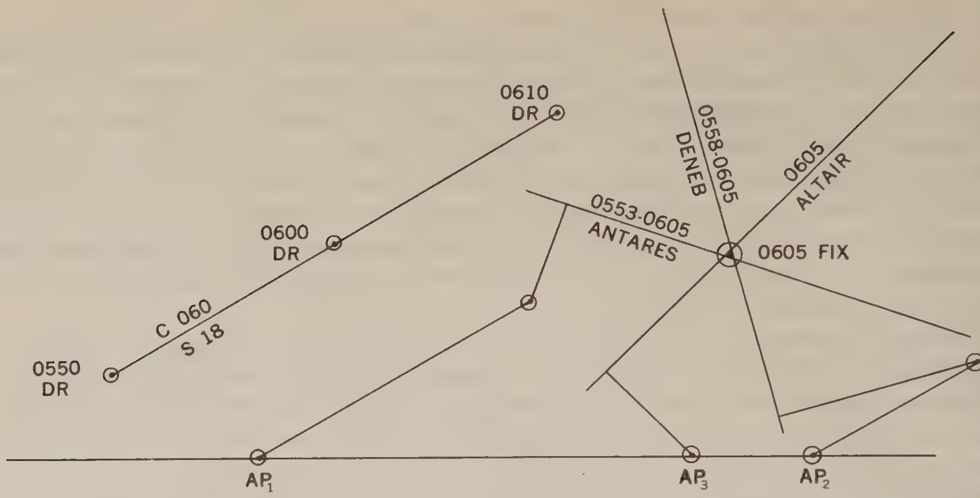

FIGURE 1707a.—A fix obtained by advancing earlier lines of position to the time of the last observation.

In figures 1707a and 1707b the assumed positions are typical of those which might be used with a modern method of sight reduction such as H.O. Pub. No. 214 (ch. XX). *Any* position in the vicinity might be used. If the dead reckoning (or estimated) position at the time of each observation is used as the assumed position for that sight, all sights are plotted from the DR position (or EP) at the time for which the fix is desired. If the same AP is used for all sights, the advanced or retired AP's are along a straight line extending in the direction of the course line, the AP corresponding to the earliest observation being farthest advanced along this line, and others progressing along it in a direction *opposite* to that of the course. If there is any change of course or speed between observations, this should be considered in advancing or retiring a line of position, as it would in running forward the dead reckoning. Under normal conditions, lines of position adjusted for a short interval to obtain a fix are moved by dead reckoning, without separate allowance for current.

Two lines of position provide a fix, but when additional celestial bodies are available, it is good practice to observe them. Additional lines serve as a check on the accuracy of the first two, and should decrease the error of the fix. However, the increased accuracy

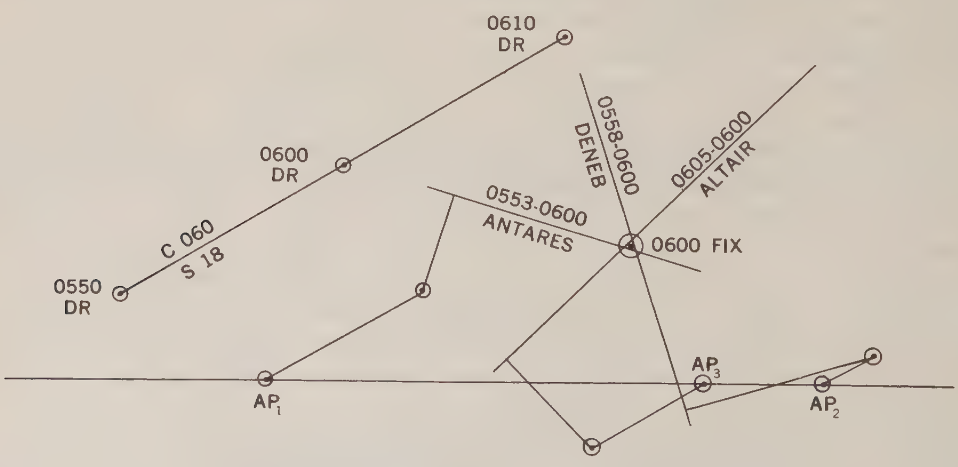

FIGURE 1707b.—A fix obtained by adjusting the lines of position of figure 1707a to a convenient time during the period of observation.

of a fix resulting from a number of lines of position, over that resulting from only two, is not great under normal conditions, and the principal reason for the additional observations is the increased confidence the navigator has in the reliability of his fix.

In selecting bodies for observation, one should generally consider azimuth primarily, and such factors as brightness, altitude, etc., secondarily. Individual circumstances, however, may dictate departures from this procedure. During twilight, when skies are clear and the entire horizon is good, one generally has ample choice of bodies to observe. It is good practice to make several more observations than the minimum considered acceptable, so that additional lines of position will be available, if needed, to resolve possible ambiguities or confirm doubtful results.

Sights need not be solved in the order taken. During evening twilight the brightest bodies should be observed first, as soon as they can be "brought down" successfully to the horizon. During morning twilight the reverse is true, the dimmer stars being observed while they are still visible. However, with advance planning, one can include in the list of bodies to be observed those which should provide the best fix.

If all observations were precisely correct, in every detail, the resulting lines of position would meet at a point. However, this is rarely the case. Three observations generally result in lines of position forming a triangle. If this triangle is not more than two or three miles on a side under good conditions, and five to ten miles under unfavorable conditions, there is normally no reason to suppose that a mistake has been made. Even a point fix, however, is not *necessarily* accurate. An uncorrected error in time, for instance, would move the entire fix eastward if early and westward if late, at the rate of 1′ of longitude for each 4^s of error in time.

With two or four observations, the ideal is to have them crossing at angles of 90°. With three observations, the ideal is angles of 60°. With three observations it is good practice to observe bodies differing in azimuth by 120°, as nearly as possible. This provides lines of position crossing at angles of 60°, and, in addition, any constant error in altitude is eliminated, serving only to increase or decrease the size of the triangle, but not affecting the position of its center. If the azimuths differ by 60°, a large constant error in altitude would result in a fix *outside* the triangle, as shown in figure 1707c.

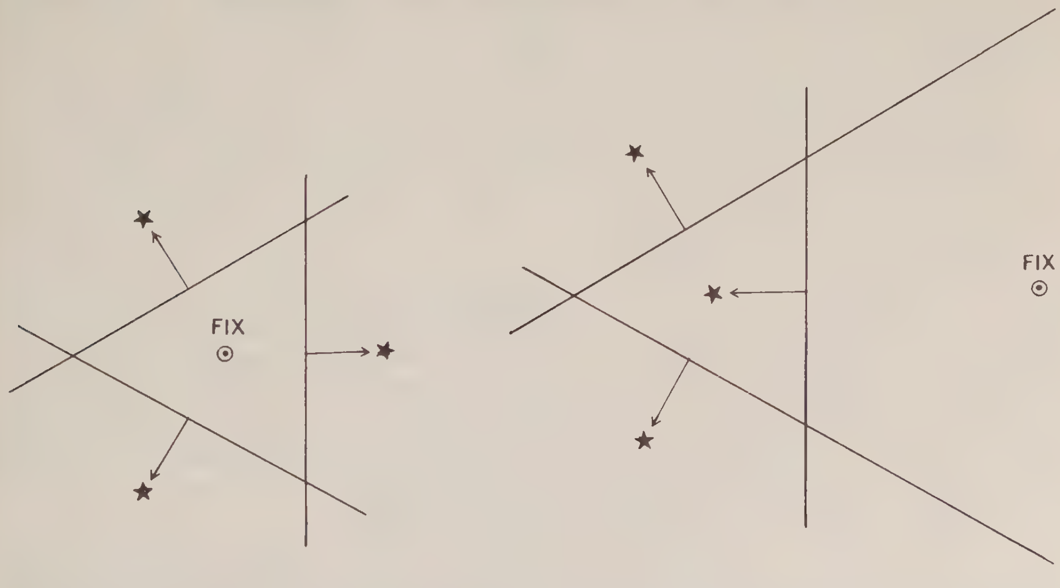

Figure 1707c.—A fix from three lines of position, assuming a constant error in altitude. If all lines are moved away (in this case) from the bodies observed, they would meet in a point which might be either inside (left) or outside (right) the triangle.

With lines of position crossing at 60°, the assumed constant error for a fix outside the triangle is three times that for a fix inside the triangle. With four bodies, azimuths differing by 90° produce a box fix, with constant error eliminated by using the mid point as the fix. With more than four observations, the selection of the fix becomes more complex, and general rules are probably undesirable. The evaluation of each observation and the exercise of judgment become of greater importance. Whatever the number of observations, common practice, backed by logic, is to take the center of the figure formed unless there is reason for deviating from this procedure. By "center" is meant the point representing the least total error of all lines considered reliable. With three lines of position, the center is considered that point, within the triangle, which is equidistant from the three sides. It may be found by bisecting the angles, but more commonly it is located by eye. If a fix outside the triangle is to be used, and eye interpolation is not considered sufficiently reliable, the point can be found by bisecting two external angles and the internal angle at the third intersection. If a constant error is assumed, the most probable position of the fix can always be found, whether within or outside the triangle, by bisecting the angle formed by azimuth lines originating at each intersection.

The matter of navigational errors as applied to this problem is further discussed in chapter XXIX.

1708. A running fix (**R fix**), in celestial navigation, is a position obtained by observations separated by a considerable time interval, usually several hours. The usual occasion for a running fix is the availability of a single celestial body for observation, generally the sun. The delay between observations is usually to permit the azimuth to change sufficiently to provide a good angle of cut between lines of position. Thus, the sun may be observed about 0900, and again about noon.

Generally, a longer wait results in a more nearly perpendicular intersection of the two lines of position, but it may also increase the error of the advanced line. The earlier line is advanced for the course and distance made good. The ability with which these can be predicted determines the accuracy of the running fix, assuming accurate observation, sight reduction, and plotting. For this reason it is impractical to set a specific time limit upon the advancement of a line of position. This should be determined by the conditions of each situation, in the best judgment of the navigator. Experience is valuable in acquiring such judgment.

When an observation of a single body is made, with the intent of later advancing it to obtain a running fix with a second observation, the line of position should be plotted for the time of observation, regardless of the method used for advancing it, for the single line usually provides some useful information, as indicated in article 1704.

Allowance for current, when advancing a line of position, can be made by solving a vector diagram, as indicated in article 807, to determine the course and speed made good. An alternative method is to advance the AP or line without allowance for current, and then to advance it a second time in the direction of set of the current, for a distance equal to the drift multiplied by the number of hours between the time of observation and the time to which the line is advanced. This method is illustrated in figure 1708a. The distance *AB* is equal to the distance between the 0800 and 1152 DR positions. The direction *BC* is the estimated set of the current, and the length *BC* is the distance through which the current is assumed to act.

A third method provides accurate results even when a reliable estimate of the current is not available, provided (1) a good fix was obtained several hours before the time of observation, and (2) the average current between the time of the previous fix and the time of observation can be assumed to continue until the time to which the

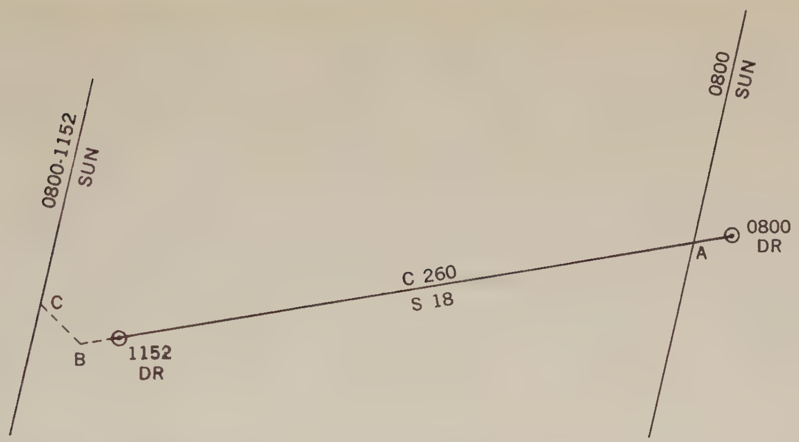

FIGURE 1708a.—Advancing a line of position with allowance for current, without determining course and speed made good.

line is to be advanced. This method is illustrated in figure 1708b. The 0510 fix is shown at the left, and the DR positions at 0830 and 1215, the ship being on course 074°, speed 12 knots. The sun is observed at 0830 and again at 1215, and it is desired to advance the earlier line to obtain a running fix at 1215. The lines of position at 0830 and 1215 are plotted. To advance the 0830 line of position, the distance *AB* is assumed to increase uniformly with time interval from 0510. The interval to 0830 is 3^h20^m, and that to 1215 is 7^h05^m. Therefore, $A'B'=AB\times\frac{7^h05^m}{3^h20^m}=AB\times 2.1$. The advanced line of position is drawn through B', parallel to the original line through B. The running fix is at the intersection of the 1215 line and the advanced 0830 line.

The set of the average current *between 0510 and 0830* is the direction from A' to the 1215 running fix, and the drift is equal to this distance divided by 7^h05^m. The direction of a straight line (not shown) from the 0510 fix to the 1215 running fix is

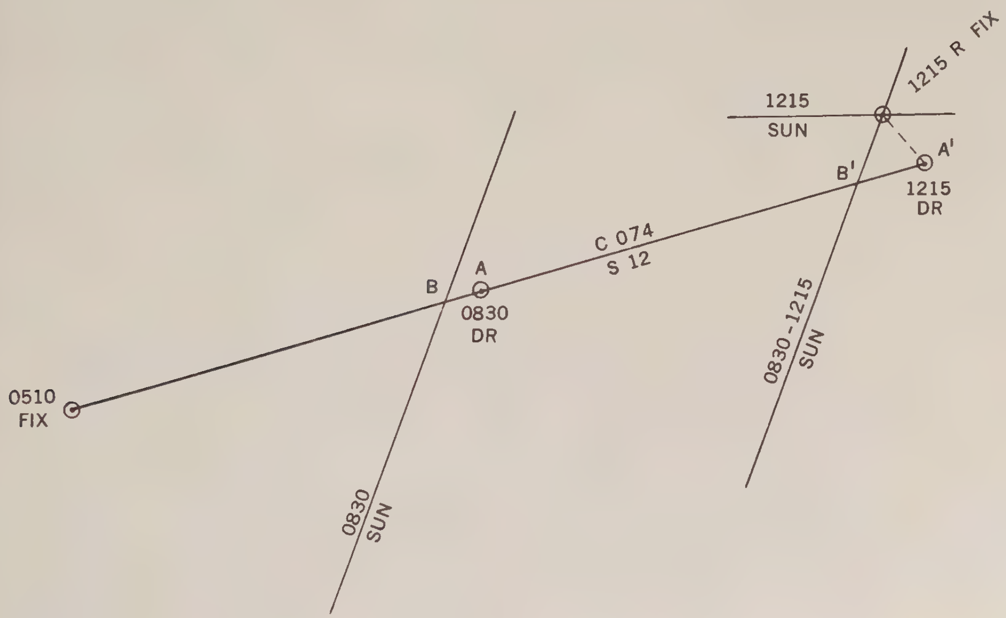

FIGURE 1708b.—Advancing a line of position without previous knowledge of the current.

the course made good between 0510 and 0830, and the length of this line divided by the time (7^h05^m) is the speed made good to 0830.

The points B and B' need not be at the intersection of the lines of position and the course line. *Any* point on the line of position can be used, and the line $A'B'$ drawn parallel to AB. Changes of course and speed do not affect the accuracy of the solution as long as $A'B'$ is parallel to AB.

Several other variations are possible. A convenient one is to measure the distance from the earlier fix to point B, and divide this by the time to determine an "assumed" speed (based upon the assumption that point B represents the position of the vessel at the time of observation), and then to use this speed to advance the line of position. This variation should not be used without adjustment if a change of course or speed is involved between the earlier fix and the time to which the line is to be advanced.

This method should be used with caution. Any error in either the earlier fix or the first line of position is *increased* in proportion to the elapsed time. Thus, in figure 1708b, if AB is in error by one mile, $A'B'$ is in error by 2.1 miles. It should not be used when there is reason to suspect a change in current between fixes.

1709. Celestial navigation and dead reckoning.—As indicated in chapter VIII, dead reckoning consists of advancing a known position for courses and speeds. Some difference in technique arises from a difference of opinion among navigators on the definition of (1) "known position" and (2) courses and speeds.

Regarding the first, no position determined by celestial navigation as commonly practiced at sea is known with perfect accuracy. An average error of two miles is realistic. Because of the varying conditions encountered, it is difficult to establish limits of a "known" position. In general, however, a reasonably reliable fix or running fix is considered sufficiently accurate to justify a new start in the dead reckoning. An estimated position or a fix or running fix of doubtful accuracy is considered an indication, but an inconclusive one, of the error in the dead reckoning. Therefore, it is considered good practice to avoid starting a new dead reckoning track from such a position unless there is a compelling reason for doing so. After long experience and the development of sound judgment, a navigator might acquire great skill in establishing a most probable position of sufficient reliability to justify more frequent breaks in the continuity of the dead reckoning, but even under these conditions any reasonable element of doubt should be given great respect.

What has been said regarding "known position" applies, also, in large measure to course and speed. The course steered and the speed at which a ship is being driven forward by its engines can be determined with relatively little error. Allowance for wind and current is a matter largely of judgment based upon experience. If the dead reckoning is to be meaningful, considerable caution should be exercised in allowing for wind and current when determining the course and speed to use for plotting. In the absence of information of a high degree of reliability, it is considered prudent to determine dead reckoning without allowing for estimated effects of wind and current.

In the absence of better information, then, it is considered good practice to start a new dead reckoning track only from a reliable fix or running fix, and to use courses and speeds without allowance for wind and current. This does not mean, however, that the navigator should not continually be aware of the possibility of error in his position as determined by dead reckoning, nor should he fail to make an estimate of the size and direction of the error. In this ability, and that of accurately interpreting all navigational information received, lies the test of a good navigator. This is largely the *art* of navigation, as distinguished from the somewhat mechanical process of making

observations and computing and plotting the results, and also from the *science* of devising the aids that are used in modern navigation.

When it is desired to determine "average current," this expression being used to mean the resultant of all dead reckoning errors, the dead reckoning should be run forward from a fix (not a running fix) to the time of the next fix (or running fix if the method of art. 1708 is used). A dead reckoning position determined in any other way is not usable, unless it is adjusted to provide a "no-current" position. A straight line connecting such a dead reckoning position and the fix at the same time indicates the current. The direction of the line *from* the DR position *to* the fix is the **set** of the current, and the length of this line divided by the number of hours since the last fix is the **drift,** as in piloting.

Problems

A plotting sheet such as H.O. 3000–9Z (or 3000–5), covering latitudes 27° to 30° north and south is needed for most of the problems of this chapter. If this is not available, one can be constructed by means of table 5, as explained in article 307; or small area plotting sheets can be constructed as explained in article 324.

1703a. In each of the following, determine the altitude difference, *a*, and label it T or A, as appropriate:

	Hc	*Ho*
(1)	18°21′.4	18°25′.9
(2)	53°02′.7	52°35′.5
(3)	(−)0°05′.2	(−)0°12′.7
(4)	(−)0°11′.1	0°01′.1

Answers.—(1) *a* 4.5 T, (2) *a* 27.2 A, (3) *a* 7.5 A, (4) *a* 12.2 T.

1703b. The 0930 DR position of a ship is lat. 29°20′.4 N, long. 130°25′.2 W. At this time the navigator observes the sun, and computes Hc and Zn for the 0930 DR position, as follows: Hc 45°42′.9, Ho 45°50′.2, Zn 157°.3. As a check, he also solves the same sight for an assumed position of lat. 29°00′.0 N, long. 130°30′.0 W, with the following results: Hc 46°00′.0, Zn 157°.0.

Required.—Plot the two lines of position, and account for the result.

Answer.—The two lines of position plot as approximately the same line, which is not dependent upon the assumed position, but only upon the observed altitude and the time of observation.

1705a. The 0500 fix of a ship is lat. 27°10′.0 N, long. 142°55′.5 W. The ship is on course 068°, speed 9 knots. At 0800 the navigator observes the sun, with the following results:

a 6.6 T	*a*L 27°00′.0 N
Zn 105°.0	*a*λ 142°39′.1 W

The current since the morning fix is estimated to set 130°, at a drift of 1.4 knots.

Required.—(1) The 0800 DR position.

(2) The 0800 EP if there were no observation, and no current was anticipated.

(3) The 0800 EP using the current, if there were no observation.

(4) The 0800 EP using the line of position, but not the current.

(5) The 0800 EP using all available information.

Answers.—(1) 0800 DR: L 27°20′.0 N, λ 142°27′.2 W; (2) 0800 EP without current and line of position: L 27°20′.0 N, λ 142°27′.2 W; (3) 0800 EP with current but no line of position: L 27°17′.4 N, λ 142°23′.5 W; (4) 0800 EP with line of position but no current: L 27°19′.5 N, λ 142°25′.3 W; (5) 0800 EP with current and line of position: L 27°18′.7 N, λ 142°25′.8 W.

1705b. The 0530 fix of a ship is lat. 28°55′.8 N, long. 161°51′.7 E. The ship is on course 060°, speed 10 knots. At 0830 the navigator observes the sun, with the following results:

a	6.7 A	*a*L	29°00′.0 N
Zn	110°.0	*a*λ	162°28′.9 E

Required.—(1) The 0830 EP if the course is believed to have been made good, and the line of position is considered accurate.

(2) The 0830 EP if the speed is believed to be correct, and the line of position is considered accurate.

(3) The 0830 EP if the course and speed are considered of equal reliability, and the line of position is considered accurate.

(4) The 0830 EP if the course is of questionable accuracy, but considered more reliable than the speed, and the line of position is considered accurate.

(5) The 0830 EP if the speed is of questionable accuracy, but considered more reliable than the course, and the line of position is considered accurate.

(6) The 0830 EP if the course is believed to have been made good, and the error contributed by the uncertainty of the line of position is believed to be twice that contributed by the uncertainty of the speed.

Answers.—(1) 0830 EP: L 29°13′.5 N, λ 162°26′.3 E; (2) 0830 EP: L 29°06′.5 N, λ 162°23′.6 E; (3) 0830 EP: L 29°09′.8 N, λ 162°25′.0 E; (4) 0830 EP: any place between (1) and (3); (5) 0830 EP: any place between (2) and (3); (6) 0830 EP: L 29°11′.4 N, λ 162°22′.8 E.

1707a. At 1740 the navigator and two assistants observe simultaneously three stars, with the following results:

	Fomalhaut	*Deneb*	*Aldebaran*
Hc	28°10′.3	34°59′.6	39°52′.8
Ho	28°05′.3	35°05′.6	39°46′.8
Zn	210°.0	308°.7	089°.3
*a*L	28°00′.0 N	28°00′.0 N	28°00′.0 N
*a*λ	42°31′.7 W	42°29′.0 W	42°23′.2 W

Required.—The 1740 fix.

Answer.—1740 fix: L 28°06′.6 N, λ 42°30′.5 W.

1707b. The 1800 DR position of a ship is lat. 27°02′.2 N, long. 170°17′.0 W. The ship is on course 045°, speed 14 knots. During evening twilight the navigator observes three stars, with the following results:

	Dubhe	*Altair*	*Spica*
Time	1815	1821	1830
Hc	34°45′.2	22°11′.8	47°24′.8
Ho	34°51′.3	22°15′.7	47°20′.4
Zn	331°.5	090°.3	219°.9
*a*L	27°00′.0 N	27°00′.0 N	27°00′.0 N
*a*λ	170°10′.2 W	170°05′.0 W	169°54′.8 W

Required.—The 1830 fix.

Answer.—1830 fix: L 27°11′.5 N, λ 170°00′.5 W.

1707c. The 1930 DR position of a ship is lat. 29°10′.5 S, long. 122°35′.4 W. The ship is on course 320°, speed 16 knots. During evening twilight the navigator observes a planet and two stars, with the following results:

	Saturn	*Regulus*	*Rigil Kent.*
Time	1931	1942	1951
Hc	46°58′.5	53°04′.0	24°19′.5
Ho	46°55′.5	53°09′.3	24°30′.0
Zn	023°.5	170°.2	297°.6
*a*L	29°00′.0 S	29°00′.0 S	29°00′.0 S
*a*λ	122°55′.0 W	122°45′.1 W	122°35′.2 W

Required.—The 1942 fix.

Answer.—1942 fix: L 29°05′.3 S, λ 122°47′.4 W.

1707d. The 0500 DR position of a ship is lat. 29°53′.9 N, long. 69°32′.1 W. The ship is on course 130°, speed 13 knots. During morning twilight the navigator observes a planet and two stars, with the following results:

	Mars	*Kochab*	*Spica*
Time	0451	0502	0511
Hc	17°14′.1	38°26′.2	33°35′.2
Ho	17°24′.5	38°19′.2	33°47′.8
Zn	130°.1	353°.2	237°.9
*a*L	30°00′.0 N	30°00′.0 N	30°00′.0 N
*a*λ	69°41′.7 W	69°30′.0 W	69°18′.3 W

Required.—The 0500 fix.

Answer.—0500 fix: L 29°54′.0 N, λ 69°30′.5 W.

1707e. The 0930 DR position of a ship is lat. 28°40′.4 N, long. 125°30′.4 E. The ship is on course 220°, speed 25 knots. The navigator observes the sun and moon, and solves each sight from the DR position at the time of sight, with the following results:

	Sun	*Moon*
Time	0936	0943
Hc	54°24′.3	37°07′.9
Ho	54°26′.3	37°14′.7
Zn	200°.2	142°.6

Required.—The 0943 fix.

Answer.—0943 fix: L 28°32′.1 N, λ 125°32′.3 E.

1707f. A ship is on course 314°, speed 24 knots. During evening twilight the navigator observes two stars and the moon, and solves all three sights using assumed latitude 28°00′.0 S, assumed longitude 41°19′.5 W as the AP, with the following results:

	Peacock	*Moon*	*Alpheratz*
Time	1855	1900	1905
Hc	57°12′.6	66°58′.2	23°00′.5
Ho	57°17′.9	67°01′.2	22°53′.7
Zn	194°.7	300°.5	038°.2

Required.—The 1900 fix.

Answer.—1900 fix: L 28°03′.5 S, λ 41°26′.5 W.

1707g. The 0400 DR position of a ship is lat. 27°01′.8 N, long. 51°36′.0 E. The ship is on course 037°, speed 20 knots. At 0545 the course is changed to 309°. During morning twilight the navigator observes two stars, with the following results:

	Vega	*Alpheratz*
Time	0537	0602
a	4.5 T	7.8 T
Zn	300°.5	075°.7
*a*L	27°00′.0 N	27°00′.0 N
*a*λ	51°45′.2 E	51°50′.1 E

Required.—The 0602 fix.

Answer.—0602 fix: L 27°28′.1 N, λ 51°51′.1 E.

1707h. The 0600 DR position of a ship is lat. 27°50′.3 N, long. 20°58′.2 W. The ship is on course 000°, speed 20 knots. During morning twilight the navigator observes four stars, with the following results:

	Dubhe	*Kaus Aust.*	*Spica*	*Vega*
Time	0551	0554	0558	0604
Hc	29°01′.1	21°57′.8	37°59′.4	54°33′.1
Ho	28°53′.4	22°11′.7	38°03′.5	54°28′.5
Zn	330°.0	149°.7	233°.3	057°.3
*a*L	28°00′.0 N	28°00′.0 N	28°00′.0 N	28°00′.0 N
*a*λ	20°54′.6 W	21°08′.4 W	20°56′.7 W	20°51′.3 W

Required.—The 0600 fix.

Answer.—0600 fix: L 27°53′.5 N, λ 20°55′.0 W.

1707i. The 1815 DR position of a ship is lat. 29°41′.5 S, long. 163°52′.3 W. The ship is on course 295°, speed 18 knots. During evening twilight the navigator observes three stars, with the following results:

	Regulus	*Pollux*	*Aldebaran*
Time	1810	1815	1821
Hc	45°18′.6	35°50′.7	22°50′.8
Ho	45°26′.2	36°03′.4	22°57′.7
Zn	040°.2	350°.7	300°.5
*a*L	30°00′.0 S	30°00′.0 S	30°00′.0 S
*a*λ	163°45′.0 W	163°49′.8 W	163°54′.0 W

Required.—(1) The 1815 fix, assuming random errors.

(2) The 1815 fix, assuming a constant error.

Answers.—(1) 1815 fix: L 29°47′.2 S, λ 163°51′.2 W; (2) 1815 fix: L 29°51′.4 S, λ 163°50′.6 W.

1708a. The 0830 DR position of a ship is lat. 29°25′.4 S, long. 9°34′.7 E. The ship is on course 326°, speed 22 knots. The sun is observed during the morning, and again at 1200, with the following results:

	Sun	*Sun*
Time	0830	1200
a	15.2 A	28.4 A
Zn	062°.3	169°.5
*a*L	29°00′.0 S	29°00′.0 S
*a*λ	9°37′.0 E	8°52′.1 E

Required.—The 1200 running fix.

Answer.—1200 R fix: L 28°31′.6 S, λ 8°50′.0 E.

1708b. The 0900 DR position of a ship is lat. 28°05′.6 N, long. 93°44′.0 W. The ship is on course 220°, speed 20 knots, and is believed to be in a current with set of 110° and a drift of 1.5 knots. The sun is observed during the morning, and again at 1200, with the following results:

	Sun	*Sun*
Time	0900	1200
a	11.2 T	17.0 A
Zn	103°.2	172°.0
*a*L	28°00′.0 N	27°00′.0 N
*a*λ	93°54′.0 W	94°38′.9 W

Required.—The 1200 running fix.

Answer.—1200 R fix: L 27°19′.8 N, λ 94°17′.5 W.

1708c. The 0715 fix of a ship is lat. 28°28′.9 S, long. 81°14′.8 W. The ship is on course 120°, speed 15 knots. During the morning the sun is observed twice, with the following results:

	Sun	*Sun*
Time	0945	1200
a	9.4 A	0
Zn	095°.0	005°.0
*a*L	29°00′.0 S	29°00′.0 S
*a*λ	80°26′.1 W	80°11′.2 W

Required.—(1) The 1200 running fix, allowing for current.

(2) Set and drift of the current.

(3) Course made good between 0715 and 0945.

Answers.—(1) 1200 R fix: L 29°01′.0 S, λ 80°00′.2 W; (2) set 049°, drift 1.1 kn.; (3) course made good 116°.0.

1708d. The 0500 fix of a ship is lat. 28°36′.5 N, long. 143°22′.0 E. The courses and speeds during the morning are as follows:

Time	*Course*	*Speed*
0500	047°	24 kn.
0600	102°	20 kn.
0715	038°	16 kn.
0845	075°	19 kn.
1000	030°	23 kn.
1045	085°	25 kn.

During the morning the sun is observed twice, with the following results:

	Sun	*Sun*
Time	0915	1200
a	8.8 A	20.0 A
Zn	125°.0	191°.7
*a*L	29°00′.0 N	29°00′.0 N
*a*λ	144°44′.8 E	145°29′.8 E

Required.—(1) The 1200 running fix, allowing for current.

(2) Set and drift of the current.

(3) Course and speed made good between fixes, assuming no change in current.

Answers.—(1) 1200 R fix: L 29°20′.0 N, λ 145°33′.0 E; (2) set 200°, drift 1.7 kn.; (3) course made good 070°, speed made good 17.7 kn.

1709a. The 0400 DR position of a ship is lat. 27°41′.8 S, long. 64°54′.0 E. This position has been run forward from a fix at 1715 the previous evening. The ship is on course 215°, speed 19 knots, but at 0600 the course is changed to 125°. At 0715 a fix locates the ship at lat. 28°23′.0 S, long. 65°04′.3 E.

Required.—Set and drift of the current between fixes.

Answers.—Set 073°, drift 1.0 kn.

1709b. The 0500 fix of a ship is lat. 27°09′.0 N, long. 158°09′.5 W. The ship is on course 310°, speed 14 knots. At 1155 a running fix locates the ship at lat. 28°01′.2 N, long. 159°33′.2 W. A new dead reckoning plot is started from this position. At 1900 a star fix is obtained, locating the ship at lat. 28°57′.8 N, long. 160°54′.9 W.

Required.—Set and drift of the average current between morning and evening fixes.

Answers.—Set 167°, drift 1.2 kn.

CHAPTER XVIII

THE ALMANAC

1801. Introduction.—A requirement of celestial navigation is the availability of accurate predictions of the positions of the celestial bodies used. These predictions, with respect to the celestial equator system of coordinates (art. 1426), are contained in three publications of the United States Naval Observatory. Recent minor modifications to these publications have not been incorporated in this printing. The solution for a celestial line of position consists principally of the conversion of tabulated coordinates to those on the horizon system of coordinates (art. 1428).

The ***American Ephemeris and Nautical Almanac*** gives, to a high precision, detailed information on a large number of celestial bodies. This annual publication is arranged to suit the convenience of the astronomer, for whom it is primarily intended. The ephemeris is not needed for ordinary purposes of navigation, although it contains some information of general interest, such as various astronomical constants, details of eclipses, information on planetary configurations (art. 1422), and miscellaneous phenomena. Each volume of the ephemeris contains instructions for its use.

The ***American Nautical Almanac,*** an annual publication, contains the astronomical information needed by the marine navigator. It is conveniently arranged to suit his needs, and the information is tabulated to a practical degree of precision (art. O3), in general to the nearest 0'.1 of arc and 1^s of time, at hourly intervals. Beginning with the edition for 1958, this volume is a joint publication of the U. S. Naval Observatory and the British Admiralty, and incorporates a number of changes from previous editions. Extracts from the *Nautical Almanac* for that year are given in appendix V. These extracts, illustrating the various features of that publication, can be used in the solution of the various illustrative and sample problems of the present volume.

The ***Air Almanac,*** published three times per year, is intended primarily for air navigators. In general, the information is similar to that of the *Nautical Almanac*, but is given to a precision of 1′ of arc and 1^s of time, at intervals of 10^m (recent editions give values for the sun and Aries to a precision of 0'.1). This publication is suitable for ordinary navigation at sea, but may lack the precision that is sometimes needed. The *Air Almanac* is a joint publication of the U.S. Naval Observatory and the British Air Council. Extracts from the *Air Almanac* are given in appendix W.

A highly abbreviated, long-term almanac is given in appendix X. Because of the large intervals between entries, and the fact that no provision is made for nutation, information taken from this almanac may be of reduced accuracy. Although this accuracy is sufficient for most purposes of navigation, the almanac is not as convenient to use as either of those published by the U. S. Naval Observatory, and is not recommended when one of them is available. Instructions for its use are included in appendix X.

1802. *American Nautical Almanac.*—The major portion of the *Nautical Almanac* is devoted to hourly tabulation of Greenwich hour angle and declination, to the nearest 0'.1 of arc. On each set of facing pages, information is given for three consecutive days. On the left-hand page, successive columns give GHA of Aries and both GHA and declination of Venus, Mars, Jupiter, and Saturn, followed by the SHA and declination of 57 stars. The GHA and declination of the sun and moon, and the horizontal parallax of the moon, are given on the right-hand page. Where applicable, the quantities v and d are given to assist in interpolation. The quantity v is the differ-

ence between the actual change of GHA in one hour and a constant value used in the interpolation tables, while *d* is the change in declination in one hour. Both *v* and *d* are given to the nearest 0ʹ.1. To the right of the moon data is given the LMT (art. 1911) of sunrise, sunset, and beginning and ending of nautical and civil twilight for various latitudes from 72° N to 60° S. The LMT of moonrise and moonset at the same latitudes is given for each of the three days for which other information is given, and for the following day. Magnitude (art. 1405) of each planet at GMT 1200 of the middle day is given at the top of the column. The GMT (art. 1907) of transit across the celestial meridian of Greenwich is given as "Mer. Pass." The value for the first point of Aries for the middle of the three days is given to the nearest $0^m.1$ at the bottom of the Aries column. The time of transit of the planets for the middle day is given to the nearest whole minute, with SHA (at GMT 0000 of the middle day) to the nearest 0ʹ.1, below the list of stars. For the sun and moon, the time of transit to the nearest whole minute is given for each day. For the moon, both upper and lower transits are given. This information is tabulated below the rising, setting, and twilight information. Given there, also, are the equation of time for 0^h and 12^h, and the age and phase of the moon (art. 1423). Equation of time is given, without sign, to the nearest whole second. Age is given to the nearest whole day. Phase is given by symbol.

The main tabulation is preceded by a list of religious and civil holidays, phases of the moon, a calendar, information on eclipses occurring during the year, and notes and a diagram giving information on the planets.

The main tabulation is followed by explanation and examples. Next are four pages of standard times (zone descriptions) in use in various places in the world. Star charts are given next, followed by a list of 173 stars in order of increasing sidereal hour angle. This list includes the stars given on the daily pages. It gives the SHA and declination each month, and the magnitude. Stars are listed by Bayer's name and also by popular name where there is one. Following the star list are three pages of Polaris tables giving the azimuth and the corrections to be applied to the observed altitude to find the latitude. Next is a table for converting arc to time units. This is followed by a 30-page table called "Increments and Corrections," used for interpolation of Greenwich hour angle and declination. This table is printed on tinted paper, for quick location. Then come tables for interpolating for times of rising, setting, and twilight; followed by two indices of the 57 stars listed on the daily pages, one index being in alphabetical order, and the other in order of decreasing SHA.

Sextant altitude corrections are given at the front and back of the almanac. Tables for the sun, stars, and planets, and a dip table, are given on the inside front cover and facing page, with an additional correction for nonstandard temperature and atmospheric pressure on the following page. Tables for the moon, and an abbreviated dip table, are given on the inside back cover and facing page. Use of the altitude correction tables is explained in chapter XVI. Corrections for the sun, stars, and planets for altitudes greater than 10°, and the dip table, are repeated on one side of a loose bookmark. The star indices are repeated on the other side.

1803. *Air Almanac.*—As in the *Nautical Almanac,* the major portion of the *Air Almanac* is devoted to a tabulation of GHA and declination. However, in the *Air Almanac* values are given at intervals of ten minutes, to a precision of 1ʹ. Values are given for the sun, first point of Aries (GHA only), the three navigational planets most favorably located for observation, and the moon. The magnitude of each planet listed is given at the top of its column, and the phase of the moon is given at the top of its column. Values for the first 12 hours of the day are given on the right-hand page, and those for the second half of the day on the back. In addition, the right-hand page has a table of the moon's parallax in altitude, and below this the semidiameter of the sun,

and both the semidiameter and age of the moon (art. 1423). To the right of this is an ecliptic diagram, explained in article 2209. The afternoon side of each daily page includes the LMT of sunrise, sunset, moonrise, and moonset; duration of civil twilight; and a difference column for finding the time of moonrise and moonset at any longitude.

Critical tables for interpolation for GHA are given on the inside front cover, which also has an alphabetical listing of the stars, with the number, magnitude, SHA, and declination of each. The inside of the back cover has the same refraction table and Coriolis correction table given in H.O. Pub. No. 249. The outside back cover has a correction table for dip of the horizon, and a table of contents.

Following the daily pages are instructions for use of the almanac; a list of symbols and abbreviations in English, French, and Spanish; a list of time differences between Greenwich and various other places; a number of sky diagrams (art. 2212); information on setting the astrograph (art. 2123); polar sunlight, twilight, and moonlight diagrams; corrections to times of sunrise and sunset when observed from flight altitudes; a table for converting arc to time; interpolation tables for finding time of moonrise and moonset at any longitude; a star list similar to that given on the inside front cover, but in order of decreasing SHA; a list of the names and numbers of the stars used in H.O. Pub. No. 249, those in H.O. Pub. No. 218, and those which can be used by declination entry in H.O. Pub. No. 249, in addition to those listed by name; and an explanation of the navigational star chart, and the chart itself. The inside front cover page is repeated on the back of the star chart. Also given there are a single Polaris correction table, a standard aircraft astrodome refraction table, and a special refraction table for use with H.O. Pub. No. 218.

Minor modifications and changes to some of the foregoing items have been made in recent editions of the *Air Almanac*.

1804. Use of the almanacs.—The time used as an entering argument in the almanacs is GMT, and the information given is for the Greenwich meridian.

Tabulated information taken from the almanacs, as from any tables, should not be recorded to a greater precision than tabulated. The *units* in which values are given are shown at the tops of the columns.

The use of work forms, such as those shown in appendix Q, permits concentration on the extraction of data, with no need for dividing one's attention between this and thought regarding the order of work. It also simplifies the taking of all needed information from the double page to which the almanac is open, before turning to a different part of the almanac.

If the entering arguments are exactly those of any table, the desired value is taken directly from the table. Often, however, this is not the case, and the detailed instructions in the following articles relate principally to the method of interpolating in the various tables. Since Greenwich hour angle is measured in a westerly direction, the same direction as the apparent motion of celestial bodies, the tables are customarily entered with the next earlier tabulated time, with interpolation toward a later time. The correction to be applied for a fractional part of an hour is then always additive. If the sum exceeds 360°, this amount is subtracted.

In the *Nautical Almanac*, v is always positive unless a negative sign ($-$) is given. This can occur only in the case of Venus. For the sun, the tabulated values of GHA have been adjusted slightly to minimize the error of interpolation, so that no v value need be given. No sign is given for tabulated values of d, which can be considered positive if declination is increasing, and negative if it is decreasing. The sign of a v or d value is given also to the related correction.

In the *Air Almanac* the tabulated declination values are those for the *middle* of the interval between the time indicated and the next *following* time for which a value

is given. It is intended that declination be taken from the tables without interpolation.

1805. Finding GHA and declination of the sun.—*Nautical Almanac.* Enter the daily-page table with the whole hour next preceding the given GMT, unless this time is itself a whole hour, and take out the tabulated GHA and declination. Record, also, the *d* value given at the bottom of the declination column. Next, enter the increments and corrections table for the number of minutes of GMT. If there are seconds, use the next *earlier* whole minute. On the line corresponding to the seconds of GMT take the value from the sun-planets column. Add this to the value of GHA from the daily page to find GHA at the given time. Next, enter the correction table for the same minute with the *d* value, and take out the correction. Give this the sign of the *d* value, and apply it to the declination from the daily page. The result is the declination at the given time.

Example 1.—Find the GHA and declination of the sun at GMT $18^h24^m37^s$ on June 1, 1958, using the *Nautical Almanac.*

Solution.—

	Sun			Sun
GMT	$18^h24^m37^s$ June 1		GMT	$18^h24^m37^s$ June 1
18^h	90°34.′6		18^h	22°03.′4 N *d*
24^m37^s	6°09.′3		corr.	(+)0.′1 (+)0.′3
GHA	96°43.′9		d	22°03.′5 N

The correction table for GHA of the sun is based upon a rate of change of 15° per hour, the average rate during a year. At most times the rate differs slightly from this. The slight error thus introduced is minimized by the method of tabulation. The tabulated values are adjusted for *half* the error during the hour following the time of tabulation. Therefore, instead of increasing for an hour following the entry time, the error *decreases* for the first half hour, to zero, and then increases during the second half hour, and the maximum error is only about *half* what it would be if unadjusted values were used. The greatest error thus introduced is about 0.′1. An additional small error may be introduced by rounding off base and correction values to the nearest 0.′1. More exact values can be obtained by interpolating between the values for the half hours, or by referring to the ephemeris.

The *d* value is the amount that the declination changes between 1200 and 1300 on the middle day of the three shown.

Air Almanac. Enter the daily page with the whole 10^m next preceding the given GMT, unless this time is itself a whole 10^m, and extract the tabulated GHA and declination, without interpolation. The tabulated declination is correct for the time 30^m later than that tabulated, so that interpolation during the hour following tabulation is not needed for most purposes. Next, enter the "interpolation of GHA" table on the inside front cover, using the "sun, etc." entry column, and take out the value for the remaining minutes and seconds of GMT. If the entry time is an exact tabulated value, use the correction given half a line *above* the entry time. Add this correction to the GHA taken from the daily page to find the GHA at the given time. No adjustment of declination is needed.

Example 2.—Find the GHA and declination of the sun at GMT $18^h24^m37^s$ on June 1, 1958, using the *Air Almanac.*

Solution.—

	Sun
GMT	$18^h24^m37^s$ June 1
18^h20^m	95°35′
4^m37^s	1°09′
GHA	96°44′
d	22°04′ N

1806. Finding GHA and declination of the moon.—*Nautical Almanac.* Enter the daily-page table with the whole hour next preceding the given GMT, unless this time is itself a whole hour, and take out the tabulated GHA and declination. Record, also, the corresponding v and d values tabulated on the same line, and determine the sign of the d value. The v value of the moon is always positive (+), and is not marked in the almanac. Next, enter the increments and corrections table for the minutes of GMT, and on the line for the seconds of GMT take the GHA correction from the moon column. Then, enter the correction table for the same minute with the v value, and extract the correction. Add both of these corrections to the GHA from the daily page to obtain the GHA at the given time. Then, enter the same correction table with the d value, and extract the correction. Give this correction the sign of the d value, and apply it to the declination from the daily page to find the declination at the given time.

Example 1.—Find the GHA and declination of the moon at GMT $21^h25^m44^s$ on June 1, 1958, using the *Nautical Almanac.*

Solution.—

	Moon	
GMT	$21^h25^m44^s$ June 1	
21^h	315°01′.6	
25^m44^s	6°08′.4	v
corr.	2′.4	(+) 5′.6
GHA	321°12′.4	

	Moon	
GMT	$21^h25^m44^s$ June 1	
21^h	18°46′.3S	d
corr.	(+) 1′.0	(+) 2′.4
d	18°47′.3S	

The correction table for GHA of the moon is based upon the *minimum* rate at which the moon's GHA increases, 14°19′.0 per hour. The v correction makes the adjustment for the actual rate. The v value itself is the difference between the minimum rate and the actual rate during the hour following the tabulated time. The d value is the amount that the declination changes during the hour following the tabulated time.

Air Almanac. Enter the daily page with the whole 10^m next preceding the given GMT, unless this time is itself a whole 10^m, and take out the tabulated GHA and the declination, without interpolation. Next, enter the "interpolation of GHA" table on the inside front cover, using the "moon" entry column, and take out the value for the remaining minutes and seconds of GMT. If the entry time is an exact tabulated value, use the correction given half a line *above* the entry time. Add this correction to the GHA taken from the daily page to find the GHA at the given time. No adjustment of declination is needed.

Example 2.—Find the GHA and declination of the moon at GMT $21^h25^m44^s$ on June 1, 1958, using the *Air Almanac.*

Solution.—

	Moon
GMT	$21^h25^m44^s$ June 1
21^h20^m	319°49′
5^m44^s	1°23′
GHA	321°12′
d	18°47′S

The declination given in the table is correct for the time *five minutes later than tabulated,* so that it can be used for the ten-minute interval without interpolation, to an accuracy to meet most requirements. If greater accuracy is needed, it can be obtained by interpolation, remembering to allow for the five minutes indicated above.

1807. Finding GHA and declination of a planet.—*Nautical Almanac.* Enter the daily-page table with the whole hour next preceding the given GMT, unless the time itself is a whole hour, and take out the tabulated GHA and declination. Record, also,

the v value given at the bottom of each of these columns. Next, enter the increments and corrections table for the minutes of GMT, and on the line for the seconds of GMT take the GHA correction from the sun-planets column. Next, enter the correction table with the v value and extract the correction, giving it the sign of the v value. Add the first correction to the GHA from the daily page, and apply the second correction in accordance with its sign, to obtain the GHA at the given time. Then, enter the correction table for the same minute with the d value, and extract the correction. Give this correction the sign of the d value, and apply it to the declination from the daily page to find the declination at the given time.

Example 1.—Find the GHA and declination of Venus at GMT $5^h24^m07^s$ on June 2, 1958, using the *Nautical Almanac*.

Solution.—

	Venus	
GMT	$5^h24^m07^s$ June 2	
5^h	295°21′.8	
24^m07^s	6°01′.8	v
corr.	(−) 0′.1	(−) 0′.3
GHA	301°23′.5	

	Venus	
GMT	$5^h24^m07^s$ June 2	
5^h	9°53′.7 N	d
corr.	(+) 0′.4	(+) 1′.0
d	9°54′.1 N	

The correction table for GHA of planets is based upon the mean rate of the sun, 15° per hour. The v value is the difference between 15° and the change of GHA of the planet between 1200 and 1300 on the middle day of the three shown. The d value is the amount that the declination changes between 1200 and 1300 on the middle day.

Venus is the only body listed which ever has a negative v value.

Air Almanac.—Enter the daily page with the whole 10^m next preceding the given GMT, unless this time is itself a whole 10^m, and extract the tabulated GHA and declination, without interpolation. The tabulated declination is correct for the time 30^m later than tabulated, so that interpolation during the hour following tabulation is not needed for most purposes. Next, enter the "interpolation of GHA" table on the inside front cover, using the "sun, etc." column, and take out the value for the remaining minutes and seconds of GMT. If the entry time is an exact tabulated value, use the correction half a line *above* the entry time. Add this correction to the GHA from the daily page to find the GHA at the given time. No adjustment of declination is needed.

Example 2.—Find the GHA and declination of Venus at GMT $5^h48^m45^s$ on June 2, 1958, using the *Air Almanac*.

Solution.—

	Venus
GMT	$5^h48^m45^s$ June 2
5^h40^m	305°22′
8^m45^s	2°11′
GHA	307°33′
d	9°54′ N

The declination is taken for the next *earlier* tabulated time, and is correct for GMT 5^h45^m.

1808. Finding GHA and declination of a star.—If the GHA and declination of each navigational star were tabulated separately, the almanacs would be several times their present size. But since the sidereal hour angle (art. 1426) and declination are nearly constant over several days (to the nearest 0′.1) or months (to the nearest 1′), separate tabulations are not needed. Instead, the GHA of the first point of Aries, from which SHA is measured, is tabulated on the daily pages, and a single listing of SHA and declination is given for each double page of the *Nautical Almanac*, and for an

entire volume of the *Air Almanac.* The finding of GHA ♈ is similar to finding GHA of the sun, moon, and planets.

Nautical Almanac. Enter the daily-page table with the whole hour next preceding the given GMT, unless this time is itself a whole hour, and take out the tabulated GHA ♈. Record, also, the tabulated SHA and declination of the star from the listing on the left-hand daily page. Next, enter the increments and corrections table for the minutes of GMT, and on the line for the seconds of GMT take the GHA correction from the Aries column. Add this correction and the SHA of the star to the GHA ♈ of the daily page to find the GHA of the star at the given time. No adjustment of declination is needed.

Example 1.—Find the GHA and declination of Canopus at GMT $3^h24^m33^s$ on June 2, 1958, using the *Nautical Almanac.*

Solution.—

	Canopus
GMT	$3^h24^m33^s$ June 2
3^h	295°04'.8
24^m33^s	6°09'.3
SHA	264°15'.0
GHA	205°29'.1
d	52°40'.6 S

The SHA and declination of 173 stars, including Polaris and the 57 listed on the daily pages, are given for the middle of each month, on almanac pages 268–273. For a star not listed on the daily pages this is the only almanac source of this information. Interpolation in this table is not necessary for ordinary purposes of navigation, but is sometimes needed for precise results. Thus, if the SHA and declination of *β Crucis* (Mimosa) are desired for March 1, 1958, they are found by simple eye interpolation to be SHA 168°40'.2 and d 59°27'.6 S.

If GHA ♈ is desired, it is found as indicated in example 1, but omitting the addition of SHA of a star. In the example GHA ♈ is 295°04'.8+6°09'.3=301°14'.1.

Air Almanac. Enter the daily page with the whole 10^m next preceding the given GMT, unless this is itself a whole 10^m, and extract the tabulated GHA ♈. Next, enter the "interpolation of GHA" table on the inside front cover, using the "sun, etc." entry column, and take out the value for the remaining minutes and seconds of GMT. If the entry time is an exact tabulated value, use the correction given half a line *above* the entry time. From the tabulation at the left side of the same page, extract the SHA and declination of the star. Add the GHA from the daily page and the two values taken from the inside front cover to find the GHA at the given time. No adjustment of declination is needed.

Example 2.—Find the GHA and declination of Peacock at GMT $12^h17^m58^s$ on June 1, 1958, using the *Air Almanac.*

Solution.—

	Peacock
GMT	$12^h17^m58^s$ June 1
12^h10^m	71°58'
7^m58^s	2°00'
SHA	54°24'
GHA	128°22'
d	56°52' S

1809. Rising, setting, and twilight.—In both almanacs the times of sunrise, sunset, moonrise, moonset, and twilight information at various latitudes between 72° N and 60° S are given to the nearest whole minute. By definition, rising or setting occurs when the *upper* limb of the body is on the *visible* horizon, assuming standard refraction

for zero height of eye. Because of variations in refraction and height of eye, computation to a greater precision than 1^m is not justified. For high elevations, as those encountered on a mountain overlooking the sea, or at flight altitudes, a correction table is provided in the *Air Almanac*.

In high latitudes some of the phenomena do not occur during certain periods. The symbols used to indicate this condition are:

□ Sun or moon does not set, but remains continuously above the horizon.

■ Sun or moon does not rise, but remains continuously below the horizon.

//// Twilight lasts all night.

The *Nautical Almanac* makes no provision for finding the times of rising, setting, or twilight in polar regions. The *Air Almanac* has graphs for this purpose. The use of these, and other sources of such information, are explained in article 2536.

In the *Nautical Almanac*, sunrise, sunset, and twilight tables are given only once for the three days on each page opening, using average declination and equation of time. The results approximate the values for the middle day. For most purposes this information can be used for all three days. For more accurate results, the information can be taken from the *Air Almanac*, which has a table for each day. Both almanacs have moonrise and moonset tables for each day.

The tabulations are in local mean time (art. 1911). On the zone meridian, this is the zone time (ZT). For every 15′ of longitude that the observer's position differs from that of the zone meridian, the zone time of the phenomena differs by 1^m, being *later* if the observer is *west* of the zone meridian, and *earlier* if he is *east* of the zone meridian. The local mean time of the phenomena varies with latitude of the observer, declination of the body, and hour angle of the body relative to that of the mean sun.

Sunrise and sunset are also tabulated in the tide tables (from 76° N to 60° S) and in a supplement to the American ephemeris of 1946 entitled *Tables of Sunrise, Sunset, and Twilight* (from 75° N to 75° S). The meridian angle of any body at the time of its rising and setting can be computed by the formulas given in article 2536. The meridian angle of a body when its center is on the celestial horizon can be computed by the formula

$$\cos t = \tan L \tan d,$$

where t is the meridian angle, L is the latitude, and d is the declination. Solutions of this formula are given in table 25, if the table is entered with a latitude 90° from the given latitude. This table can be used for this purpose only when latitude and declination are of contrary name.

1810. Finding time of sunrise and sunset.—*Nautical Almanac.* Enter the table on the daily page, and extract the LMT for the tabulated latitude next *smaller* than the observer's latitude (unless this is an exact tabulated value). Apply a correction from table I on almanac page xxxii to interpolate for latitude, determining the sign of the correction by inspection. Then convert LMT to ZT by means of the difference in longitude (dλ) between the local and zone meridians.

Example.—Find the zone time of sunrise and sunset at lat. 43°31.′4 N, long. 36°14.′3 W on June 1, 1958.

Solution.—

L 43°31.′4 N June 1
λ 36°14.′3 W

	Sunrise		Sunset
40°	0433	40°	1922
T I	(−) 11	T I	(+) 11
LMT	0422	LMT	1933
dλ	(+) 25	dλ	(+) 25
ZT	0447	ZT	1958

Air Almanac. The procedure is the same as that for the *Nautical Almanac*, except that correction for latitude is made by linear interpolation directly from the tabulation, since no interpolation table is provided.

The tabulated times are for the Greenwich meridian. Except in high latitudes near the times of the equinoxes, the time of sunrise and sunset varies so little from day to day that no interpolation is needed for longitude. If such an interpolation is considered justified, it can be made in the same manner as for the moon (art. 1812).

In high latitudes, interpolation is not always possible. For instance, on June 1, 1958, sunrise at latitude 66° N occurs at 0114, but at latitude 68° N the sun does not set. Between these two latitudes the time of sunrise might be found from the graphs in the *Air Almanac*, or by computation, as explained in article 2536. However, in such a marginal situation, the time of sunrise itself is uncertain, being greatly affected by a relatively small change of refraction or height of eye.

1811. Finding time of twilight.—Morning twilight *ends* at sunrise, and evening twilight *begins* at sunset. The time of the darker limit can be found from the almanacs. The *time* of the darker limits of both *civil* and *nautical* twilights (center of the sun 6° and 12°, respectively, below the celestial horizon) is given in the *Nautical Almanac*. The *duration* (in minutes) of *civil* twilight is tabulated in the *Air Almanac*. The brightness of the sky at any given depression of the sun below the horizon may vary considerably from day to day, depending upon the amount of cloudiness and other atmospheric conditions. In general, however, the most effective period for observing stars and planets occurs when the center of the sun is between about 3° and 9° below the celestial horizon. Hence, the darker limit of civil twilight occurs at about the mid point of this period. At the darker limit of nautical twilight the horizon is generally too dark for good observations. At the darker limit of *astronomical twilight* (center of the sun 18° below the celestial horizon) full night has set in. The time of this twilight is given in the ephemeris. Its approximate value can be determined by extrapolation (art. P6) in the *Nautical Almanac*, noting that the duration of the different kinds of twilight is not proportional to the number of degrees of depression at the darker limit. More precise determination of the time at which the center of the sun is any given number of degrees below the celestial horizon can be determined by a large-scale diagram on the plane of the celestial meridian (art. 1432) or by computation (art. 2536). Duration of twilight at various angles of depression between 1°3 and 12° is given on pages A52 and A53 of the *Air Almanac* (not shown in appendix W).

Nautical Almanac. The method of finding the darker limit of twilight is the same as that for sunrise and sunset (art. 1810).

Example 1.—Find the zone time of beginning of morning nautical twilight and ending of evening nautical twilight at lat. 21°54′.7 S, long. 109°34′.2 E on June 1, 1958.

Solution.—

L 21°54′.7 S June 1
λ 109°34′.2 E

	Nautical twilight		Nautical twilight
20° S	0537	20° S	1819
T I	(+)3	T I	(−)3
LMT	0540	LMT	1816
dλ	(−) 18	dλ	(−) 18
ZT	0522	ZT	1758

Air Almanac. Find the ZT of sunrise and sunset as explained in article 1810, except that correction for latitude is made by linear interpolation, since no table is provided for this purpose. While taking the LMT from the almanac, extract, also, the duration of civil twilight, in minutes. *Subtract* this value from the time of sunrise

to find the time of beginning of morning civil twilight, and *add* it to the time of sunset to find the time of ending of evening civil twilight.

Example 2.—Find the zone time of beginning of morning civil twilight and ending of evening civil twilight at lat. 47°18.′8 S, long. 87°28.′3 W on June 1, 1958.

Solution.—

L 47°18.′8 S June 1
λ 87°28.′3 W

	Sunrise			Sunset	
45° S	0727		45° S	1628	
corr.	(+) 9		corr.	(−) 9	
LMT	0736		LMT	1619	
dλ	(−) 10		dλ	(−) 10	
ZT	0726	(sunrise)	ZT	1609	(sunset)
dur.	(−) 35		dur.	(+) 35	
ZT	0651	(twilight)	ZT	1644	(twilight)

Sometimes in high latitudes the sun does not rise but twilight occurs. This is indicated in the *Air Almanac* by the symbol ■ in the sunrise and sunset column. In this case the value in the twilight column indicates *half* the duration of twilight. To find the time of beginning of morning twilight, *subtract* this interval from the time of meridian transit of the sun; and for the time of ending of evening twilight, *add* it to the time of meridian transit. The LMT of meridian transit never differs by more than $16^{m}.4$ (approximately) from 1200. The actual time on any date can be determined from the almanac (art. 2104).

1812. Finding time of moonrise and moonset is similar to finding time of sunrise and sunset, with one important difference. Because of the moon's rapid change of declination, and its fast eastward motion relative to the sun, the time of moonrise and moonset varies considerably from day to day. These changes of position on the celestial sphere (art. 1403) are continuous, as moonrise and moonset occur successively at various longitudes around the earth. Therefore, the change in time is distributed over all longitudes. For precise results, it would be necessary to compute the time of the phenomena at any given place, by the method described in article 2536. For ordinary purposes of navigation, however, it is sufficiently accurate to interpolate between consecutive moonrises or moonsets at the Greenwich meridian. Since apparent motion of the moon is westward, relative to an observer on the earth, interpolation in west longitude is between the phenomenon on the given date and the *following* one. In east longitude it is between the phenomenon on the given date and the *preceding* one.

Nautical Almanac. For the given date, enter the daily-page table with latitude, and extract the LMT for the tabulated latitude next *smaller* than the observer's latitude (unless this is an exact tabulated value). Apply a correction from table I of the almanac "Tables for Interpolating Sunrise, Moonrise, etc." to interpolate for latitude, determining the sign of the correction by inspection. Repeat this procedure for the day following the given date, if in west longitude; or for the day preceding, if in east longitude. Using the difference between these two times, and the longitude, enter table II of the almanac "Tables for Interpolating Sunrise, Sunset, etc." and take out the correction. Apply this correction to the LMT of moonrise or moonset at the Greenwich meridian on the given date to find the LMT at the position of the observer. The sign to be given the correction is such as to make the corrected time fall between the times for the two dates between which interpolation is being made. This is nearly always positive (+) in west longitude and negative (−) in east longitude. Convert the corrected LMT to ZT.

Example 1.—Find the zone time of moonrise and moonset at lat. 58°23.′6 N, long. 144°07.′5 W on June 1, 1958, using the *Nautical Almanac.*

Solution.—

L 58°23'.6 N June 1
λ 144°07'.5 W

Moonrise			Moonset		
58° N	2011	June 1	58° N	0314	June 1
T I	(+)3		T I	(−)2	
LMT (G)	2014	June 1	LMT (G)	0312	June 1
58° N	2113	June 2	58° N	0401	June 2
T I	(+)3		T I	(−)3	
LMT (G)	2116	June 2	LMT (G)	0358	June 2
LMT (G)	2014	June 1	LMT (G)	0312	June 1
diff.	62		diff.	46	
T II	(+)25		T II	(+)18	
LMT (G)	2014	June 1	LMT (G)	0312	June 1
LMT	2039	June 1	LMT	0330	June 1
dλ	(−)24		dλ	(−)24	
ZT	2015	June 1	ZT	0306	

Air Almanac. For the given date, determine LMT for the observer's latitude at the Greenwich meridian, in the same manner as with the *Nautical Almanac,* except that linear interpolation is made directly from the main tabulation, since no interpolation table is provided. Extract, also, the value from the "Diff." column to the right of the moonrise and moonset column, interpolating if necessary. This "Diff." is the difference between the time of occurrence of the phenomenon at longitude 90° E and 90° W, and is intended for use in both east and west longitudes. The error introduced by this approximation is generally not more than a few minutes, although it increases with latitude. Using this difference, and the longitude, enter the "Interpolation of Moonrise, Moonset" table on page A54 of the *Air Almanac* and take out the correction. The *Air Almanac* recommends the taking of the correction from this table without interpolation. The results thus obtained are sufficiently accurate for ordinary purposes of navigation. If greater accuracy is desired, the correction can be taken by interpolation. However, since the "Diff." itself is an approximation, the *Nautical Almanac* or computation (art. 2536) should be used if accuracy is a consideration. Apply the correction to the LMT of moonrise or moonset at the Greenwich meridian on the given date to find the LMT at the position of the observer. The correction is positive (+) for west longitude, and negative (−) for east longitude, unless the "Diff." on the daily page is preceded by a negative sign (−), when the correction is negative (−) for west longitude, and positive (+) for east longitude. If the time is near midnight, record the date at each step, as in the *Nautical Almanac* solution.

Example 2.—Find the zone time of moonrise and moonset at lat. 58°23'.6 N, long. 144°07'.5 W on June 1, 1958, using the *Air Almanac.*

Solution.—

L 58°23'.6 N June 1
λ 144°07'.5 W

Moonrise		Moonset	
diff.	(+)34	diff.	(+)21
58° N	2011	58° N	0314
corr.	(+)3	corr.	(−)3
LMT (G)	2014	LMT (G)	0311
corr.	(+)29	corr.	(+)16
LMT	2043	LMT	0327
dλ	(−)24	dλ	(−)24
ZT	2019	ZT	0303

As with the sun, there are times in high latitudes when interpolation is inaccurate or impossible. At such periods, the times of the phenomena themselves are uncertain, but an approximate answer can be obtained by moonlight graph in the *Air Almanac* or by computation, as explained in article 2536. With the moon, this condition occurs when the moon rises or sets at one latitude, but not at the next higher tabulated latitude, as with the sun. It also occurs when the moon rises or sets on one day but not on the preceding or following day. This latter condition is indicated in the *Air Almanac* by the symbol ∗ in the "Diff." column.

Because of the eastward revolution of the moon around the earth, there is one day each synodical month (art. 1412) when the moon does not rise, and one day when it does not set. These occur near last quarter and first quarter, respectively. Since this day is not the same at all latitudes or at all longitudes, the time of moonrise or moonset found from the almanac may occasionally be the preceding or succeeding one to that desired. When interpolating near midnight, one should exercise caution to prevent an error.

Refer to the right-hand daily page of the *Nautical Almanac* for June 12, 13, 14 (app. V). On June 14 moonrise occurs at 0015 at latitude 70° N, and at 2326 at latitude 72° N. These are *not* the same moonrise, the one at 2326 occurring approximately one day *later* than the one occurring at 0015. This is indicated by the two times, which differ by nearly 24 hours. The table indicates that with increasing northerly latitude, moonrise occurs *earlier.* Between 70° N and 72° N the time crosses midnight *to the preceding day.* Hence, between these latitudes interpolation should be made between 0015 on June 14 and 2344 on June 13.

The effect of the revolution of the moon around the earth is to cause the moon to rise or set *later* from day to day. The daily retardation due to this effect does not differ greatly from 50^{m}. The change in declination of the moon may increase or decrease this effect. The effect due to change of declination increases with latitude, and in extreme conditions it may be greater than the effect due to revolution of the moon. Hence, the interval between successive moonrises or moonsets is more erratic in high latitudes than in low latitudes. When the two effects act in the same direction, daily differences can be quite large. Thus, at latitude 72° N the moon sets at 1834 on June 13, and at 2029 on June 14. When they act in opposite directions, they are small, and when the effect due to change in declination is larger than that due to revolution, the moon rises *earlier* on succeeding days. Thus, at latitude 72° N the moon rises at 2344 on June 13, and at 2326 on June 14. This condition is reflected in the *Air Almanac* by a negative "Diff." If this happens near last quarter or first quarter, two moonrises or moonsets might occur on the same day, one a few minutes after the day begins, and the other a few minutes before it ends. On June 12, 1958, for instance, at latitude 72° N, the moon rises at 0003, sets at 1649, and rises again at 2354 the same day. On those days on which no moonrise or no moonset occurs, the next succeeding one is shown with 24^{h} added to the time. Thus, at latitude 70° N the moon rises at 2358 on June 2, while the next moonrise occurs $24^{h}21^{m}$ later, at 0019 on June 4. This is listed both as 2419 on June 3 and as 0019 on June 4 (not shown in app. V).

Interpolation for longitude is always made between *consecutive* moonrises or moonsets, regardless of the days on which they fall.

Example 3.—Find the zone time of moonrise at lat. 71°38′.7 N, long. 56°21′.8 W during the night of June 12–13, 1958, using the *Nautical Almanac.*

Solution.—

L 71°38′.7 N June 12–13
λ 56°21′.8 W

	Moonrise	
70° N	0014	June 13
T I	(−) 16	
LMT (G)	2358	June 12
70° N	0015	June 14
T I	(−) 25	
LMT (G)	2350	June 13
LMT (G)	2358	June 12
diff.	8	
T II	(−) 2	
LMT (G)	2358	June 12
LMT	2356	June 12
dλ	(−) 15	
ZT	2341	June 12

Interpolation for the first entry is between 0014 on June 13 (lat. 70° N) and 2354 on June 12 (lat. 72° N); for the second entry, between 0015 on June 14 and 2344 on June 13. This solution might be more easily visualized by considering the 0014 moonrise of June 13 as occurring at 2414 on June 12, and that of 0015 on June 14 as occurring at 2415 on June 13.

1813. Rising, setting, and twilight at a moving craft.—Instructions given in the preceding three articles relate to a fixed position on the earth. Aboard a moving craft the problem is complicated somewhat by the fact that time of occurrence depends upon position of the craft, and vice versa. At ship speeds, it is generally sufficiently accurate to make an approximate mental solution, and use the position of the vessel at this time to make a more accurate solution. If higher accuracy is required, the position at the time indicated in the second solution can be used for a third solution. If desired, this process can be repeated until the same answer is obtained from two consecutive solutions. However, it is generally sufficient to alter the first solution by 1^m for each 15′ of longitude that the position of the craft differs from that used in the solution, adding if west of the estimated position, and subtracting if east of it. In applying this rule, use both longitudes to the nearest 15′.

1814. Miscellaneous.—*Sextant altitude corrections* are explained in chapter XVI.

Equation of time is given below the sunset and twilight information on the right-hand daily page of the *Nautical Almanac*, at intervals of twelve hours. Simple interpolation can be used for intervening values. By convention, the sign is positive (+) if the time in the sun's "Mer. Pass." column is earlier than 1200 (or if GHA indicates the sun has crossed the upper branch of the celestial meridian before 1200 or the lower branch before 0000), and negative (−) if later than 1200. In Great Britain, this convention is reversed. A heavy line is used to indicate a change of sign between consecutive entries, as shown between 00^h and 12^h on June 14, when the sign changes from positive to negative. The equation of time is not needed for ordinary purposes of modern navigation. Its use is explained in chapter XIX.

Time of transit. The GMT of transit of the sun across the upper branch of the celestial meridian of Greenwich is tabulated in the *Nautical Almanac*, to the right of the equation of time tables. Similar information is given for both the upper and lower transits of the moon in the "Mer. Pass." tables below the moonset tables. On a day when the moon does not transit the Greenwich meridian, the time for the next

day is given with 24^h added. Thus, on May 31 the upper transit is at 2308. The next transit is at 2407 on June 1, or at 0007 on June 2, as shown in appendix V. For the four navigational planets, time of upper transit for the middle day is given below the star list on the left-hand daily page. For all of these bodies the time is given to the nearest whole minute. Time of transit of the first point of Aries across the upper branch on the middle day is given to the nearest $0^m.1$, below the GHA Aries column. The tabulated times can be considered the LMT of transit at the Greenwich meridian, since LMT at 0° longitude is GMT. The LMT of transit at the observer's meridian can then be found by interpolation for longitude, as for moonrise and moonset (art. 1812). Eye interpolation is usually sufficient for bodies other than the moon. This information is of little value to the navigator. It is further discussed in chapter XIX.

Moon phases are indicated symbolically in the *Nautical Almanac* at the lower right-hand corner of the double-page opening. In the *Air Almanac* this information is given at the top of the GHA-declination column on each daily page. An open circle is used for full moon, and a solid black circle for new moon. The time of occurrence of each phase is given below the list of holidays, near the front of the *Nautical Almanac*. The *age* of the moon (art. 1423) is given between the "Mer. Pass." and phase listings in the *Nautical Almanac* and at the bottom of the right-hand daily page of the *Air Almanac*, near the right side.

Semidiameters of the sun and moon are given at the bottom of the sun and moon columns of the *Nautical Almanac*. In the *Air Almanac* they are given immediately above the age of the moon, on the right-hand daily page.

Magnitude of each planet listed is given at the top of its column on the daily pages of each almanac.

Ecliptic diagram. The diagram at the right of each right-hand daily page of the *Air Almanac* indicates the positions of the moon, navigational planets, the first point of Aries, and certain stars, relative to the sun. This diagram is discussed in article 2209. A single *Planet Location Diagram* has been substituted in recent editions.

GHA and declination for following year. If an almanac for the preceding year is available, but not for the current year, the approximate declination of the sun can be found by entering the almanac for the previous year with a time 5^h49^m *earlier*. The GHA of the sun can also be found in this way, if 87°15′ is *added* to the result. For stars, use the declination for the preceding year, and from the GHA subtract 15′.1. Every reference to the same date of the preceding year refers to the day 365 days earlier than the given date. When a February 29 has intervened, the day one day later should be used for the preceding year.

Right ascension (art. 1426), if required, can be found by subtracting SHA from 360°, and converting it from arc to time units (art. 1904). The SHA of the stars and planets is listed on the left-hand daily page. For the sun and moon, SHA can be found by subtracting the GHA of Aries from the GHA of the body.

Conversion of arc to time, or vice versa, can be made by the "Conversion of Arc to Time" tables of the almanacs, or mathematically as explained in article 1904.

Polaris tables are explained in article 2105.

Navigational star charts. These charts are explained in article 2204.

Sky diagrams of the *Air Almanac* are explained in article 2212.

Several additional items of general interest, such as a list of religious and civil holidays, a calendar, information on eclipses, planet notes for the year, and a list of standard times (zone descriptions) at various places throughout the world, are given in the *Nautical Almanac*. Items such as symbols and abbreviations in English with their French and Spanish equivalents, and a list of stars used in H.O. Pub. No. 249, are included in the *Air Almanac*.

Recent issues of the *Air Almanac* have been modified slightly. Beginning with the 1961 edition, references to H.O. Pub. No. 218, *Astronomical Navigation Tables*, have been omitted and an azimuth of Polaris table added. In the 1962 edition, both pages of tables of Corrections for Height and Depression were omitted. These two pages were replaced by five pages of Rising, Setting and Depression Graphs, and one page containing supplementary tables and an explanation of use of these graphs and tables.

Problems

1805a. Find the GHA and declination of the sun at GMT $7^h25^m54^s$ on June 2, 1958, using the *Nautical Almanac*.

Answers.—GHA 292°01′.9, d 22°07′.9 N.

1805b. Find the GHA and declination of the sun at GMT $23^h49^m04^s$ on June 1, 1958, using the *Air Almanac*.

Answers.—GHA 177°50′, d 22°05′ N.

1806a. Find the GHA and declination of the moon at GMT $0^h24^m18^s$ on June 1, 1958, using the *Nautical Almanac*.

Answers.—GHA 18°14′.8, d 17°28′.4 S.

1806b. Find the GHA and declination of the moon at GMT $12^h01^m22^s$ on June 1, 1958, using the *Air Almanac*.

Answers.—GHA 185°40′, d 18°19′ S.

1807a. Find the GHA and declination of Mars at GMT $2^h25^m39^s$ on May 31, 1958, using the *Nautical Almanac*.

Answers.—GHA 288°25′.5, d 3°53′.3 S.

1807b. Find the GHA and declination of Jupiter at GMT $21^h06^m21^s$ on June 1, 1958, using the *Air Almcnac*.

Answers.—GHA 5°22′, d 7°20′ S.

1808a. Find the GHA and declination of Procyon at GMT $4^h25^m18^s$ on June 1, 1958, using the *Nautical Almanac*.

Answers.—GHA 201°12′.0, d 5°19′.8 N.

1808b. Find the GHA and declination of γ *Velorum* at GMT $16^h24^m11^s$ on May 31, 1958, using the *Nautical Almanac*.

Answers.—GHA 12°38′.7, d 47°13′.2 S.

1808c. Find GHA ♈ at GMT $20^h25^m32^s$ on June 1, 1958, using the *Nautical Almanac*.

Answer.—GHA ♈ 196°11′.6.

1808d. Find the GHA and declination of Gienah at GMT $2^h53^m21^s$ on June 2, 1958, using the *Air Almanac*.

Answers.—GHA 109°59′, d 17°19′ S.

1810. Find the zone time of sunrise and sunset at lat. 52°18′.7 S, long. 58°43′.6 W on June 1, 1958.

Answers.—Sunrise, ZT 0751; sunset, ZT 1554.

1811a. Find the zone time of beginning of morning nautical twilight and ending of evening nautical twilight at lat. 16°22′.7 N, long. 163°19′.7 E on June 1, 1958.

Answers.—Morning twilight, ZT 0441; evening twilight, ZT 1928.

1811b. Find the zone time of beginning of morning civil twilight and ending of evening civil twilight at lat. 55°35′.6 N, long. 51°13′.7 W on June 1, 1958, using the *Air Almanac*.

Answers.—Morning twilight, ZT 0253; evening twilight, ZT 2153.

1812a. Find the zone time of moonrise and moonset at lat. 44°26′.3S, long. 172°29′.3E on June 3, 1958, using the *Nautical Almanac.*

Answers.—Moonrise, ZT 1732; moonset, ZT 0743.

1812b. Find the zone time of moonrise and moonset at lat. 3°27′.4S, long. 107°22′.8 W on June 1, 1958, using the *Air Almanac.*

Answers.—Moonrise, ZT 1815; moonset, ZT 0554.

1812c. Find the zone time of moonrise at lat. 71°44′.7N, long. 176°18′.1E on the night of June 13–14, 1958, using the *Nautical Almanac.*

Answer.—Moonrise, ZT 0007 June 14.

1813. The zone time of sunrise at a moving ship is desired. The first solution, based upon an estimate of the position, is 0537. The longitude used for the solution is 51°22′.2W. At 0537 the longitude will be 51°38′.8W.

Required.—The zone time of sunrise at the ship.

Answer.—Sunrise, ZT 0539.

1814a. Find the equation of time at GMT $16^h21^m04^s$ on June 1, 1958.

Answer.—Eq. T(+)2^m19^s.

1814b. Find the zone time of transit of the moon across the upper branch of the celestial meridian at long. 137°14′.4W on May 31, 1958.

Answer.—Transit, ZT 2340.

1814c. What are the phase and age of the moon on June 2, 1958?

Answers.—Phase, full moon; age, 15 days.

1814d. What are the semidiameters of the sun and moon on June 2, 1958?

Answers.—Sun, SD 15′.8; moon, SD 16′.1.

1814e. What is the magnitude of Jupiter on June 1, 1958?

Answer.—Mag.(−) 1.9.

1814f. Which of the navigational planets is nearest Aldebaran on June 2, 1958?

Answer.—Venus.

1814g. Find the GHA and declination of the sun at GMT $11^h14^m07^s$ on May 31, 1959, using the 1958 *Nautical Almanac.*

Answers.—GHA 349°09′.7, d 21°50′.5N.

1814h. Find the GHA and declination of Alioth at GMT $19^h25^m23^s$ on June 1, 1959, using the 1958 *Nautical Almanac.*

Answers.—GHA 347°48′.5, d 56°11′.3N.

CHAPTER XIX

TIME

1901. Introduction.—Time serves to regulate affairs aboard ship, as it does ashore. But to the navigator, it has additional significance. It is not enough to know *where* the ship is, was, or might be located in the future. The navigator wants to know *when* the various positions were or can reasonably be expected to be occupied. Time serves as a measure of progress. By considering the time at which a ship occupied various positions in the past, and by comparing the speed and various conditions it has encountered with those anticipated for the future, the skillful navigator can predict with reasonable accuracy the time of arrival at various future positions. Time can serve as a measure of safety, for it indicates when a light or other aid to navigation might be sighted, and if it is not seen by a certain time, the navigator knows he has cause for concern.

To the celestial navigator, time is of added significance, for it serves as a measure of the *phase* of the earth's rotation. That is, it indicates the position of the celestial bodies relative to meridians on the earth. Until an accurate *measure* of time became available at sea, longitude could not be found.

Very small *intervals* of time are used in certain electronic navigational aids, such as radar and loran.

Whatever the type of navigation, a thorough mastery of the subject of time is important to the navigator. The use of a time diagram (art. 1427) may help in understanding the principles or solution of the problems of this chapter.

1902. Kinds of time.—As a measure of part of a day, time can be stated in a number of different ways. At any given moment, the time depends upon (1) the point on the celestial sphere used as reference, (2) the reference meridian on the earth, and (3) the somewhat arbitrary starting point of the day.

When the sun is used as the celestial reference point, **solar time** results. If the actual sun observable in the sky is used, **apparent solar time** is involved, and if a fictitious **mean sun** is used to provide a time having an almost constant rate, **mean solar time** results. Time reckoned by use of the first point of Aries (♈) as the celestial reference point is called **sidereal time.** Use of the moon as the celestial reference point provides a variable-length **lunar day,** the basis of **lunar time,** which is useful in tide prediction and analysis. Because of its application, a lunar day is sometimes called a **tidal day.** It averages about 24^h50^m (mean solar units) in length.

If the meridian of the observer is used as the terrestrial reference, **local time** is involved. If a **zone** or **standard meridian** is used as the **time meridian** for mean solar time over an area, **zone** or **standard time** results. Use of a meridian farther east than would normally be used, so that the period of daylight is shifted later in the day, produces a form of zone time called **daylight saving** or **summer time.** Time based upon the Greenwich meridian is called **Greenwich time. Greenwich mean time** (**GMT**) is of particular interest to a navigator because it is the principal entering argument for the almanacs.

One complete revolution of the earth with respect to a celestial reference point is called a **day.** In modern usage every kind of solar time has its zero or starting point at **midnight,** when the celestial reference point is directly over the *lower branch* of the

terrestrial reference meridian. This has not always been so. Until January 1, 1925, the **astronomical day** began at *noon*, 12 hours *later* than the start of the calendar day of the same date. The **nautical day** began at *noon*, 12 hours *earlier* than the calendar day, or 24 hours earlier than the astronomical day of the same date. The **sidereal day** begins at **sidereal noon,** when the first point of Aries is over the *upper* branch of the reference meridian. There is no sidereal date.

1903. Expressing time.—Time is customarily expressed in time units, from 0^h through 24^h. To the nearest 1^m it is generally stated by navigators in a four-digit unit without punctuation. Thus, 0000 is midnight at the start of the day. One minute later the time is 0001. Half an hour after the start of the day the time is 0030, at one hour the time is 0100, at one hour and four minutes it is 0104, at 19 minutes after noon (solar time) it is 1219, at four hours and 23 minutes after (solar) noon it is 1623, etc. The term "hours" is sometimes used with the four-digit system to indicate that the number refers to the time or "hour" of the day. However, in those few occasions when any reasonable doubt may exist as to whether time is indicated, the fact can better be indicated in another way. Thus, the expression "1600 hours" to indicate "1600" or "16 hours" is not strictly correct, and is better avoided. **Watch time (W),** indicated by a watch or clock having a 12-hour dial, and **chronometer time** (C) are expressed on a 12-hour basis, with designations AM (ante meridian) and PM (post meridian), as in ordinary civil life ashore.

In contrast, a time interval is expressed as hours and minutes, as 5^h26^m. When either the time of day or a time interval is given to seconds, this same form is used, as $21^h15^m18^s$. The kind of time may be indicated, usually by abbreviation.

When a time interval is to be added to or subtracted from a time, the solution can be arranged conveniently in tabular form.

Example 1.—What is the time and date $14^h36^m53^s$ after $21^h14^m18^s$ on July 24?

Solution.—

$$\begin{array}{ll} 21^h14^m18^s & \text{July 24} \\ \underline{14^h36^m53^s} & \\ 35^h51^m11^s & \text{July 24} \\ =11^h51^m11^s & \text{July 25} \end{array}$$

The fact that the sum of hours exceeds 24 is an indication that the date increases by one. Similarly, in *subtracting* an interval, the date is one day earlier if 24^h must be added to the time before the subtraction can be made. That is, since 2400 of one day is 0000 of the following day, one might say that 2700 on one day is $2700-2400=0300$ on the following day. In the example above, $11^h51^m11^s$ on July 25 is the same as $11^h51^m11^s+24^h00^m00^s=35^h51^m11^s$ on July 24.

Date is sometimes expressed as an additional unit of the time sequence. Thus, $21^h14^m18^s$ on July 24 might be stated $24^d21^h14^m18^s$. This system is of particular value when an interval of several days is to be added or subtracted.

Example 2.—What is the time and date $9^d16^h35^m04^s$ before $5^h11^m33^s$ on September 15?

Solution.—

$$\begin{array}{l} 15^d05^h11^m33^s \\ \underline{9^d16^h35^m04^s} \\ 5^d12^h36^m29^s \text{ or } 12^h36^m29^s \text{ on Sept. 5.} \end{array}$$

By this method the month and day, if of significance, are recorded separately, or they, too, can be added to the sequence.

Example 3.—What is the time and date 3 years, 6 months, 25 days, 12 hours, 19 minutes, and 44 seconds after $7^h52^m24^s$ on November 14, 1958?

Solution.—

$$\begin{array}{r} 1958^y11^m14^d07^h52^m24^s \\ 3^y06^m25^d12^h19^m44^s \\ \hline 1962^y06^m08^d20^h12^m08^s \end{array} = 20^h12^m08^s \text{ on June 8, 1962.}$$

Since a month may contain a variable number of days, both the months and days should be solved together. Thus, in the example above, the answer would be 17 months, 39 days. If 12 months are converted to one year, this becomes five months, 39 days. Since the fifth month is May, this might be stated as May 39. Since there are 31 days in May, this is 39−31=8 days into the next month, or June 8.

A simpler method of determining the number of elapsed *days* between any two dates is to use the **Julian day** of each date, if the information is available. This also eliminates possible error due to change of calendar if long intervals are involved. The Julian day is the consecutive number of the day starting at 1200 on January 1, 4713 BC. Julian day is listed in the *American Ephemeris and Nautical Almanac.*

1904. Time and arc.—The time of day is an indication of the interval since the day began. One day represents one complete rotation of 360° of the earth with respect to a selected celestial point. Each day is divided into 24 **hours** of 60 **minutes,** each minute having 60 **seconds.** Thus, each day has $24\times60=1{,}440$ minutes or $1{,}440\times60=86{,}400$ seconds. This is time regardless of the celestial reference point used, and since the various references are in motion with respect to each other, as "seen" from the earth, apparent solar, mean solar, and sidereal days are of different lengths. Since they all have the same number and kind of fractional parts, these parts are themselves of different length in the different kinds of time. Mean solar units are customarily used to indicate time intervals. The smallest unit normally used in celestial navigation is the second, but in some electronic equipment the **millisecond** (one-thousandth of a second), **microsecond** (one-millionth of a second), and the **millimicrosecond** or **nanosecond** (one-billionth of a second) are used.

Time of day is an indication of the *phase* of rotation of the earth. That is, it indicates how much of a day has elapsed, or what part of a rotation has been completed. Thus, at zero hours the day begins. One hour later, the earth has turned through 1/24 of a day, or 1/24 of 360°, or $\frac{360°}{24}=15°$. Six hours after the day begins, it has turned through $6/24=1/4$ day, or $\frac{360°}{4}=90°$. Twelve hours after the start of the day, the day is half gone, having turned through 180°. Smaller intervals can also be stated in angular units, for since one hour or 60 minutes is equivalent to 15°, one minute of time is equivalent to $\frac{15°}{60}=0.°25=15'$, and one second of time is equivalent to $\frac{15'}{60}=0.'25=15''$. Thus,

$$\begin{array}{rrl} & \textit{Time} & \textit{Arc} \\ 1^d= & 24^h= & 360°=1 \text{ circle} \\ 60^m= & 1^h= & 15° \\ & 4^m= & 1°=60' \\ 60^s= & 1^m= & 15' \\ & 4^s= & 1'=60'' \\ & 1^s= & 15''=0.'25 \end{array}$$

Any time interval can be expressed as an angle of rotation, and vice versa. Interconversion of these units can be made by the relationships indicated above.

To convert time to arc:

1. Multiply the hours by 15 to obtain degrees.

2. Divide the minutes of time by four to obtain degrees, and multiply the remainder by 15 to obtain minutes of arc.

3. Divide the seconds of time by four to obtain minutes and tenths of minutes of arc, or multiply the remainder by 15 to obtain seconds of arc.

4. Add degrees, minutes, and tenths (or seconds).

Example 1.—Convert $14^h21^m39^s$ to arc units.

Solution.—

(1) $14^h \times 15 = 210°$
(2) $21^m \div 4 = \quad 5°15'$ (remainder $1^m \times 15 = 15'$)
(3) $39^s \div 4 = \quad 9'45''$ (remainder $3^s \times 15 = 45''$)
(4) $14^h21^m39^s = 215°24'45'' = 215°24.'8$ (to the nearest $0.'1$).

To convert arc to time:

1. Divide the degrees by 15 to obtain hours, and multiply the remainder by four to obtain minutes of time.

2. Divide the minutes of arc by 15 to obtain minutes of time, and multiply the remainder by four to obtain seconds of time.

3. Divide the seconds of arc by 15 to obtain seconds of time.

4. Add hours, minutes, and seconds.

Example 2.—Convert $215°24'45''$ to time units.

Solution.—

(1) $215° \div 15 = 14^h20^m$ (remainder $5° \times 4 = 20^m$)
(2) $24' \div 15 = \quad 1^m36^s$ (remainder $9' \times 4 = 36^s$)
(3) $45'' \div 15 = \quad 3^s$
(4) $215°24'45'' = 14^h21^m39^s$

Example 3.—Convert $161°53.'7$ to time units.

Solution.—

(1) $161° \div 15 = 10^h44^m$ (remainder $11° \times 4 = 44^m$)
(2) $53.'7 \div 15 = \quad 3^m34.^s8$ (remainder $8.'7 \times 4 = 34.^s8$)
(3) $161°53.'7 = 10^h47^m34.^s8 = 10^h47^m35^s$.

The navigator should be able to make these solutions mentally, writing only the answer. As a check, the answer can be converted back to the original value. Solution can also be made by means of arc to time tables in the almanacs. In the *Nautical Almanac* the table, given near the back of the volume (app. V), is in two parts, permitting separate entries with degrees, minutes, and quarter minutes of arc. The table is arranged in this manner because the navigator is confronted with the problem of converting arc to time more often than the reverse.

Example 4.—Convert $334°18'22''$ to time units, using the *Nautical Almanac* arc to time conversion table.

Solution.—

$$334° = 22^h16^m$$
$$18.'25 = \quad 1^m13^s$$
$$334°18'22'' = 22^h17^m13^s$$

The $22''$ are converted to the nearest quarter minute of arc for solution to the nearest second of time. Interpolation can be used if more precise results are required, since exact relationships are tabulated in the *Nautical Almanac* conversion table.

Example 5.—Convert 83°29′.6 to time units, using the *Nautical Almanac* arc to time conversion table.

Solution.—

$$\begin{aligned} 83° &= 5^h32^m \\ 29'.6 &= \underline{\quad 1^m58^s.4} \\ 83°29'.6 &= 5^h33^m58^s.4 \end{aligned}$$

In this solution, 58ˢ.4 was obtained by eye interpolation in the quarter-minute part of the table.

Example 6.—Convert $17^h09^m42^s$ to arc units, using the *Nautical Almanac* arc to time conversion table.

Solution.—

$$\begin{aligned} 17^h08^m &= 257° \\ 1^m42^s &= \underline{\quad 25'.5} \\ 17^h09^m42^s &= 257°25'.5 \end{aligned}$$

A similar table appears near the back of the *Air Almanac* (app. W), but values are given only to 180°, and quarter minutes of arc are not included. For angles greater than 180°, subtract 180° and add 12^h to the result.

Example 7.—Convert 334°47′.2 to time units, using the *Air Almanac* arc to time conversion table.

Solution.—

$$\begin{aligned} 334°-180°=154° &= 10^h16^m \\ 47'.2 &= \underline{\quad 3^m09^s} \\ 154°47'.2 &= 10^h19^m09^s \\ 334°47'.2 &= 22^h19^m09^s \end{aligned}$$

Example 8.—Convert $15^h13^m18^s$ to time units, using the *Air Almanac* arc to time conversion table.

Solution.—

$$\begin{aligned} 15^h12^m-12^h=3^h12^m &= 48° \\ 1^m18^s &= \underline{\quad 19'.5} \\ 3^h13^m18^s &= 48°19'.5 \\ 15^h13^m18^s &= 228°19'.5 \end{aligned}$$

Because the almanac conversion tables are exact relationships, interpolation in them can be carried to any degree of precision desired without introducing an error.

1905. Time and longitude.—As indicated in the preceding article, time is a measure of rotation of the earth, and any given time interval can be represented by a corresponding angle through which the earth turns. Suppose the celestial reference point were directly over a certain reference of the earth. An hour later the earth would have turned through 15°, and the celestial reference would be directly over a meridian 15° farther west. Any difference of longitude is a measure of the angle through which the earth must rotate for the local time at the western meridian to become what it was at the eastern meridian before the rotation took place. Therefore, places to the eastward of an observer have *later* time, and those to the westward have *earlier* time, and the difference is exactly equal to the difference in longitude, expressed in time units. When a meridian other than the local meridian is used as the time reference, the difference in time of two places is equal to the difference of longitude of their time reference meridians.

1906. The date line.—Since time becomes later toward the east, and earlier toward the west, time at the lower branch of one's meridian is 12 hours earlier or later depending upon the direction of reckoning. A traveler making a trip around the world gains or loses an entire day. To prevent the *date* from being in error, and to provide a starting place for each day, a **date line** is fixed by international agreement. This line coincides with the 180th meridian over most of its length. In crossing this line, one alters his

date by one day. In effect, this changes his time 24 hours to compensate for the slow change during a trip around the world. Therefore, it is applied in the opposite direction to the change of time. Thus, if a person is traveling *eastward* from east longitude to west longitude, time is becoming *later*, and when the date line is crossed, the date becomes one day *earlier*. That is, at any moment the date immediately to the *west* of the date line (east longitude) is one day *later* than the date immediately to the *east* of the line, except at GMT 1200, when the (mean time) date is the same all over the world. At any other time two dates occur, one boundary between dates being the date line, and the other being the midnight line along the lower branch of the meridian over which the mean sun is located. At GMT 1200 these two boundaries coincide. In the solution of problems, error can sometimes be avoided by converting local time to Greenwich time, and then converting this to local time on the opposite side of the date line. Examples are given in following articles.

1907. Zone time.—At sea, as well as ashore, watches and clocks are normally set approximately to some form of **zone time** (**ZT**). At sea the *nearest* meridian exactly divisible by 15° is usually used as the **time meridian** or **zone meridian.** Thus, within a **time zone** extending 7°5 on each side of each time meridian the time is the same, and time in consecutive zones differs by exactly one hour. The time is changed as convenient, usually at a whole hour, near the time of crossing the boundary between zones. Each time zone is identified by the number of times the longitude of its zone meridian is divisible by 15°, positive in west longitude and negative in east longitude. This number and its sign, called the **zone description** (**ZD**), is the number of whole *hours* that are added to or subtracted from the zone time to obtain **Greenwich mean time** (**GMT**), which is the zone time at the Greenwich (0°) meridian, and is sometimes called **universal time** (**UT**). The mean sun is the celestial reference point for zone time.

Example 1.—For an observer at long. 141°18′4 W the ZT is $6^h18^m24^s$.

Required.—(1) Zone description.

(2) GMT.

Solution.—(1) The nearest meridian exactly divisible by 15° is 135° W, into which 15° will go nine times. Since longitude is west, ZD is (+) 9.

	ZT	$6^h18^m24^s$
	ZD (+)	9
(2)	GMT	$15^h18^m24^s$

In converting GMT to ZT, a positive ZD is *subtracted*, and a negative one *added*, but its sign remains the same, being part of the description. The word "reversed" (rev.) is written to the right in the work form to indicate that the "reverse" process is to be performed.

Example 2.—The GMT is $15^h27^m09^s$.

Required.—(1) ZT at long. 156°24′4 W.

(2) ZT at 39°04′8 E.

Solution.—

(1) GMT	$15^h27^m09^s$			(2) GMT	$15^h27^m09^s$	
ZD (+)	10	(rev.)		ZD (−)	3	(rev.)
ZT	$5^h27^m09^s$			ZT	$18^h27^m09^s$	

When time at one place is converted to that at another, the date should be watched carefully. If a sum exceeds 24 hours, subtract this amount and add one day. If 24 hours are added before a subtraction is made, the date at the place is one day *earlier*.

Example 3.—At long. 73°29′2 W the ZT is $21^h12^m53^s$ on May 14.

Required.—(1) GMT and date.

(2) ZT and date at long. 107°15′7 W.

Solution.—

	ZT	$21^h12^m53^s$ May 14	
	ZD	(+) 5	
(1)	GMT	$2^h12^m53^s$ May 15	
	ZD	(+) 7	(rev.)
(2)	ZT	$19^h12^m53^s$ May 14	

The second part of this problem might have been solved by using the *difference* in zone description. Since the second place is two zones farther west, its time is two hours earlier. Problems involving zone times at various places generally involve nothing more than addition or subtraction of one small number, so solutions can generally be made mentally. However, when this forms part of a larger problem, or when a record of the solution is desired, the full solution should be recorded, including labels.

Example 4.—On November 30 the 1430 DR long. of a ship is 51°32′.4 W. Ten hours later the DR long. is 53°07′.2 W.

Required.—ZT and date of arrival at the second longitude.

Solution.—

ZT	1430 Nov. 30	
ZD	(+) 3	
GMT	1730 Nov. 30	
int.	10	
GMT	0330 Dec. 1	
ZD	(+) 4	(rev.)
ZT	2330 Nov. 30	

If a time zone boundary had not been crossed, there would have been no need to find GMT. It is particularly helpful to retain this step when the date line is crossed. This line is the *center* of a time zone, the western (east longitude) half being designated (−) 12, and the eastern (west longitude) half (+) 12.

Example 5.—On December 31 the 0800 DR long. of a ship is 177°23′.9 E. Forty hours later the DR long. is 171°53′.9 W.

Required.—ZT and date of arrival at the second longitude.

Solution.—

			Alternative solution		
ZT	0800 Dec. 31		ZT	$31^d08^h00^m$	
ZD	(−) 12		ZD	(−) 12	
GMT	2000 Dec. 30		GMT	$30^d20^h00^m$	
int.	40		int.	1^d16^h	
GMT	1200 Jan. 1		GMT	$1^d12^h00^m$	
ZD	(+) 11	(rev.)	ZD	(+) 11	(rev.)
ZT	0100 Jan. 1		ZT	$1^d01^h00^m$	

For certain communication purposes it is sometimes convenient to designate a time zone by a single letter. The system used is shown in figure 1907.

Use of time zones on land began in 1883, when railroads adopted four standard zones for the continental United States. The division of the United States into time zones was not officially adopted by Congress, however, until March 19, 1918, when a fifth zone was also established for Alaska. The system of time zones is now used almost universally throughout the world, although on land the zone boundaries are generally altered somewhat for convenience. In a few places, half-hour zones are used but these are not standard time zones.

On land, normal zone time is usually called **standard time,** often with an adjective to indicate the zone, as **eastern standard time.** In some areas timepieces are *advanced* one or more hours during the summer to provide greater use of daylight. This "fast" time is called **daylight saving time** in the United States, and **summer time** elsewhere.

FIGURE 1907. Time zone chart of the world (from H.O. Chart No. 5192, 1958 edition).
THE LATEST EDITION OF THIS CHART SHOULD BE CONSULTED.

When time is one hour fast, the zone description is (algebraically) one *less* than normal. When daylight saving or summer time is specified, an advance of one hour is understood unless a greater number is indicated.

Example 6.—What is the standard time and date at Tokyo, long. 140° E, when the daylight saving time at Washington, long. 77° W, is 1600 on Oct. 5?

Solution.—

$$\begin{array}{rll}
\text{ZT} & 1600 & \text{Oct. 5} \\
\text{ZD} & (+)\,4 & \\ \hline
\text{GMT} & 2000 & \text{Oct. 5} \\
\text{ZD} & (-)\,9 & \text{(rev.)} \\ \hline
\text{ZT} & 0500 & \text{Oct. 6}
\end{array}$$

During hostilities daylight saving time may be kept all year long throughout a nation, and designated **war time (WT).**

1908. Chronometer time (C) is time indicated by a chronometer. Since a chronometer is set approximately to GMT, and not reset until it is overhauled and cleaned, perhaps three years later (art. 1514), there is nearly always a **chronometer error** (CE), either *fast* (F) or *slow* (S). The change in chronometer error in 24 hours is called **chronometer rate,** or **daily rate,** and designated *gaining* or *losing.* With a consistent rate of 1^{s} per day for three years, the chronometer error would be approximately 18^{m}. Since chronometer error is subject to change, it should be determined from time to time, preferably daily at sea. Chronometer error is found by radio time signal (art. 1909), by comparison with another timepiece of known error, or by applying chronometer rate to previous readings of the same instrument. It is recorded to the nearest whole or half second. Chronometer rate is recorded to the nearest $0^{s}.1$.

Example 1.—At GMT 1200 on May 12 the chronometer reads $12^{h}04^{m}21^{s}$. At GMT 1600 on May 18 it reads $4^{h}04^{m}25^{s}$.

Required.—(1) Chronometer error at both comparisons.

(2) Chronometer rate.

(3) Chronometer error at GMT 0530 on May 27.

Solution.—

$$\begin{array}{rl}
\text{GMT} & 12^{h}00^{m}00^{s}\ \text{May 12} \\
\text{C} & 12^{h}04^{m}21^{s} \\ \hline
\text{(1) CE} & \text{(F)}\ 4^{m}21^{s}
\end{array}$$

$$\begin{array}{rl}
\text{GMT} & 16^{h}00^{m}00^{s}\ \text{May 18} \\
\text{C} & 4^{h}04^{m}25^{s} \\ \hline
\text{(1) CE} & \text{(F)}\ 4^{m}25^{s}
\end{array}$$

$$\begin{array}{rl}
\text{GMT} & 12^{d}12^{h} \\
\text{GMT} & 18^{d}16^{h} \\ \hline
\text{diff.} & 6^{d}04^{h}=6^{d}.2
\end{array}$$

$$\begin{array}{rll}
\text{CE} & \text{(F)}\ 4^{m}21^{s}\ 1200\ \text{May 12} & \\
\text{CE} & \text{(F)}\ 4^{m}25^{s}\ 1600\ \text{May 18} & \\ \hline
\text{diff.} & 4^{s}\ \text{gained} & \\
\text{(2) daily rate} & 0^{s}.6\ \text{per day, gaining.} & (4^{s} \div 6^{d}.2)
\end{array}$$

$$\begin{array}{rl}
\text{GMT} & 18^{d}16^{h}00^{m} \\
\text{GMT} & 27^{d}05^{h}30^{m} \\ \hline
\text{diff.} & 8^{d}13^{h}30^{m}=8^{d}.5
\end{array}$$

$$\begin{array}{rl}
\text{CE} & \text{(F)}\ 4^{m}25^{s}\ 1600\ \text{May 18} \\
\text{corr.} & (+)\ 5^{s}\ (8^{d}.5 \times 0^{s}.6\ \text{per day}) \\ \hline
\text{(3) CE} & \text{(F)}\ 4^{m}30^{s}\ 0530\ \text{May 27}
\end{array}$$

Because GMT is stated on a 24-hour basis, and chronometer time on a 12-hour basis, a 12-hour ambiguity exists. This is ignored in finding chronometer error. However, if chronometer error is applied to chronometer time to find GMT, a possible 12-hour error can result. This can be resolved by mentally applying zone description to local time to obtain approximate GMT. A time diagram can be used for resolving doubt as to approximate GMT and Greenwich date. If the sun for the kind of time used (mean or apparent) is between the *lower* branches of two time meridians (as the standard meridian for local time, and the Greenwich meridian for GMT), the date at the place farther *east* is one day *later* than at the place farther *west*.

Example 2.—On August 14 the DR long. of a ship is about 124° E, and the zone time is about 0500. Chronometer error is 12^m27^s slow.

Required.—GMT and date when the chronometer reads $8^h44^m22^s$.

Solution.—

approx.	ZT	0500 Aug. 14
	ZD	(−)8
approx.	GMT	2100 Aug. 13
	C	$8^h44^m22^s$
	CE	(S) 12^m27^s
	GMT	$20^h56^m49^s$ Aug. 13

The *A* chronometer, usually the best (having the most nearly uniform rate), is compared directly with the time signal (art. 1909). Other chronometers, designated *B*, *C*, etc., may then be compared with the *A* chronometer.

Example 3.—At GMT 1400 chronometer *A* is checked by time signal, and found to read $1^h57^m09^s$. A little later, when it reads $2^h05^m00^s$, chronometer *B* reads $2^h11^m38^s$.

Required.—(1) Error of chronometer *A*.

(2) Error of chronometer *B*.

Solution.—

GMT	$14^h00^m00^s$
C_A	$1^h57^m09^s$
(1) CE_A	(S) 2^m51^s
C_A	$2^h05^m00^s$
GMT	$14^h07^m51^s$
C_B	$2^h11^m38^s$
(2) CE_B	(F) 3^m47^s

If time signals are not available at the chronometer, a good comparing watch (art. 1515) should be compared with the radio signal, and this watch used to determine chronometer error, as indicated in example 3, substituting the watch for chronometer *A*.

1909. Time signals.—The usual method of determining chronometer error and daily rate is by radio **time signals,** popularly called **time ticks.** Most maritime nations broadcast time signals several times daily from one or more stations, and a vessel equipped with radio receiving equipment normally has no difficulty in obtaining a time tick anywhere in the world. The times of emission of signals transmitted by the U.S. are the same to about $0\overset{s}{.}001$ as those of Argentina, Australia, Canada, Japan, U.K., Republic of South Africa, and Switzerland. The time transmitted is maintained virtually uniform with respect to atomic clocks but follows GMT closely. The difference seldom amounts to $0\overset{s}{.}050$. The time, as received by a vessel, may be considered to be GMT to $0\overset{s}{.}1$. *Radio Navigational Aids*, H.O. Pubs. Nos. 117–A and 117–B, lists all time signals, together with their hours of transmission, system used, frequency, and other useful information.

At sea the chronometer should be checked daily by radio time signal, and in port daily checks should be maintained, or begun at least three days prior to departure, if conditions permit. Error and rate are entered in the chronometer record book (or record sheet) each time they are determined.

Prior to the development of radio time signals, chronometers were checked in port by **visual signals** which consisted of dropping a **time ball** or shape by telegraphic action, or firing a gun. Visual signals are still used in some ports. If a gun is used, the flash marks the correct time, as the report may not reach the observer until several seconds after the gun is fired.

The various time signal systems used throughout the world are explained in detail in H.O. Pubs. Nos. 117–A and B. Only the United States signals are discussed here.

The U. S. Naval Observatory at Washington, D. C., controls the transmissions of time signals from U. S. Naval radio stations. Beginning at 5 minutes before each even hour of GMT, dashes are transmitted on every second, except the 29th and certain others near the end of each minute, as shown in the following diagram:

Minutes	Seconds										
	50	51	52	53	54	55	56	57	58	59	60
55	—		—	—	—	—					—
56	—	—		—	—	—					—
57	—	—	—		—	—					—
58	—	—	—	—		—					—
59	—										——

The seconds marked "60" indicate the start of the next minute. The final dash, marking the hour, is considerably longer than any of the others. The number of dashes in the group near the end of any minute indicates the number of minutes before the hour. This is known as the **United States system.** In all cases the beginnings of the dashes indicate the beginning of the seconds, and the ends of the dashes are without significance.

Station WWV, near Washington, D. C., broadcasts continuous time signals obtained from the U. S. Naval Observatory time service. Station WWVH in Hawaii broadcasts the same signals, except for certain periods during which the station is off the air to compare its standards with those of WWV and to obtain ionospheric soundings. The signals broadcast by these stations are intended primarily for measurement of time *intervals*, and checking of frequencies of two standard audible tones, but signals can also be used for checking time. The system used is fully explained in H.O. Pubs. Nos. 117–A and 117–B.

1910. Watch time (**W**) is time indicated by a watch. This is usually an approximation of zone time, except that for timing celestial observations it is good practice to set a comparing watch (art. 1515) to GMT. If the watch has a second setting hand, the watch can be set exactly to ZT or GMT, and the time is so designated. If the watch is not set exactly to one of these times, the difference is known as **watch error** (**WE**), labeled *fast* (F) or *slow* (S) to indicate whether the watch is ahead of or behind the correct time, respectively.

If a watch is to be set exactly to ZT or GMT, it is set to some whole minute slightly ahead of the correct time, and stopped. When the set time arrives, the watch is started. It should then be checked for accuracy.

Example 1.—A chronometer 9^m46^s fast on GMT reads approximately 7^h23^m. At the next whole five minutes of GMT a comparing watch is to be set to GMT exactly.

Required.—(1) What should the watch read at the moment of starting?
(2) What should the chronometer read?
Solution.—

$$\begin{array}{lrl}
 & \text{C} & 7^h23^m00^s \\
 & \text{CE} & \text{(F) } 9^m46^s \\
 & \text{GMT} & 7^h13^m14^s \\
(1) & \text{GMT} & 7^h15^m00^s \text{ (next whole } 5^m) \\
 & \text{CE} & \text{(F) } 9^m46^s \\
(2) & \text{C} & 7^h24^m46^s
\end{array}$$

The GMT may be in error by 12^h, but if the watch is graduated to 12 hours, this will not be reflected. If a watch with a 24-hour dial is used, the actual GMT should be determined.

If watch error is to be determined, it is done by comparing the reading of the watch with that of the chronometer at a selected moment. This may be at some selected GMT, as in example 1.

Example 2.—If, in example 1, the watch had read $7^h14^m48^s$ at the moment the chronometer read $7^h24^m46^s$, what would be the watch error on GMT?

Solution.—

$$\begin{array}{rl}
\text{GMT} & 7^h15^m00^s \\
\text{W} & 7^h14^m48^s \\
\text{WE} & \text{(S) } 12^s
\end{array}$$

A more convenient chronometer time might be selected, as a whole minute. .

Example 3.—A watch is set to zone time approximately. The longitude is about 48° W. The watch is compared with a chronometer which is 19^m44^s fast on GMT. When the chronometer reads $5^h22^m00^s$, the watch reads $2^h01^m53^s$.

Required.—Watch error on zone time.

Solution.—

$$\begin{array}{rll}
\text{C} & 5^h22^m00^s & \\
\text{CE} & \text{(F) } 19^m44^s & \\
\text{GMT} & 5^h02^m16^s & \\
\text{ZD} & (+)\,3 & \text{(rev.)} \\
\text{ZT} & 2^h02^m16^s & \\
\text{W} & 2^h01^m53^s & \\
\text{WE} & \text{(S) } 23^s &
\end{array}$$

The possible 12^h error is not of significance. When such a watch is used for determining GMT, however, as for entering an almanac, the 12-hour ambiguity is important. Unless a watch is graduated to 24 hours, its time is designated AM before noon and PM after noon.

Example 4.—On January 3 the DR long. is 94°14.′7 E. An observation of the sun is made when the watch reads $12^h16^m23^s$ PM. The watch is 22^s fast on zone time.

Required.—GMT and date.

Solution.—

$$\begin{array}{rl}
\text{W} & 12^h16^m23^s \text{ PM Jan. 3} \\
\text{WE} & \text{(F) } 22^s \\
\text{ZT} & 12^h16^m01^s \\
\text{ZD} & (-)\,6 \\
\text{GMT} & 6^h16^m01^s \text{ Jan. 3}
\end{array}$$

Note that between 1200 and 1300 watch designations are PM. Between 0000 and 0100 they are AM.

Comparison of a watch and chronometer should be made carefully. If two observers are available, one can give a warning "stand-by" a few seconds before the selected time, and a "mark" at the appointed moment, while the other notes the time of the watch. A single observer can make a satisfactory comparison by counting with the chronometer. Chronometers beat in half seconds, with an audible "tick." Ten seconds before the selected time (perhaps a whole minute), the observer starts counting with the beats, as he watches the chronometer second hand, "50, and, 1, and, 2, and, 3, and, ... 9, and, mark." During the count the observer shifts his view from the chronometer to the second hand of the watch, continuing to count in cadence with the chronometer beats. At the "mark," the second, minute, and hour hands of the watch are read in that order, and the time recorded. A comparison of this time with the GMT or ZT corresponding to the selected chronometer time indicates the watch error.

Even though a watch is set to zone time approximately, its error on GMT can be determined and used for timing observations. In this case the 12-hour ambiguity in GMT should be resolved, and a time diagram used to avoid possible error. This method requires additional work, and presents a greater probability of error, without compensating advantages.

Still another method of determining GMT, generally used before zone time came into common use at sea, is to *subtract* watch time from chronometer time, to find C–W. This is then *added* to the watch time of an observation to obtain chronometer time (C−W+W=C). Chronometer error is then applied to the result to obtain GMT. A time diagram should *always* be used with this method, to resolve the 12-hour ambiguity and to be sure of the correct Greenwich date, unless an auxiliary solution is made using approximate ZT and ZD. This method has little to recommend it.

If a watch has a **watch rate** of more than a few seconds per day, watch error should be determined both before and after a round of sights, and any difference distributed proportionally among observations.

If a stop watch is used for timing observations, it should be started at some convenient GMT, as a whole 5^m or 10^m. The time of each observation is then this GMT *plus* the reading of the watch.

1911. Local mean time (**LMT**), like zone time, uses the mean sun as the celestial reference point. It differs from zone time in that the local meridian is used as the terrestrial reference, rather than a zone meridian. Thus, the local mean time at each meridian differs from that of every other meridian, the difference being equal to the difference of longitude, expressed in time units. At each zone meridian, including 0°, LMT and ZT are identical.

Example 1.—At long. 124°37′.2 W the LMT is $17^h24^m18^s$ on March 21.

Required.—(1) GMT and date.

(2) ZT and date at the place.

Solution.—

LMT	$17^h24^m18^s$	Mar. 21
λ	$8^h18^m29^s$ W	
(1) GMT	$1^h42^m47^s$	Mar. 22
ZD (+) 8		(rev.)
(2) ZT	$17^h42^m47^s$	Mar. 21

In navigation the principal use of LMT is in rising, setting, and twilight tables. The problem is usually one of converting the LMT taken from the table to ZT. At sea, the difference between these times is normally not more than 30^m, and the conver-

sion is made directly, without finding GMT as an intermediate step. This is done by applying a correction equal to the difference of longitude (dλ). If the observer is *west* of his time meridian, the correction is *added*, and if *east* of it, the correction is *subtracted*. If Greenwich time is desired, it is found from ZT.

Example 2.—At long. 63°24′.4 E the LMT is 0525 on January 2.

Required.—(1) ZT and date.

(2) GMT and date.

Solution.—

LMT	0525	Jan. 2
dλ	(−) 14	
(1) ZT	0511	Jan. 2
ZD	(−) 4	
(2) GMT	0111	Jan. 2

On land, with an irregular zone boundary, the longitude may differ by more than 7°.5 (30^m) from the time meridian.

If LMT is to be corrected to daylight saving time, the difference in longitude between the local and time meridian can be used, or the ZT can first be found and then increased by one hour.

Conversion of ZT (including GMT) to LMT is the same as conversion in the opposite direction, except that the sign of dλ is reversed. This problem is not normally encountered in navigation.

1912. Apparent time utilizes the **apparent** (real) **sun** as its celestial reference, and a meridian as the terrestrial reference. **Local apparent time** (**LAT**) uses the local meridian. The LAT at the 0° meridian is called **Greenwich apparent time** (**GAT**).

The LAT at one meridian differs from that at any other by the difference in longitude of the two places, the place to the eastward having the later time, and conversion is the same as converting LMT at one place to LMT at another.

Use of the apparent sun as a celestial reference point for time results in time of nonconstant rate for at least three reasons. First, revolution of the earth in its orbit is not constant. Second, motion of the apparent sun is along the ecliptic, which is tilted with respect to the celestial equator, along which time is measured. Third, rotation of the earth on its axis is not constant. The effect due by this third cause is extremely small.

For the various forms of mean time, the apparent sun is replaced by a fictitious **mean sun** conceived as moving eastward along the *celestial equator* at a uniform speed equal to the average speed of the apparent sun along the ecliptic, thus providing a nearly uniform measure of time equal to the approximate average apparent time. At any moment the accumulated difference between LAT and LMT is indicated by the **equation of time** (**Eq. T**), which reaches a maximum value of about $16^m.4$ in November. This quantity is tabulated at 12-hour intervals at the bottom of the right-hand daily page of the *Nautical Almanac*. In the United States, the sign is considered positive (+) if the time of sun's "Mer. Pass." is earlier than 1200, and negative (−) if later than 1200. If the "Mer. Pass." is given as 1200 (as on June 12–14, 1958), the sign is positive if the GHA at GMT 1200 is between 0° and 1°, and negative if it is greater than 359°. The sign is correct for conversion of GMT to GAT. In Great Britain, this convention is reversed. Since GMT is the entering argument for the almanacs, interconversion of apparent and mean time should preferably be made from Greenwich time, rather than from local time.

Example.—Find the LAT and date at ZT $15^h10^m40^s$ on May 31, 1958, for long. 73°18′.4 W.

Solution.—

$$\begin{array}{rl}
\text{ZT} & 15^h10^m40^s \text{ May } 31 \\
\text{ZD } (+) & \underline{5} \\
\text{GMT} & 20^h10^m40^s \text{ May } 31 \\
\text{Eq. T} & \underline{(+)2^m27^s} \\
\text{GAT} & 20^h13^m07^s \text{ May } 31 \\
\lambda & \underline{4^h53^m14^s \text{W}} \\
\text{LAT} & 15^h19^m53^s \text{ May } 31
\end{array}$$

In conversion from apparent to mean time, a second solution may be needed if the equation of time is large and changing rapidly, using the GAT for entering the almanac for the first solution, and using the GMT from this solution as the almanac entry value for the second solution.

Apparent time can also be found by converting hour angle to time units, and adding or subtracting 12 hours. If LAT is required, but not GAT, conversion of arc to time should be made from LHA, rather than GHA, to avoid the need for conversion of longitude to time units. Equation of time can be found by *subtracting* mean time from apparent time at the same meridian. This method of finding apparent time and equation of time is the only one available with the *Air Almanac*, which does not tabulate equation of time.

The navigator has little or no use for apparent time, as such. However, it can be used for finding the time of **local apparent noon (LAN),** when the apparent sun is on the celestial meridian.

The mean sun averages out the irregularities in time due to the variations of the speed of revolution of the earth in its orbit and the fact that the apparent sun moves in the ecliptic while hour angle is measured along the celestial equator. It does not eliminate the error due to slight variations in the *rotational* speed of the earth. When a correction for the accumulated error from this source is applied to mean time, **ephemeris time** results. This time is of interest to astronomers, but is not used directly by the navigator.

1913. Sidereal time uses the first point of Aries (vernal equinox) as the celestial reference point. Since the earth revolves around the sun, and since the direction of the earth's rotation and revolution are the same, it completes a rotation with respect to the stars in less time (about $3^m56\overset{s}{.}6$ of mean solar units) than with respect to the sun, and during one revolution about the sun (one year) it makes one complete rotation more with respect to the stars than with the sun. This accounts for the daily shift of the stars nearly 1° westward each night. Hence, sidereal days are shorter than solar days, and its hours, minutes, and seconds are correspondingly shorter. Because of nutation (art. 1417) sidereal time is not quite constant in rate. Time based upon the average rate is called **mean sidereal time,** when it is to be distinguished from the slightly irregular sidereal time. The ratio of mean solar time units to mean sidereal time units is 1:1.00273791.

The sidereal *day* begins when the first point of Aries is over the *upper* branch of the meridian, and extends through 24 hours of sidereal time. The sun is at the first point of Aries at the time of the vernal equinox, about March 21. However, since the solar day begins when the sun is over the *lower* branch of the meridian, apparent solar and sidereal times differ by 12 hours at the vernal equinox. Each month thereafter, sidereal time *gains* about two hours on solar time. By the time of the summer solstice, about June 21, sidereal time is 18 hours *ahead* or six hours *behind* solar time. By the time of the autumnal equinox, about September 23, the two times are together, and by the time of the winter solstice, about December 22, the sidereal time is six hours *ahead* of solar time. There need be no confusion of the date, for there is no sidereal date.

Local sidereal time (LST) uses the local meridian as the terrestrial reference. At the prime meridian this is called **Greenwich sidereal time (GST).** The difference between LST at two meridians is equal to the difference of longitude between them, the place to the eastward having the later time. Local sidereal time is LHA ♈ expressed in time units. To determine LST at any given moment, find GHA ♈ by means of an almanac, and then apply the longitude to convert it to LHA ♈. Then convert LHA ♈ in arc to LST in time units.

Example.—Find LST at ZT $8^h25^m51^s$ on May 31, 1958, for long. 103°16′.3 E.

Solution.—

ZT	$8^h25^m51^s$ May 31
ZD	(−) 7
GMT	$1^h25^m51^s$ May 31
1^h	263°01′.6
25^m51^s	6°28′.8
GHA ♈	269°30′.4
λ	103°16′.3 E
LHA ♈	12°46′.7
LST	$0^h51^m07^s$

Unless GST is required, conversion from arc to time units should be made from LHA ♈, rather than from GHA ♈, to avoid the need for converting longitude from arc to time units.

Conversion of sidereal to solar time is the reverse. Local sidereal time is converted to arc (LHA ♈), and the longitude is applied to find GHA ♈. This is used as an argument for entering the almanac to determine GMT, which can then be converted to any other kind of time desired. This is similar to one method of finding time of meridian transit, described in article 2104. Normally, the problem is not encountered by the navigator.

Sidereal time, as such, is little used by the navigator. It is the basis of star charts (art. 2204) and star finders (art. 2210), and certain sight reduction methods (notably H.O. Pub. No. 249), but generally in the form LHA ♈. This kind of time is used for these purposes because its celestial reference point remains almost fixed in relation to the stars. Sidereal time is used by astronomers to regulate mean time. Timepieces regulated to sidereal time can be purchased.

1914. Time and hour angle.—Both time and hour angle are a measure of the phase of rotation of the earth, since both indicate the angular distance of a celestial reference point *west* of a terrestrial reference meridian. Hour angle, however, applies to *any* point on the celestial sphere. Time might be used in this respect, but only the apparent sun, mean sun, the first point of Aries, and occasionally the moon are commonly used.

Hour angles are usually expressed in arc units, and are measured from the upper branch of the celestial meridian. Time is customarily expressed in time units. Sidereal time is measured from the upper branch of the celestial meridian, like hour angle, but solar time is measured from the lower branch. Thus, LMT = LHA mean sun plus or minus 180°, LAT = LHA apparent sun plus or minus 180°, and LST = LHA ♈.

As with time, **local hour angle (LHA),** based upon the local celestial meridian, at two places differs by the longitude between them, and LHA at longitude 0° is called **Greenwich hour angle (GHA).** In addition, it is often convenient to express hour angle in terms of the *shorter* arc between the local celestial meridian and the body. This is similar to measurement of longitude from the Greenwich meridian. Local hour angle measured in this way is called **meridian angle (t),** which is labeled *east* or *west*, like longitude, to indicate the direction of measurement. A westerly meridian angle is numerically equal to LHA, while an easterly meridian angle is equal to 360° − LHA; also, LHA = t (W), and LHA = 360° − t (E). Meridian angle is used in the solution of the navigational triangle (art. 1433).

Example 1.—Find LHA and t of the sun at GMT $3^h24^m16^s$ on June 1, 1958, for long. 118°48′.2 W.

Solution.—

GMT	$3^h24^m16^s$ June 1
3^h	225°36′.0
24^m16^s	6°04′.0
GHA	231°40′.0
λ	118°48′.2 W
LHA	112°51′.8
t	112°51′.8 W

Example 2.—Find LHA and t of Kochab at ZT $18^h24^m47^s$ on May 31, 1958, for long. 55°27′.3 W.

Solution.—

	Kochab	
ZT	$18^h24^m47^s$	May 31
ZD	(+) 4	
GMT	$22^h24^m47^s$	May 31
22^h	218°53′.4	
24^m47^s	6°12′.8	
SHA	137°17′.2	
GHA	2°23′.4	
λ	55°27′.3 W	
LHA	306°56′.1	
t	53°03′.9 E	

Problems

1903a. What is the time and date $9^h13^m29^s$ before $3^h16^m34^s$ May 9?

Answer.—T $18^h03^m05^s$ May 8.

1903b. What is the time and date $4^d19^h22^m50^s$ after $9^h31^m04^s$ on December 25?

Answer.—T $4^h53^m54^s$ on Dec. 30.

1903c. What is the time and date 2 years, 11 months, 16 days, 10 hours, 23 minutes, and 48 seconds before $2^h46^m17^s$ on October 4, 1958?

Answer.—T $16^h22^m29^s$ on Oct. 17, 1955.

1903d. What is the time and date 412 days, 15 hours, 6 minutes, and 56 seconds after $22^h27^m03^s$ on March 16, 1958?

Answer.—T $13^h33^m59^s$ on May 3, 1959.

1904a. Convert $6^h28^m31^s$ to arc units, without use of a conversion table.

Answer.—97°07′45″ or 97°07′.8.

1904b. Convert 217°28′.8 to time units, without use of a conversion table.

Answer.—$14^h29^m55^s.2$ or $14^h29^m55^s$.

1904c. Convert 196°21′46″ to time units, without use of a conversion table.

Answer.—$13^h05^m27^s.1$ or $13^h05^m27^s$.

1904d. Convert 107°49′44″ to time units, using appendix V.

Answer.—$7^h11^m19^s$.

1904e. Convert 211°37′.3 to time units, using appendix V.

Answer.—$14^h06^m29^s.2$.

1904f. Convert $8^h49^m33^s$ to arc units, using appendix V.

Answer.—132°23′.2.

1904g. Convert 251°09′.2 to time units, using appendix W.

Answer.—$16^h44^m37^s$.

1904h. Convert $23^h07^m38^s$ to time units, using appendix W.

Answer.—346°54′.5.

1907a. For an observer at long. 97°24′.6 E the ZT is $19^h10^m26^s$.

Required.—(1) Zone description.

(2) GMT.

Answers.—(1) ZD (−) 6, (2) GMT $13^h10^m26^s$.

1907b. The GMT is $11^h32^m07^s$.

Required.—(1) ZT at long. 133°24′.7 W.

(2) ZT at long. 111°43′.9 E.

Answers.—(1) ZT $2^h32^m07^s$, (2) ZT $18^h32^m07^s$.

1907c. At long. 165°18′.2 E the ZT is $17^h08^m51^s$ on July 11.

Required.—(1) GMT and date.

(2) ZT and date at long. 125°36′.7 W.

Answers.—(1) GMT $6^h08^m51^s$ on July 11, (2) ZT $22^h08^m51^s$ on July 10.

1907d. On January 26 the 0800 DR long. of a ship is 128°03′.2 E. Twenty-six hours later the EP long. is 125°01′.4 E.

Required.—ZT and date of arrival at the second longitude.

Answer.—ZT 0900 Jan. 27.

1907e. On April 1 the 1200 running fix long. of a ship is 179°55′.2 W. Eight hours later the DR long. is 178°48′.9 E.

Required.—ZT and date of arrival at the second longitude.

Answer.—ZT 2000 Apr. 2.

1907f. Inch'ŏn, long. 137° E, uses ZD (−) 8^h30^m for standard time. Find the standard time and date at San Francisco, long. 122° W, when the summer time at Inch'ŏn is 2000 on August 9.

Answer.—ZT 0230 Aug. 9.

1908a. At GMT 1400 on July 2 the chronometer reads $1^h42^m28^s$. At GMT 0800 on July 12 it reads $7^h42^m40^s$.

Required.—(1) Chronometer error at GMT 1400 on July 2.

(2) Chronometer error at GMT 0800 on July 12.

(3) Chronometer rate.

(4) Chronometer time at ZT 1800 July 20, at long. 153°21′.7 W.

Answers.—(1) CE 17^m32^s slow, (2) CE 17^m20^s slow, (3) rate $1^s.2$ gaining, (4) C $3^h42^m51^s$.

1908b. On March 5 the DR long. of a ship is about 151° E, and the zone time is about 1800. Chronometer error is 6^m40^s fast.

Required.—GMT and date when the chronometer reads $8^h02^m23^s$.

Answer.—GMT $7^h55^m43^s$ on Mar. 5.

1908c. On November 7 the EP long. of a ship is about 71° W, and the zone time is about 1900. Chronometer error is 1^m18^s slow.

Required.—GMT and date when the chronometer reads (1) $11^h55^m20^s$, (2) $11^h59^m50^s$.

Answers.—(1) GMT $23^h56^m38^s$ Nov. 7, (2) GMT $0^h01^m08^s$ Nov. 8.

1908d. At GMT 2200 a comparing watch is checked by time signal, and found to read $10^h00^m05^s$. The chronometer errors are then determined by means of the comparing watch. When the watch reads $10^h06^m00^s$, chronometer *A* reads $10^h11^m17^s$, and when the watch reads $10^h08^m00^s$, chronometer *B* reads $9^h59^m06^s$.

Required.—(1) Watch error.

(2) Error of chronometer *A*.

(3) Error of chronometer *B*.

Answers.—(1) WE 5^s fast on GMT, (2) CE_A 5^m22^s fast, (3) CE_B 8^m49^s slow.

1910a. A chronometer 7^m22^s slow on GMT reads approximately 3^h45^m. About two minutes later, when the GMT is a whole minute, a comparing watch will be set to GMT exactly.

Required.—(1) Reading of the watch at starting.

(2) Reading of the chronometer.

Answers.—(1) W $3^h54^m00^s$, (2) C $3^h46^m38^s$.

1910b. A chronometer 5^m10^s fast on GMT reads approximately 5^h50^m. About one minute later, when the GMT is a whole minute, a comparing watch with a 24-hour dial will be set to GMT exactly. The ZT is approximately 1145 and the long. 94° W.

Required.—(1) Reading of the watch at starting.

(2) Reading of the chronometer.

(3) Watch error if, instead of being set to GMT, the watch setting is unchanged and the watch reads $17^h45^m32^s$ at comparison.

Answers.—(1) W $17^h46^m00^s$, (2) C $5^h51^m10^s$, (3) WE 28^s slow on GMT.

1910c. A watch is set to zone time,approximately. The long. is about 160°E. The watch is compared with a chronometer which is 3^m16^s fast on GMT. When the chronometer reads $1^h48^m00^s$, the watch reads $12^h45^m02^s$.

Required.—Watch error on zone time.

Answer.—WE 18^s fast on ZT.

1910d. On February 14 the DR long. is 63°46′.1 W. An observation of Dubhe is made when the watch reads $6^h07^m30^s$ PM. The watch is 11^s slow on zone time.

Required.—GMT and date.

Answer.—GMT $22^h07^m41^s$ Feb. 14.

1910e. On December 11 a watch is set to zone time, approximately. The long. is 137° W. The chronometer is 3^m36^s fast on GMT. When the chronometer reads $4^h40^m00^s$, the watch reads $7^h36^m06^s$ PM.

Required.—(1) Watch error on GMT.

(2) GMT and date about 20 minutes later, when the watch reads $7^h55^m52^s$.

Answers.—(1) WE $2^h59^m42^s$ fast on GMT, (2) GMT $4^h56^m10^s$ Dec. 12.

1910f. Shortly before taking morning sights on January 17 the navigator compares his watch with the chronometer. When the chronometer reads $2^h30^m00^s$, the watch reads $6^h13^m12^s$ AM. The chronometer is 17^m15^s fast on GMT. The long. is 118° W.

Required.—(1) C–W.

(2) GMT and date a little later when Regulus is observed at W $6^h28^m47^s$ AM.

Answers.—(1) C–W $8^h16^m48^s$, (2) GMT $14^h28^m20^s$ Jan. 17.

1911a. At long. 138°09′.3 E the LMT is $0^h09^m57^s$ on April 23.

Required.—(1) GMT and date.

(2) ZT and date at the place.

Answers.—(1) GMT $14^h57^m20^s$ Apr. 22, (2) ZT $23^h57^m20^s$ Apr. 22.

1911b. At long. 157°18′.4 W the LMT is 1931 on June 29.

Required.—(1) ZT and date.

(2) GMT and date.

Answers.—(1) ZT 2000 June 29, (2) GMT 0600 June 30.

1911c. At long. 99°35′.7 W the daylight saving time is $21^h29^m45^s$ on August 31.

Required.—(1) Standard time and date.

(2) LMT and date.

Answers.—(1) Standard time $20^h29^m45^s$ Aug. 31, (2) LMT $20^h51^m22^s$ Aug. 31.

1912a. Find the LAT and date at ZT $5^h26^m13^s$ on June 12, 1958, for long. 9°28′.1 E.

Answer.—LAT $5^h04^m31^s$ June 12.

1912b. At long. 77°15′.5 W the LAT is 1500 on June 13, 1958.

Required.—(1) ZT.

(2) LMT.

Answers.—(1) ZT $15^h08^m56^s$, (2) LMT $14^h59^m54^s$.

1912c. Using the *Air Almanac*, find (1) LAT at long. 117°55′ W, and (2) the Eq. T, at ZT $20^h43^m09^s$ on June 1, 1958.

Answers.—(1) LAT $20^h53^m44^s$, (2) Eq. T (+) 2^m15^s.

1913a. Find LST at ZT $19^h24^m26^s$ on June 1, 1958, for long. 87°51′.2 E.

Answer.—LST $11^h53^m56^s$.

1913b.—Find the ZT at LST $21^h20^m07^s$ on May 31, 1958, for long. 54°21′.3 W.

Answer.—ZT $4^h24^m13^s$.

1914. Find LHA and t of the moon at GMT $9^h25^m07^s$ on May 31, 1958, (1) for long. 43°19′.0 W, and (2) for long. 43°19′.0 E. Use appendix V.

Answers.—(1) LHA 118°54′.8, t 118°54′.8 W; (2) LHA 205°32′.8, t 154°27′.2 E.

CHAPTER XX

SIGHT REDUCTION

2001. Introduction.—The process of deriving from a celestial observation the information needed for establishing a line of position is called **sight reduction.** The observation itself consists of measuring the altitude of a celestial body and noting the time. Although special methods may be used for finding certain coordinates such as latitude or longitude, the modern navigator generally thinks in terms of lines of position without regard to any special significance of these lines. The process of finding such a line of position may be divided into six steps:

1. Correction of sextant altitude (ch. XVI).
2. Determination of GHA and declination (ch. XVIII).
3. Selection of assumed position and finding meridian angle at that point.
4. Computation of altitude and azimuth.
5. Comparison of computed and observed altitudes (ch. XVII).
6. Plot of the line of position.

Broadly speaking, tables which assist in any of these steps can be considered **sight reduction tables.** However, the expression is generally limited to tables intended primarily for computation of altitude and azimuth. A great variety of such tables exists. In chapter XXI various methods of sight reduction, including graphical and mechanical solutions, are contrasted. All are based, directly or indirectly, upon solution of the navigational triangle (art. 1433). Thus, the process of sight reduction, in its limited sense, is one of converting coordinates of the celestial equator system (art. 1426) to those of the horizon system (art. 1428).

The U. S. Navy Hydrographic Office publishes a set of sight reduction tables giving tabulated solutions of the navigational triangle, intended primarily for use with the *Nautical Almanac* aboard ship. These *Tables of Computed Altitude and Azimuth*, popularly known by their publication number, "H.O. 214," are widely used among mariners of various nations. In addition to the United States printing, editions are published by Great Britain, Spain, and Italy. They are suitable for reduction of nearly all observations made aboard ship, and will be used to explain the principles of sight reduction as given in this chapter. Extracts from H.O. Pub. No. 214 are given in appendix AA.

2002. Preliminary computation.—Certain computations precede the use of sight reduction tables. The correction of the sextant altitude (hs) to find observed altitude (Ho), as explained in chapter XVI, is usually performed first, but not necessarily so. If any form of time other than GMT is used for timing the observation, it is first converted to GMT because this is the kind of time used for entering the almanacs. From the almanac, the GHA and declination are determined, as explained in chapter XVIII.

To enter H.O. Pub. No. 214 and most other sight reduction tables, the following variables are needed:

1. Latitude (L).
2. Declination (d).
3. Meridian angle (t).

The latitude to use in entering the tables is that of the **assumed position (AP).** This latitude is usually called the **assumed latitude (*a*L).** The assumed position should

be in the general vicinity of the actual position, which, of course, is usually unknown. Several methods of selecting an AP are in use. The dead reckoning position or estimated position might be used. However, when H.O. Pub. No. 214 and certain other methods of sight reduction are used, unnecessary interpolation can be avoided by selecting an AP that will result in two of the three variables being exact entry values. In H.O. Pub. No. 214, altitudes and azimuths are given for each whole degree of latitude. Therefore, it is customary to select an AP on the *nearest* whole degree of latitude to the DR or EP at the time of sight.

Declination is taken from the almanac, as explained in chapter XVIII. This value is used without adjustment to simplify the solution.

Meridian angle is the angular distance that the celestial body is east or west of the celestial meridian. It is found from local hour angle (LHA), which, in turn, is found from Greenwich hour angle by adding east longitude or subtracting west longitude. A time diagram (art. 1427) is useful in visualizing this relationship.

Example 1.—The GHA is 168°42.′6.

Required.—The LHA and t at (1) long. 137°24.′6 W, and (2) 158°24.′7 E.

Solution.—

(1)	GHA	168°42.′6	(2) GHA	168°42.′6
	λ	137°24.′6 W	λ	158°24.′7 E
	LHA	31°18.′0	LHA	327°07.′3
	t	31°18.′0 W	t	32°52.′7 E

In west longitude, if GHA is less than longitude, add 360° to GHA before subtracting. In east longitude, if the sum exceeds 360°, subtract this amount. If LHA is less than 180°, it is numerically equal to meridian angle, which is labeled W (west). If LHA is greater than 180°, t is 360°−LHA and is labeled E (east).

In H.O. Pub. No. 214, t (labeled "H.A.") is given at intervals of 1°. If t is to be a whole degree, the longitude of the assumed position, called **assumed longitude** (*a*λ), must be selected so that no minutes of arc will remain after it is applied to GHA. This means that in west longitude the minutes of *a*λ must be the same as those of GHA; while in east longitude the minutes of *a*λ must be equal to 60′ minus the minutes of GHA.

Example 2.—The GHA is 57°18.′9.

Required.—The LHA, t, and AP for use with H.O. Pub. No. 214 without interpolation for t or L, if the DR position is (1) lat. 11°48.′8 N, long. 151°53.′3 W; and (2) lat. 62°21.′7 N, long. 4°31.′3 E.

Solution.—

(1)	GHA	57°18.′9	(2) GHA	57°18.′9
	*a*λ	152°18.′9 W	*a*λ	4°41.′1 E
	LHA	265°00.′0	LHA	62°00.′0
	t	95°00.′0 E	t	62°00.′0 W
	*a*L	12°00.′0 N	*a*L	62°00.′0 N
	*a*λ	152°18.′9 W	*a*λ	4°41.′1 E

2003. *Tables of Computed Altitude and Azimuth* (H.O. Pub. No. 214).—These popular sight reduction tables are published by the U. S. Navy Hydrographic Office in nine volumes, each covering 10° of latitude in increments of 1°. For each degree of latitude there is a series of tables, with cutaway tabs providing quick reference to the first page of the tables for that latitude. Declination entries are given at intervals of 0.°5 from 0° to 29°. Beyond this, 37 selected declination entries are given to provide solutions for all of the stars listed on the daily pages of the almanacs, and most of the additional stars listed near the back of the *Nautical Almanac*. A total of 96 declination

entries are given for each latitude, arranged eight to a page. Each declination entry is given at the top of a column. The third variable, meridian angle, is given in the column at the extreme left and right sides of each page. These columns are labeled "H.A.", the abbreviation for "hour angle," the expression formerly used for meridian angle, but replaced because of confusion with *local* hour angle, *Greenwich* hour angle, etc. Meridian angle entries are given at intervals of 1° from 0° at the top of the page to the maximum value at which the altitude is 5° or greater.

At most page openings, separate tables are given for declination having the *same* name (N or S) as the latitude and those having *contrary* name (one N, the other S). That is, declination values on the left-hand page (same name) are duplicated on the right-hand page (contrary name). A maximum of ninety-one meridian angle entries (0°–90°) are given on the left-hand page (same name). As either the declination or the latitude increases, the number of same-name entries increases, and the number of contrary-name entries decreases. When the same-name entries exceed 90° of meridian angle, the additional ones are placed on the right-hand page, below the contrary-name entries. At extreme values of declination and latitude there are no contrary-name entries, the same-name entries occupying both pages.

In each declination column there are four sets of figures. The first, given in bold type, is the altitude (labeled "Alt.") to the nearest 0′.1. Following this is Δd in small type. This is the change of altitude for a unit change of declination. Except when the value is 1.0, entries are given in hundredths of a unit, although the position of the decimal point is not shown. Following Δd, and also in small type, is Δt, the change of altitude for a unit change of meridian angle. This is given in the same form as Δd. The last set of figures in the column is the azimuth angle (labeled "Az."), to the nearest 0°.1.

At latitude 0° the arrangement is modified because there is no "same" or "contrary" name of declination. Here a single set of declination entries is given. Declination replaces latitude as the prefix label for azimuth angle.

Following the altitude-azimuth section of each latitude is a two-page star identification table. The use of this table is explained in article 2213.

On the inside front cover and its facing page is a speed-time-distance table, which is useful in advancing or retiring lines of position, as well as for other purposes. This table contains information similar to that in table 19 of this publication, but in somewhat different form. Volume VIII and older printings of other volumes have sextant altitude correction tables on these pages.

Following the speed-time-distance table is an arc to time conversion table.

Following the title page and preface are given a description of the tables, and sample problems.

On the inside back cover and facing page is given a "multiplication table" to multiply Δd or Δt by the number of minutes between the declination or meridian angle and the value used for entering the main table. This is used in interpolating the altitude for declination or meridian angle.

On the two pages next preceding the multiplication table is given a somewhat similar table to provide easy interpolation for latitude.

The use of the various parts of H.O. Pub. No. 214 is explained in articles 2004–2007 and 2213. The primary purpose of H.O. Pub. No. 214 is to provide an easy method of sight reduction for use with the *Nautical Almanac* aboard ship. It may also be used with the *Air Almanac*, and for solution of any spherical triangle for which entry values are given. Therefore, it can be used in great-circle sailing for determining the initial course and the distance.

In the British edition (H.D. 486) the main tables are identical to those of H.O. Pub. No. 214, being a reproduction of the United States tables, but arranged with 15° of latitude in each of six volumes. The explanation has been rewritten to suit British usage. The Spanish edition is identical to H.O. Pub. No. 214, except that the explanation is in Spanish. The Italian edition is based on H.O. Pub. No. 214.

2004. H.O. Pub. No. 214 solution by Δd only.—If interpolation is made for all three variables—latitude, declination, and meridian angle—a triple interpolation is needed. A simpler solution, almost universally used with H.O. Pub. No. 214, is to select an assumed position that will eliminate interpolation for latitude and meridian angle, leaving a simple interpolation for declination.

Example.—Find computed altitude (Hc) and azimuth (Zn) if *a*L is 41°00′.0 N, d is 22°14′.3 N, and t is 36°00′.0 W.

Solution.—

t	36°00′.0 W		
d	22°14′.3 N	d diff. 14′.3	
*a*L	41°00′.0 N		
ht	54°16′.8	Δd (+)0.65	Z N111°.0W
corr.	(+) 9′.3		
Hc	54°26′.1		
Zn	249°.0		

The main table is entered with the three variables, t, d, and *a*L (being sure to note whether d and *a*L are of same or contrary name); and the values of ht (tabulated altitude, labeled "Alt." in H.O. Pub. No. 214), Δd, and Z are taken directly from the table, without interpolation. The tabulated altitude (ht) is the computed altitude (Hc) for the values used for entering the table. The designation ht is used to distinguish it from the Hc obtained by applying a correction to the value taken from the table.

The declination entry argument used should be the tabulated entry nearest the declination for which a solution is sought, normally differing by not more than half a degree. The difference between this value and the actual declination is recorded as "d diff." No sign (+ or −) is assigned to this value. It is good practice to show Δd as a decimal, even though it is not tabulated in this way. The sign of this value should be determined carefully by inspection of the main table of H.O. Pub. No. 214. Interpolation of altitude for declination is made between the base value taken from the table and the value given on the same line in the next column to the right or left. The choice of the second column depends upon the actual declination. If it is *greater* than the value used for entering the table, use the next column to the *right,* and if less, use the next column to the *left.* If the value in the second column is greater than the base value, the sign is plus (+), and if less, the sign is minus (−). The accuracy of this important step can be checked by comparing the computed altitude (Hc) with the altitudes given in the main table of H.O. Pub. No. 214. If Δd has been given the correct sign (and applied correctly), Hc should lie between the tabulated altitudes in the columns for tabulated declination next smaller and next larger than the actual declination.

The azimuth angle is given a prefix N or S to agree with the latitude, and a suffix E or W to agree with the meridian angle. For this reason it is good practice to label these values *when they are recorded.*

The next step is to multiply Δd by d diff., to interpolate between the altitude entries for consecutive declination columns. In most instances, the easiest way to do this is to use the multiplication table on the inside back cover of H.O. Pub. No. 214 and its facing page, entering separately with minutes and tenths of minutes of Δd and

adding the two parts. The correction, which is recorded below ht, is given the sign of Δd. The correction is then added or subtracted, in accordance with its sign, to ht. The answer is computed altitude (Hc).

Azimuth (Zn), which is recorded below Hc, is found by converting azimuth angle (Z) in accordance with its labels, as explained in article 1428. Usually, azimuth angle is found without interpolation. For exceptions to this practice, see article 2007.

If Δd is changing rapidly, or when it changes sign (at the maximum altitude for the given meridian angle and latitude), interpolation may be somewhat less accurate than in other parts of the tables, but this should not introduce a large error unless the celestial body is near the zenith, when the method of H.O. Pub. No. 214 is not recommended.

2005. H.O. Pub. No. 214 solution by Δd and Δt is similar to that using Δd only, but with the additional step of interpolating between the altitude entries for consecutive meridian angle entries, in a similar manner to interpolation for declination.

Example.—Find computed altitude and azimuth if *a*L is 41°00′.0 N, d is 20°48′.7 S, and t is 22°14′.0 E.

Solution.—

t	22°14′.0 E	t diff. 14′.0		t corr.	(−) 4′.2
d	20°48′.7 S	d diff. 11′.3		d corr.	(+) 10′.8
*a*L	41°00′.0 N			corr.	(+) 6′.6
ht	24°43′.1	Δd (+) 0.95	Δt (−) 0.30	Z	N 157°.4 E
corr.	(+) 6′.6				
Hc	24°49′.7				
Zn	157°.4				

In this solution, t diff. is the difference between the meridian angle and the nearest whole degree of t used for entering the table. The t corr. is t diff. × Δt, found by using the same multiplication table used for the d corr. The sign of Δt is found by inspection of the main table. In this example interpolation is between the base altitude for t 22°, and the altitude for t 23°. Since the altitude for t 23° is less than that for t 22°, the correction should be subtracted, so that the interpolated value will lie between the two values between which interpolation is being made. The sign of Δd is found by comparing the altitude for d 21°00′ with that for d 20°30′. The total correction is the algebraic sum of the t corr. and d corr.

The principal advantage of this solution is that a round of sights can be worked and plotted from the same assumed position. However, this advantage is offset by the additional length of the solution. The method is little used.

2006. H.O. Pub. No. 214 solution by Δd, Δt, and ΔL.—If the altitude and azimuth at a particular place are desired, interpolation should be made for all three variables, t, d, and L, if needed. The change in altitude for a change of latitude of 1′ (ΔL) is not tabulated. The table on the two pages *preceding* the multiplication table of H.O. Pub. No. 214 is used for finding the correction for latitude.

Example.—Find computed altitude and azimuth if *a*L is 41°12′.8 S, d is 21°32′.5 S, and t is 8°52′.3 W.

Solution.—

					+	−
t	8°52′.3 W	t diff. 7′.7		t corr.	2′.4	
d	21°32′.5 S	d diff. 2′.5		d corr.	2′.4	
*a*L	41°12′.8 S	L diff. 12′.8		L corr.		11′.7
ht	69°04′.0	Δd (+) 0.94	Δt (+) 0.32	sum	4′.8	11′.7
corr.	(−) 6′.9			corr.		(−) 6′.9
Hc	68°57′.1			Z		S 156°.0 W
Zn	336°.0					

The corrections for meridian angle and declination are found as explained in articles 2004 and 2005. The L corr. is found by entering the correction table with azimuth angle and L diff., the difference between the latitude of the assumed position and the nearest whole degree used for entering the main table. It is customary to interpolate in this table, where applicable, but the error introduced by not doing so is always less than 0'3 if the *nearest* whole degree of azimuth angle is used. The sign of the latitude correction is determined by the rules given at the bottom of the correction table. The total correction is the algebraic sum of the three individual corrections.

All of these are *altitude* corrections. The azimuth is that corresponding to the values used for entering the main table. If the exact value at the place is desired, it can be found by interpolation, as explained in article 2007. If such an interpolation is made, the interpolated value should be used for entering the latitude correction table for altitude interpolation.

2007. Interpolation for azimuth.—In sight reduction for plotting lines of position, it is not customary to interpolate for azimuth angle when H.O. Pub. No. 214 is used. However, if greater accuracy is desired, as for determining compass error, triple interpolation should be made. This is customarily accomplished by entering the main table of H.O. Pub. No. 214 with the *nearest* values of t, d, and L, and taking out the corresponding tabulated value. Simple eye interpolation is then used to determine separately the correction for each of the three variables. The algebraic sum of these is the correction applied to the base value. The Δd, Δt, and ΔL corrections are not used because these refer to the *altitude*, not the azimuth. Corrections are made to azimuth angle *before* it is converted to azimuth.

Example.—Find the azimuth by interpolation if L is 41°25'9 S, d is 22°19'6 N, and t is 17°22'4 E.

Solution.—

					+	−
t	17°4 E	t diff. 0°4	Z diff. (−) 1°0	t corr.		0°4
d	22°3 N	d diff. 0°2	Z diff. (−) 0°1	d corr.		—
L	41°4 S	L diff. 0°4	Z diff. (+) 0°2	L corr.	0°1	
tab.	162°7			sum	0°1	0°4
corr.	(−) 0°3			corr.		(−) 0°3
Z	S 162°4 E					
Zn	017°6					

The corrections are determined by inspection. In this example the tabulated value used as a base is compared with the value for the same d and L, but t 18°, to determine the t corr. Similarly, it is compared with the value for the same t and L, but d 22° to determine the d corr.; and with the value for the same t and d, but L 42° to determine the L corr. Interpolation is between whole degrees of t and L, but between half degrees of d. For declinations of more than 29°, the d interpolation interval varies.

If azimuth is needed to a greater precision than the nearest tenth of a degree, it should be determined by H.O. Pub. No. 260 or 261 (art. 2126), or by computation (art. 2125).

2008. Complete solution.—The complete solution includes all of the parts listed in article 2001. Because of the various alternatives available for the separate parts, a large number of variations might be used in the complete solution. The following examples combine some of the most commonly used variations.

Example 1.—On May 31, 1958, the 1425 DR position of a ship is lat. 40°39'6 N, long. 64°17'2 W. At watch time $2^h25^m51^s$ PM the navigator observes the lower limb of

the sun with a marine sextant having an IC of (−) 2'.0, from a height of eye of 36 feet. The watch is 23^s fast on zone time. The hs is 56°10'.9.

Required.—The *a*, Zn, and AP, using H.O. Pub. No. 214 (Δd only) and the *Nautical Almanac.*

Solution.—

	May 31	Sun		+	⊙	−
W	$2^h25^m51^s$ PM	18^h 21°55'.1 N *d*	IC			2'.0
WE	(F) 23^s	corr. (+) 0'.1 (+) 0'.3	D			5'.8
ZT	$14^h25^m28^s$	d 21°55'.2 N	⊙	15'.3		
ZD	(+) 4		sum	15'.3		7'.8
GMT	$18^h25^m28^s$ May 31		corr.			(+) 7'.5

Ho	56°18'.4					
a	0.6 A	*a*L 41°00'.0 N				
Zn	245°.8	*a*λ 63°58'.8 W				

It is good practice to have a standard work form. If this is not printed, or on a rubber stamp, it should be copied in its entirety before the solution is started. The first step should then be to fill in the known information. If the solution for observed altitude is made first, this value can then be copied in the main solution at the left of the form, so that it will be ready for comparison when Hc is determined. The best form to use is that which the individual navigator finds most logical and least likely to result in errors. Those shown in appendix Q, and used here, are slight modifications of forms developed at the United States Naval Academy, where they evolved as a result of long experience. Their use reduced materially the number of mistakes made in solutions. Some navigators include a time diagram (art. 1427) in the form, immediately below the name of the celestial body, as a check both on the time and meridian angle computation.

There is a growing tendency among navigators to keep the navigational watch set to GMT. This is particularly helpful when a number of observations are made, as during twilight, to eliminate the need for repeated application of watch error and zone description, and determination of Greenwich date. The use of a GMT watch is illustrated in the following example of a complete sight of the moon:

Example 2.—On June 2, 1958, the 0420 DR position of a ship is lat. 41°07'.6 N, long. 131°51'.2 W. At GMT $13^h24^m52^s$ the navigator observes the upper limb of the moon with a marine sextant having an IC of (+) 1'.5, from a height of eye of 29 feet. The hs is 7°40'.1.

Required.—The *a*, Zn, and AP, using H.O. Pub. No. 214 (Δd only) and the *Nautical Almanac.*

Solution.—

	June 2

The local date is used as the heading of the first column of the solution. The Greenwich date is recorded opposite GMT. In this example, the two dates are different. Even when they are the same, it is good practice to record both dates, to avoid possible error. It is desirable to show all closely related information on the same line, as t, t diff., and t corr. This is not always possible because of interference of other information. When this occurs, the form is changed in a way to cause the least upset to the usual form. Thus, in this example, it would be desirable to show ht, Δd, Δt, and Z on the same line and in the order these values are taken from H.O. Pub. No. 214. However, the sum of the t, d, and L corrections is at the logical place for Z, which is therefore kept in the same column, but moved *down* two spaces.

Example 4.—During evening twilight on June 1, 1958, the 1730 DR position of a ship is lat. 40°39.′2 S, long. 75°01.′2 E. At GMT $12^h31^m17^s$ the navigator observes Arcturus with a marine sextant having no IC, from a height of eye of 38 feet. The hs is 7°55.′2.

Required.—The *a*, Zn, and AP, using H.O. Pub. No. 214 (Δd only) and the *Air Almanac.*

Solution.—

	June 1	Arcturus		+	☆ −
GMT	$12^h31^m17^s$ June 1		IC	—	—
12^h30^m	76°59′		D		6′

Zn	056.°2	*a*λ 75°09′E			

Both ht and its correction are shown to tenths of a minute of arc, to avoid a possible error of 1′ in the algebraic sum, Hc.

There is no significance to the type of solution and almanac used with the various celestial bodies shown in the examples above. The combinations used for examples 1 (sun) and 2 (moon) are most commonly used by marine navigators, but the other two are shown to illustrate variations sometimes used at sea.

2009. Precomputation.—Sometimes it is desired to determine computed altitude *before* the observation, generally for the purpose of obtaining a line of position quickly after the observation has been completed. This is called **precomputation.** When it is done, sextant altitude corrections are generally applied *with reversed sign* to Hc to obtain **precomputed altitude (Hp)**, which is then compared directly with hs to obtain the altitude difference for plotting a line of position. Where altitude is needed for entering correction tables, the computed altitude (Hc) is used. The error introduced by this practice is negligible except at low altitudes, where the corrections should be adjusted by using the Hp to reenter the tables. If greater accuracy is required, limit precomputation to Hc and Zn, and apply corrections to the sextant altitude after observation.

Example.—On June 2, 1958, the 1025 DR position of a ship is lat. 42°21′.4 S, long. 118°47′.1 W. The navigator plans to observe the lower limb of the sun at this time with a marine sextant having an IC of (+)2′.5, from a height of eye of 25 feet.

Required.—(1) Precomputed altitude by H.O. Pub. No. 214, Δd only, (2) the *a*, Zn, and AP if hs is 22°23′.6. Use *Nautical Almanac.*

Solution.—

	June 2		Sun			+ $\odot$	−

(2) *a*	4.6 A	*a*L	42°00′.0 S				
Zn	022°.1	*a*λ	118°47′.3 W				

At the AP used in the calculation, Hp is correct only for the time used. However, if the observation is made early or late, the same Hp and Zn can be used by moving the AP along the parallel of latitude, eastward for early observations, or westward for late observations, a distance equal to 0′.25 of longitude for each second (15′.0 for each minute) difference between actual and predicted times. This adjustment is based upon the assumptions that the apparent motion of the body is westward at the rate of 15° per hour, and the declination is constant. Over the seconds or minutes likely to be involved, these assumptions and the possible increased length of the plotted lines do not introduce a significant error, except possibly for the moon.

2010. Low altitudes.—When Hc is determined by inspection tables such as H.O. Pub. No. 214, a minimum tabulated altitude may be available. In H.O. Pub. No. 214, altitudes below 5° are not given. These tables can be used for low-altitude observations by selection of an AP that will result in Hc being 5° or greater. To do this, proceed as follows: At the time of observation, note the approximate azimuth of the celestial body. Plot the azimuth line through the DR or EP and measure off, toward the celestial body, a distance equal to 6°−hs (or 6°−Ho). Select the AP in relation to this point as if it were the DR or EP. Occasionally it may be necessary to use 7°−hs (or 7°−Ho). The increased length of the altitude difference line does not introduce a significant error over the distance that a rhumb line can be considered identical to a great circle. Only in high latitudes is this a problem, and here the error can be virtually eliminated by using a chart projection on which a great circle plots as a straight line or approximately so. The error introduced by using a rhumb line to represent the circle of equal altitude (the line of position) is not increased because the AP selected is near the azimuth line.

Example.—On June 1, 1958, the 1625 DR position of a ship is lat. 43°39.′7 S, long. 15°07.′0 W. At GMT $17^h24^m22^s$ the navigator observes the lower limb of the sun as it breaks out below an overcast, shortly before setting. He uses a marine sextant having no IC, and makes his observation from a height of eye of 52 feet. The hs is 1°00.′8, air temperature (art. 1614) 24°F, and the atmospheric pressure (art. 1615) 30.16 inches. The sun's azimuth is approximately 305°.

Required.—The *a*, Zn, and AP using H.O. Pub. No. 214 (Δd only), the *Nautical Almanac*, and tables 23 and 24.

Solution.—

Ho	0°43.′1		hr			0°53.′8
a	276.2 A	*a*L 41°00.′0 S	Ho			0°43.′1
Zn	305.°5	*a*λ 20°40.′2 W				

Refer to figure 2010. From the 1625 DR position, the approximate azimuth of 305° is plotted, as shown by the broken line. Along this line a distance of 6°00.′0−0°43.′1=5°16.′9, or 316.9 miles, is measured, locating the point labeled *A*. The AP is selected with respect to this point as if it were the DR position. The sight is plotted from this AP as in any observation. If it makes the plot easier, record *a* in the solution in degrees and minutes of arc instead of in miles (5°19.′3−0°43.′1=4°36.′2=276.′2=276.2 miles).

Large altitude differences can be avoided by using a method of solution that provides for low altitudes. Among such methods are H.O. Pub. No. 249; nearly any trigonometric method such as the cosine-haversine formula, H.O. Pub. No. 208, or H.O. Pub. No. 211; and most graphical and mechanical methods. All of these methods are discussed in chapter XXI. If a trigonometric method is used, the *signs* of the various functions (or special rules) should be used if there is a possibility of Hc being negative. The rules needed for H.O. Pub. No. 208 and H.O. Pub. No. 211 are given in articles 2110 and 2111, respectively. The need for special care can be eliminated by using an assumed position about half a degree or more from the DR position or EP, in the direction of the celestial body, if the altitude is less than 0°30′.

By any method of solution, if *either* Hc or Ho (but not both) is negative, the altitude difference is found by numerically *adding* the two altitudes. Thus, if Hc is (+) 0°12.′6 and Ho is (−) 0°03.′2, the altitude difference, *a*, is 15.′8, or 15.8 miles. The positive altitude is greater than the negative one. Therefore, the *a* in this case is *away*. If *both* Hc and Ho are negative, the difference is found by subtraction, but in this case the one which is numerically smaller is the greater altitude. Thus, if Hc is (−) 0°09.′6 and Ho is (−) 0°04.′3, the altitude difference is 5.3 T.

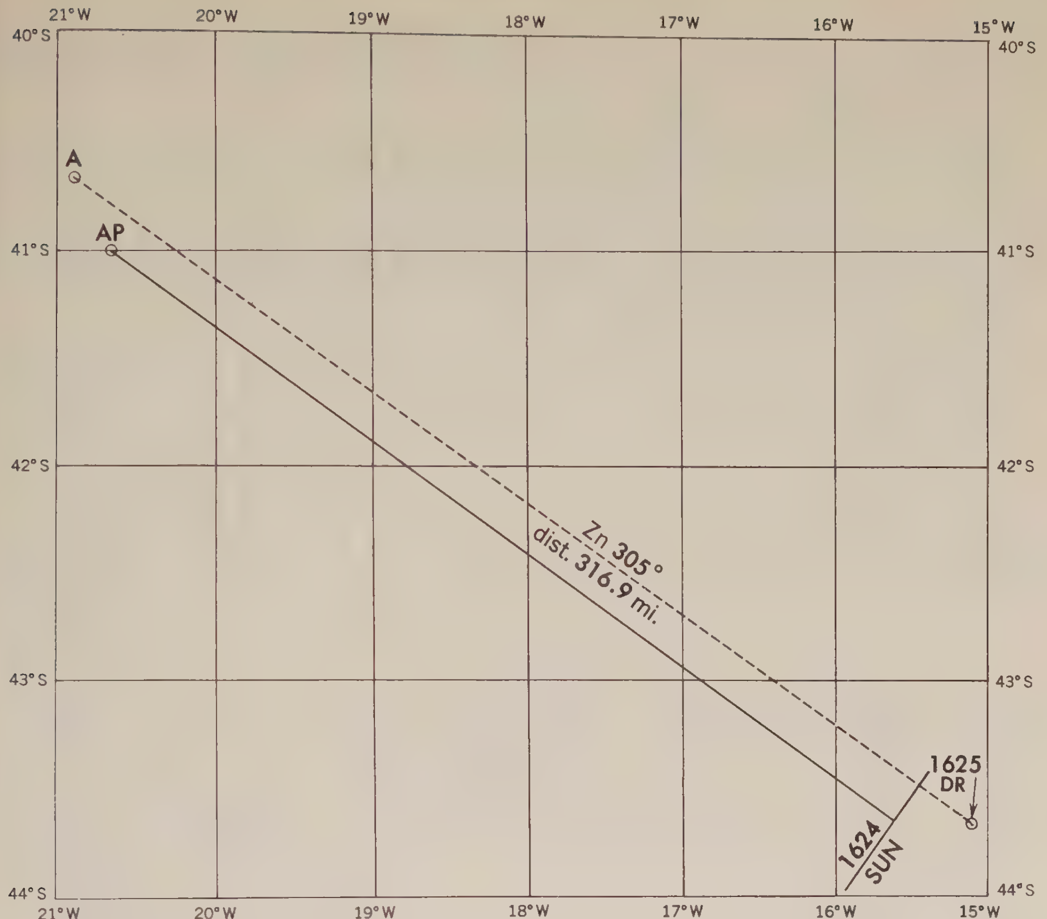

FIGURE 2010.—Selecting an AP for low-altitude solutions by H.O. Pub. No. 214.

2011. High altitudes are usually avoided for at least two reasons. First, bodies near the zenith are difficult to observe. A star or planet is difficult to "bring down" to the horizon. It is not always easy to determine the azimuth accurately, and when near the zenith, a body may be changing azimuth rapidly. On the other hand, such observations are little affected by astronomical refraction. The second reason for avoiding high altitudes is one of geometry. As the altitude increases, the radius of the circle of position decreases. For a body near the zenith, the radius is so small that the use of a straight line to approximate the circle may introduce serious error.

With higher altitudes, it is good practice to avoid use of lines of position extending a considerable distance from the azimuth line. Since the decrease in radius is gradual, there is no one altitude at which the curvature becomes excessive. However, a safe general rule, if one is needed, is to use the DR position or EP as the assumed position, and interpolate for azimuth angle, for all altitudes greater than 70°. The purpose of this is not primarily to decrease the altitude difference, as sometimes suggested, but to decrease the length of the line of position.

Within perhaps three degrees of the zenith, the curvature of the circle of position becomes so great that even for a short distance a straight line is not an adequate representation of the circle. At these altitudes, it is good practice to plot the line of position as a circle. This is done by using the geographical position (GP) of the celestial body as the center, and the zenith distance as the radius. Hence, no sight reduction tables

are needed. The same body can be used for obtaining a fix from two observations separated by several minutes. In celestial navigation, as in piloting, a circle of position is advanced or retired by moving its center.

Example.—On May 31, 1958, the 1224 DR position of a ship is lat. 20°17′.4 N, long. 50°07′.4 W. The ship is on course 127°, speed 18 knots. Using a marine sextant having no IC, the navigator observes the lower limb of the sun twice, from a height of eye of 65 feet. The first observation is made at GMT $15^h15^m15^s$, and hs is 88°01′.1. The second observation is made at GMT $15^h24^m13^s$, and hs is 87°34′.7. The GHA of the sun at GMT $15^h15^m15^s$ is 49°25′.9. Use the same declination as at GMT $15^h24^m13^s$.

Required.—The 1224 fix.

Solution.—

	May 31	
GMT	$15^h15^m15^s$	May 31

z			2°17′.2

Answer.—1224 fix: L 20°09′.0 N, λ 50°06′.0 W.

The plot of this problem is shown in figure 2011. No significant error would be introduced by assuming the same declination and sextant altitude correction for both observations, and a change of GHA equal to the arc equivalent of the time difference between observations (art. 1904). In east longitude the GP longitude would be 360° − GHA.

Problems

2002a. The GHA is 51°47′.3.

Required.—The LHA and t at (1) long. 138°14′.1 W, and (2) 65°11′.7 E.

Answers.—(1) LHA 273°33′.2, t 86°26′.8 E; (2) LHA 116°59′.0, t 116°59′.0 W.

2002b. The GHA is 135°17′.3.

Required.—The LHA, t, and AP for use with H.O. Pub. No. 214 without interpolation for t or L, if the DR position is (1) lat. 71°36′.9 N, long. 137°25′.3 W, and (2) lat. 8°14′.1 S, long. 96°41′.7 E.

Answers.—(1) LHA 358°00′.0, t 2°00′.0 E, *a*L 72°00′.0 N, *a*λ 137°17′.3 W; (2) LHA 232°00′.0, t 128°00′.0 E, *a*L 8°00′.0 S, *a*λ 96°42′.7 E.

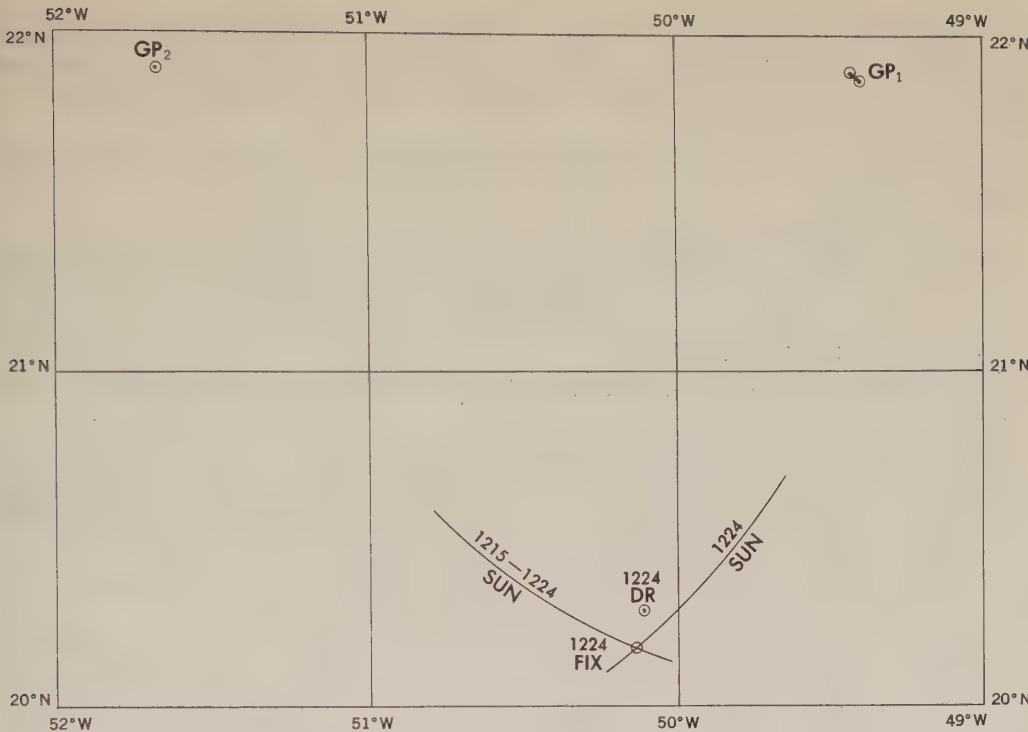

FIGURE 2011.—Plotting high-altitude observations.

2004. Find computed altitude (Hc) and azimuth (Zn) if *a*L is 42°00′.0 S, d is 21°09′.5 N, and t is 11°00′.0 E.

Answers.—Hc 26°01′.6, Zn 011°.4.

2005. Find computed altitude and azimuth if *a*L is 41°00′.0 S, d is 20°49′.1 S, and t is 37°11′.3 W.

Answers.—Hc 52°40′.1, Zn 291°.3.

2006. Find computed altitude and azimuth if *a*L is 41°53′.4 N, d is 19°45′.8 S, and t is 18°12′.7 W.

Answers.—Hc 26°05′.1, Zn 198°.8.

2007. Find the azimuth by interpolation if L is 41°33′.7 N, d is 20°18′.7 S, and t is 56°40′.5 E.

Answer.—Zn 127°.5.

2008a. On June 1, 1958, the 0425 DR position of a ship is lat. 41°07′.3 N, long. 153°03′.9 E. At GMT $18^h25^m16^s$ (May 31) the navigator observes Saturn with a marine sextant having no IC, from a height of eye of 30 feet. The hs is 9°13′.4.

Required.—The *a*, Zn, and AP, using H.O. Pub. No. 214 (Δd only) and the *Nautical Almanac.*

Answers.—*a* 2.0 A, Zn 230°.3, *a*L 41°00′N, *a*λ 152°48′.6 E.

2008b. On June 2, 1958, the 0625 DR position of a ship is lat. 40°38′.1 S, long. 24°08′.3 E. At watch time $6^h24^m48^s$ AM the navigator observes the upper limb of the moon with a marine sextant having an IC of (−) 2′.7, from a height of eye of 56 feet. The watch is 19^s slow on zone time. The hs is 14°38′.8.

Required.—The *a*, Zn, and AP, using H.O. Pub. No. 214 (Δd, Δt) and the *Nautical Almanac.*

Answers.—*a* 7.1 A, Zn 257°.9, *a*L 41°00′.0 S, *a*λ 24°08′.3 E.

2008c. During the morning of June 2, 1958, the 1025 DR position of a ship is lat. 41°12′.3 S, long. 13°45′.7 W. At GMT $11^h25^m42^s$ the navigator observes the lower limb of the sun with a marine sextant having an IC of (+) 1′.0, from a height of eye of 38 feet. The hs is 23°37′.3.

Required.—The *a*, Zn, and AP, using H.O. Pub. No. 214 (Δd, Δt, ΔL) and the *Nautical Almanac.*

Answers.—*a* 16.5 T, Zn 022°.3, *a*L 41°12′.3 S, *a*λ 13°45′.7 W.

2008d. During evening twilight on June 1, 1958, the 2100 DR position of a ship is lat. 40°47′.3N, long. 67°28′.7W. At ZT $21^h08^m01^s$ the navigator observes Arcturus through a break in the clouds, with a marine sextant having no IC, from a height of eye of 42 feet. The hs is 65°31′.8.

Required.—The *a*, Zn, and AP, using H.O. Pub. No. 214 (Δd only) and the *Air Almanac.*

Answers.—*a* 7 T, Zn 146°.8, *a*L 41°00′ N, *a*λ 67°33′ W.

2009. On June 3, 1958, the 0625 DR position of a ship is lat. 41°03′.7 S, long. 104°25′.6 E. The navigator plans to observe the upper limb of the moon at this time with a marine sextant having no IC, from a height of eye of 57 feet.

Required.—(1) Precomputed altitude by H.O. Pub. No. 214 (Δd, Δt, ΔL). (2) The *a*, Zn, and AP if hs is 19°09′.8. Use *Nautical Almanac.*

Answers.—(1) Hp 19°07′.1; (2) *a* 2.7 T, Zn 261°.6, *a*L 41°03′.7 S, *a*λ 104°25′.6 E.

2010a. On June 2, 1958, the 0725 DR position of a ship is lat. 45°07′.3 S, long. 48°05′.8 E. At GMT $4^h25^m21^s$ the navigator observes the lower limb of the sun shortly after the upper limb disappears behind an overcast, soon after sunrise. He uses a marine sextant having an IC of (+) 1′.2, and makes his observations from a height of eye of 35 feet. The hs is 0°45′.2, air temperature 30° F, and the atmospheric pressure 29.74 inches. The sun bears approximately 050°.

Required.—The *a*, Zn, and AP using H.O. Pub. No. 214 (Δd only), the *Nautical Almanac,* and tables 23 and 24.

Answers.—*a* 289.1A, Zn 053°.8, *a*L 42°00′.0 S, *a*λ 53°06′.0 E.

2010b. If Hc is 5°09′.2 and Ho is (−) 0°03′.4, find *a*.

Answer.—*a* 5°12′.6 A, or 312.6 A.

2010c. If Hc is (−) 0°18′.4 and Ho is (−) 0°01′.3, find *a*.

Answer.—*a* 17.1 T.

2011. On June 2, 1958, the 1225 DR position of a ship is lat. 23°47′.8 N, long. 130°13′.2 E. The ship is on course 200°, speed 20 knots. Using a marine sextant having an IC of (−) 2′.2, the navigator observes the lower limb of the sun twice, from a height of eye of 43 feet. The first observation is made at GMT $3^h10^m35^s$, and hs is 87°34′.8. The second observation is made at GMT $3^h25^m10^s$, and hs is 87°13′.4. The GHA of the sun at GMT $3^h10^m35^s$ is 228°12′.6. Assume no change in declination between observations.

Required.—The GP at the time of each observation, the radius of each circle of position, and the 1225 fix.

Answers.—GP L_1 22°06′.5 N, GP λ_1 131°47′.4 E, GP L_2 22°06′.5 N, GP λ_2 128°08′.7 E; radius$_1$ 137.9 mi., radius$_2$ 159.3 mi.; 1225 fix: L 23°52′.5 N, λ 130°17′.1 E.

CHAPTER XXI

COMPARISON OF VARIOUS METHODS OF SIGHT REDUCTION

2101. Introduction.—Before the development of a means of determining accurate time at sea (art. 127), longitude could not be found by celestial observation. Celestial bodies were used for determination of latitude, and as an indication of direction, often in a very general way. The development of the marine chronometer opened up a whole new vista to the navigator. Immediately, methods began to appear to utilize this new dimension of navigation. During the two centuries that have elapsed, many of the best minds have been directed to the problem of providing easier or more adequate methods of "reducing" the observations to a form suitable for determination of position.

2102. Kinds of methods.—Various "special" methods have been devised to take advantage of some unique relationship to provide a simplified solution. The most widely used are **latitude methods** for determination of latitude by meridian altitude or observation of Polaris, and **longitude methods** for determination of longitude by observation of a body near the prime vertical. Both latitude and longitude methods have now been largely superseded by the **altitude method,** based upon the discovery of the altitude difference, or intercept, by the Frenchman Marcq St.-Hilaire (art. 131). Most modern methods are of this type, although some latitude and longitude methods are still in use.

The most commonly used methods utilize computation for determining certain information which is then plotted as a line of position, two or more such lines being needed for a fix. The "method" might consist of one or more formulas to be solved by general mathematical tables, a set of special tables conveniently arranged for use with the formulas, or a set of tables constituting a list of computed answers. A method which determines latitude or longitude separately requires no plot. In fact, a plot would be misleading unless the celestial body were almost exactly on the celestial meridian or prime vertical, or unless the azimuth were considered. While a number of methods determine latitude and longitude by computation, without plotting, other methods substitute a graphical or mechanical solution for computation.

2103. Meridian altitudes.—If a celestial body is on the celestial meridian at the time of observation, a modification of the high-altitude method (art. 2011) can be used at any altitude, without plotting the GP. Both GP and observer are on the same meridian, and the difference of latitude between them is the zenith distance of the body ($90°-$Ho). The direction of the GP is the direction faced during observation (unless a backsight is made). The line of position is a latitude line.

Example 1.—At GMT $16^h24^m15^s$ on June 2, 1958, the navigator observes the lower limb of the sun on the celestial meridian, bearing north. He makes the observation with a marine sextant having an IC of (+) 2.′6, from a height of eye of 33 feet. The hs is 29°14.′6.

Required.—The latitude.

Solution.—

June 2
GMT $16^h24^m15^s$ June 2
GP L 22°10.′8N
l 60°34.′1S
L 38°23.′3S

Sun		
16^h 22°10.′7N	*d*	
corr.	(+)0.′1	(+)0.′3
d 22°10.′8N		

	+	⊙ −
IC	2.′6	
D		5.′6
⊙	14.′3	
sum	16.′9	5.′6
corr.		(+) 11.′3
hs		29°14.′6
Ho		29°25.′9
z		60°34.′1

Since the observer faces *north,* he is *south* of the GP. The GP latitude is equal to the declination, and the difference of latitude is equal to the zenith distance of the body. Since the body is known to be over the meridian, a knowledge of the longitude is not needed. Neither is a knowledge of the approximate latitude of the observer needed, but this information is useful, as it provides a check to prevent a gross error. Also, it can serve as the basis for precomputation, most of the solution being made before observation. The time is needed only for determining declination. If the body is observed at *lower* transit, the latitude is equal to observed altitude (Ho) plus polar distance (p=90°−d) of the body: L=Ho+p.

If an observation is made near but not exactly at meridian transit, it can be solved as a meridian altitude, with one modification. Enter table 29 with the approximate latitude of the observer and the declination of the body, and take out the **altitude factor** (*a*). This is the difference between meridian altitude and the altitude one minute of time later (or earlier). Next, enter table 30 with the altitude factor and the difference of time between meridian transit and the time of observation, and take out the correction. *Add* this value to Ho if near upper transit, or *subtract* it from Ho if near lower transit. Then proceed as for a meridian altitude, remembering that the value obtained is the latitude at the time of observation, not at the time of meridian transit. This method should not be used beyond the limits of table 30 unless reduced accuracy is acceptable. This process is called **reduction to the meridian,** the altitude before adjustment an **ex-meridian altitude,** and the observation an **ex-meridian observation.** It requires knowledge of the meridian angle, which depends upon knowledge of longitude. If reasonable doubt exists regarding the longitude, the azimuth of the body at the time of observation should be determined, and the line of position drawn perpendicular to it (through the point defined by the "observed" latitude and the assumed longitude), rather than as a latitude line. There are alternative methods available. A correction to latitude can be applied, using the factor f from table 26. In 1899 A. A. Vilkitskiy, a captain in the Russian Navy, developed a mechanical device for determining the correction to be applied for reduction to the meridian.

Several hundred years ago, when longitude could not be found accurately, and logarithms had not been invented, the finding of latitude furnished the only reliable navigation available on long sea voyages. Since most of these were in a generally easterly or westerly direction, it became common practice to sail first to the latitude of destination ("run down the latitude") and then to follow this parallel until landfall was made. The meridian observation of the sun at local apparent noon was the most important navigational event of the day, and became a well-established routine. On the basis of this observation at "high noon," clocks were reset, and a new day, the **nautical day,** began. Intentional meridian altitudes of other celestial bodies were not as widely used as those of the sun.

As accurate time became available at sea, and then more convenient tables and more accurate almanacs appeared, the noon sight lost its importance. Since the modern inspection table has been available, the use of meridian altitudes has decreased rapidly, and reduction to the meridian has all but disappeared. True, the solution of a meridian altitude is simple and quick, but this is more than offset by the need for determining the time at which to make the observation (art. 2104), the dislike of many mariners for having to make an observation at a predetermined time, the inconvenience sometimes experienced when local apparent noon occurs at a time when other activities conflict with observation, and the possibility of missing the observation because of overcast conditions. The practice of observing a body when a line of position is desired, and solving those which happen to have a meridian angle of 0° or 180° in the same manner as other observations, is a growing practice that eliminates the need for remembering a separate procedure for bodies on the celestial meridian. The modern navigator thinks primarily in terms of lines of position, rather than of latitude and longitude observations.

Example 2.—On June 2, 1958, the 1225 DR position of a ship is lat. 41°21′.2 S, long. 127°07′.3 W. At GMT $20^h25^m48^s$ the navigator observes the lower limb of the sun with a marine sextant having no IC, from a height of eye of 40 feet. The hs is 26°20′.1.

Required.—(1) The *a*, Zn, and AP, using H.O. Pub. No. 214 (Δd only) and the *Nautical Almanac.*

(2) The latitude at the time of observation.

Solution.—

	June 2		Sun		+ ☉	−
GMT	$20^h25^m48^s$ June 2	20^h	22°12′.0 N *d*	IC	—	—
20^h	120°32′.1	corr.	(+)0′.1 (+)0′.3	D		6′.1
25^m48^s	6°27′.0	d	22°12′.1 N	☉	14′.1	
GHA	126°59′.1			sum	14′.1	6′.1
*a*λ	126°59′.1 W			corr.		(+)8′.0
LHA	0°00′.0			hs		26°20′.1
t	0°00′.0			Ho		26°28′.1
d	22°12′.1 N	d diff.	12′.1			
*a*L	41°00′.0 S					
ht	27°00′.0	Δd	(−)1.0	Z	S180°.0 (E or W)	
corr.	(−) 12′.1					
Hc	26°47′.9					
Ho	26°28′.1					
(1) *a*	19.8 A	*a*L	41°00′.0 S			
Zn	000°.0	*a*λ	126°59′.1 W			

(2) L 41°19′.8 S

Since the azimuth is 000°, the line of position is a latitude line. It is 19′.8 south (*away* from 000°) of the assumed latitude of 41°00′.0, or latitude 41°19′.8 S.

When Δd is 1.0, the altitude changes one minute for each one minute change of declination. Therefore, the correction to ht is numerically equal to d diff. For this reason, no entry is given in the "multiplication table" for a Δ value of 100 (1.0). A Δ value of 1.0 should not be confused with one of 0.01 or 0.10.

2104. Finding time of meridian transit.—If a meridian altitude is to be observed, other than by chance, a knowledge of the time of transit of the body across the meridian is needed.

On a slow-moving vessel, or one traveling approximately east or west, the time need not be known with great accuracy. The right-hand daily page of the *Nautical*

Almanac gives the GMT of transit of the sun and moon across the Greenwich meridian (approximately LMT of transit across the local meridian) under the heading "Mer. Pass." In the case of the moon, an interpolation should be made for longitude. This is performed in the same manner as finding the LMT of moonrise and moonset (art. 1812). In the case of planets, the tabulated accuracy is normally sufficient without interpolation. The time of transit of the navigational planets is given at the lower right-hand corner of each left-hand daily page of the *Nautical Almanac*. The tabulated values are for the middle day of the page. These times are the GMT of transit across the Greenwich meridian, but are approximately correct for the LMT of transit across the local meridian. Observations are started several minutes in advance and continued until the altitude reaches a maximum and starts to decrease (a minimum and starts to increase for lower transit). The greatest altitude occurs at upper transit (and the least at lower transit). This method is not reliable if there is a large northerly or southerly component of the vessel's motion, because the altitude at meridian transit changes slowly, particularly at low altitudes. At this time the change due to the vessel's motion may be considerably greater than that due to apparent motion of the body (rotation of the earth), so that the highest altitude occurs several minutes before or after meridian transit.

If the moment at which the azimuth is 000° or 180° can be determined accurately, the observation can be made at this time. However, this generally does not provide a high order of accuracy.

If the longitude is known with sufficient accuracy, the time of transit can be computed. A number of methods of computation have been devised, but perhaps the simplest is to consider the GHA of the body equal to the longitude if west, or 360°–λ if east, and find the time at which this occurs.

Example.—Find the zone time of meridian transit of the sun at longitude 156° 44!2 W on May 31, 1958.

Solution.—

		May 31
λ		156°44!2 W
GHA		156°44!2
22^h		150°36!4
24^m31^s		6°07!8
GMT		$22^h24^m31^s$ May 31
ZD	(+)	10 (rev.)
ZT		$12^h24^m31^s$

This solution is the reverse of finding GHA. The largest tabulated value of GHA that does not exceed the desired GHA is found in the tabulation for the day, and recorded, with its time. The difference between this value and the desired GHA is then used to enter the "Increments and Corrections" table. The time interval corresponding to this value is added to the time taken from the daily page. If there is a *v* correction, it is subtracted from the GHA difference before the time interval is determined. For such bodies, the *Air Almanac* solution is easier, but not as precise by a fraction of a second of time. The GMT can be converted to any other kind of time desired. If the Greenwich date differs from the local date at the time of transit (for the sun this can occur only near the 180th meridian), a second solution may be needed. This possibility can often be avoided by making an approximate mental solution in advance. As the basis for this approximate solution, it is convenient to remember that the GMT of Greenwich transit (GHA 0°) is about the same as the LMT of local transit. To find the time of transit of a star, subtract its SHA from the desired GHA to find the

desired GHA♈. Determine the time corresponding to GHA♈, as explained above for the sun.

Aboard a moving vessel, the longitude at transit usually depends upon the time of transit. An approximate mental solution may provide a time sufficiently close. In the absence of better information, use ZT 1200 for the sun. Find the time of transit for the position at this time, and then make an adjustment, if necessary, for the sun between 1200 and the time found by computation. This adjustment is equal to four seconds for each minute of longitude involved. If the ship is *west* of the 1200 position at the computed time of transit, *add* the correction; and if *east*, *subtract* it. For high accuracy a second adjustment may occasionally be needed, but this is seldom justified because of the uncertainty of the vessel's position.

The time of transit of the sun can also be found by means of apparent time (art. 1912). Meridian transit occurs at LAT $12^h00^m00^s$. This can be converted to any other kind of time desired.

2105. Latitude by Polaris.—Another special method of finding latitude, available in most of the northern hemisphere, utilizes the fact that Polaris is less than 1° from the north celestial pole. As indicated in article 1432, the altitude of the elevated pole above the celestial horizon is equal to the latitude. Since Polaris is never far from the pole, its observed altitude (Ho), with suitable corrections, is the latitude.

Three corrections are commonly applied. The first, and principal one, is illustrated in figure 2105. In this figure, *P* is the north celestial pole, and the circle is the path followed by Polaris as it circles the pole daily. When Polaris is directly above the pole, at *A*, on the upper branch of the celestial meridian, the polar distance (90°−d) is subtracted from Ho to obtain latitude. At *B*, on the lower branch of the celestial meridian, this value is *added*. At *C* and *C′*, with meridian angle approximately 90°E or W (see below), there is no correction. At any other point, such as *D*, the correction is between these extreme values, being equal to the polar distance multiplied by the cosine of the meridian angle (approximately). This is shown at *D′P*.

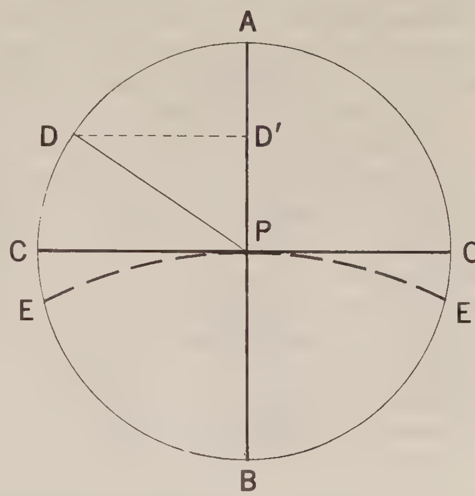

FIGURE 2105.—Latitude by Polaris.

The second correction corrects for the tilt of the diurnal circle of Polaris with respect to the vertical. Refer again to figure 2105. Zero correction occurs at *C* and *C′*, when Polaris is at the same altitude as the north celestial pole. Thus, point *C*, *P*, and *C′* are all on a parallel of altitude, which is a small circle everywhere the same angular distance above the celestial horizon. However, a meridian angle of 90°E or W occurs when Polaris is on an hour circle 90° from the celestial meridian. These 90° hour circles are not horizontal, like the circle of equal altitude, but are tilted *downward* toward the celestial horizon, which they cross at the prime vertical. Therefore, these 90° hour circles (*EPE′*) do not intersect the diurnal circle of Polaris at *C* and *C′* but at *E* and *E′*, which are at a lower altitude than the pole. The discrepancy between these points (*C–E* and *C′-E′*) increases as the latitude increases from zero at the equator to a maximum at the pole.

The third correction is needed because Polaris, being near the celestial pole, has a relatively large change in coordinates due to precession of the equinoxes (art. 1419) and aberration (art. 1417). The correction is the difference between actual coordinates and those used for the first correction.

In the Polaris correction tables of the *Nautical Almanac*, a constant is added to each correction so that all tabulated values are positive. The sum of the constants is 1°. Therefore, this value (1°) is subtracted from the result. The table at the top of each Polaris correction page is entered with LHA Aries, and the first correction (a_0) is taken out by single interpolation. The second and third corrections (a_1 and a_2, respectively) are taken from the double entry tables without interpolation, using the LHA Aries column with the latitude for the second correction and with the month for the third correction.

Example.—During morning twilight on June 2, 1958, the 0525 DR position of a ship is lat. 15°43′.6 N, long. 110°07′.3 W. At watch time $5^h24^m49^s$ AM the navigator observes Polaris with a marine sextant having an IC of (−)3′.0, from a height of eye of 44 feet. The watch is 23^s slow on zone time. The hs is 16°24′.0.

Required.—The latitude.

Solution.—

	June 2
W	$5^h24^m49^s$ AM
WE	(S) 23^s
ZT	$5^h25^m12^s$
ZD	(+)7
GMT	$12^h25^m12^s$ June 2
12^h	70°27′.0
25^m12^s	6°19′.0
GHA ♈	76°46′.0
λ	110°07′.3 W
LHA ♈	326°38′.7
Ho	16°11′.3
corr.	(−) 26′.2
L	15°45′.1 N

Polaris	+	−
a_0	33′.2	
a_1	0′.3	
a_2	0′.3	
add'l		60′.0
sum	33′.8	60′.0
corr.		(−) 26′.2

	+ ☆ −
IC	3′.0
D	6′.4
☆-P	3′.3
sum	(−) 12′.7
corr.	(−) 12′.7
hs	16°24′.0
Ho	16°11′.3

Since LHA ♈ is an entering value in all three correction tables, and since this is affected by the longitude, other observations, if available, should be solved and plotted first, to obtain a good longitude for the Polaris solution. For greater accuracy, particularly in higher latitudes, and especially if considerable doubt exists as to the longitude, it is good practice to find the azimuth of Polaris and draw the line of position perpendicular to it, through the point defined by the latitude found in the computation and the longitude used in the solution. The azimuth at various latitudes to 65° N is given below the Polaris corrections. This table can be extrapolated to higher latitudes, but Polaris would not ordinarily be used much beyond latitude 65°. In the example given above the azimuth is 000°.9.

The *Air Almanac* provides only the first correction, which it designates Q.

Polaris observations can be solved like those of other celestial bodies, using the declination and SHA given in the tabulation near the back of the *Nautical Almanac*, if a method of solution providing for such a high declination is available. H.O. Pub. No. 214 is not designed for solution of Polaris observations.

Like other special solutions, latitude by Polaris has lost much of its popularity since modern inspection tables have become available. Being of magnitude 2.1, Polaris is not a bright star. It is normally considered available to the mariner only during twilight, when the azimuths of various celestial bodies relative to each other are of

more interest than an "easy" solution which is little, if at all, simpler than the usual solution by inspection table. If provision were made for solution of Polaris sights by inspection table, the special method would no longer be needed for ordinary navigation.

2106. Longitude methods.—A celestial observation for a line of position, whether reduction is to be by longitude method or by latitude method, consists of measurement of the altitude of a body with the noting of the time. If sight reduction is to be by the longitude method, the latitude must be known, or the best estimate used. With altitude, latitude, and declination (from the almanac), one is able to solve the navigational triangle (art. 1433) for meridian angle. This is converted to local hour angle. The Greenwich hour angle at the time of observation is determined by means of the almanac. The difference between the GHA and LHA is the longitude. A time diagram (art. 1427) is useful in establishing the correct relationship.

Longitude can also be determined by establishing the exact time of meridian transit, at which time the GHA (or 360°−GHA) is the longitude (art. 2104).

If the latitude is known accurately, the longitude method provides a direct and relatively simple solution for position. However, since latitude is rarely known to the desired accuracy, a line of position is usually needed. This is obtained by either (1) solving for longitude at two or more assumed latitudes, and drawing a straight line through the points thus found (the Sumner method), or (2) solving for longitude at one point, determining the azimuth at this point, and drawing the line of position through the single point thus found, perpendicular to the azimuth of the body.

The error introduced in the computed longitude as a result of an inaccurate latitude used in the solution increases as the celestial body departs from the prime vertical. If it is learned that an incorrect latitude has been used in the solution, a correction can be applied, using the factor F from table 26. If the body is near the celestial meridian, a small error in the latitude introduces a large error in the longitude. At any location, the azimuth of the body can be determined by observation or computation, and a line of position drawn perpendicular to it, through the position defined by the latitude used in the computation, and the calculated longitude. Alternatively, solution can be made at two or more latitudes, and the line of position drawn through the two positions. It was the use of this second method in 1837 by Captain Thomas H. Sumner, when his latitude was in doubt, that led to the discovery of the line of position from celestial observation (art. 131).

No longitude method is more accurate than the GMT used for timing the observation. Before chronometers (art. 1514) and time signals (art. 1909) were available, relatively few navigators attempted to determine longitude, and it was never established reliably. The search for a method of "discovering" longitude at sea was primarily a search for a means of determining time at the Greenwich meridian (arts. 126, 127).

If the longitude is to be determined, most accurate results are obtained by observation of a body on the prime vertical. The observation having been made, sight reduction can be made by time sight or, more conveniently, by an ordinary solution for a line of position, using an inspection table such as H.O. Pub. No. 214. Any general method of sight reduction can be used, without need for a special solution.

Solution by the longitude method is usually called a **time sight.** The various longitude methods are all basically the same, differing only in choice of formulas and arrangement of tables. The basic formula is

$$\cos t = \frac{\sin h - \sin L \sin d}{\cos L \cos d},$$

in which t is the meridian angle, h is the altitude, L is the latitude, and d is the declination. Early tables for solution of meridian angle were called **horary tables.**

The time sight came into use following the development of the marine chronometer in 1763. Solution for meridian angle is usually by the formula

$$\text{hav } t = \sec L \csc p \cos s \sin (s-h),$$

in which $p=90°-d$ if L and d have same name, and $90°+d$ if L and d have contrary names; and $s=\frac{1}{2}(h+L+p)$.

When azimuth angle is used with the method, it is usually computed by one of the formulas

$$\sin Z = \sin t \cos d \sec h$$

or

$$\text{hav } (180°-Z) = \sec h \sec L \cos s \cos (s-p).$$

There are no rules with this method, but it is subject to possible large errors in high latitudes or if the body has a high declination. Various special tables have appeared for solution of the time sight:

Cassini. The first "inspection tables" were probably prepared by M. Cassini, a Frenchman, in 1770. These "horary tables" provided tabulated solutions for meridian angle.

Lalande. The horary tables prepared in 1793 by Jerome Lalande, a Frenchman, provided tabulated solution for meridian angle for the sun and stars for all latitudes to 61°.

Lynn Horary Tables, by Thomas Lynn, a commander of the East India Company Service, were published in 1827. These 242-page tables consisted of tabulated solutions of meridian angle computed by the time sight formula. Two years later they were followed by a volume of 364 pages of azimuth angle (*Lynn Azimuth Tables*) computed by the haversine azimuth formula. Entries are given for whole degrees of latitude to 60°, declination to 24°, and altitude to 60° (later 90°). The tables are accurate and well arranged, but the triple interpolation is tedious.

Hommey. Louis Hommey's *Table d'angles horaires* (horary tables), published in two volumes in France in 1863, contained more than 40,000 hour angles calculated for "all latitudes." These tables were an improvement on those of Cassini and Lalande.

Martelli. In 1873 a small volume of 49 pages by G. F. Martelli, an Italian, was published in New Orleans. This book, called simply *Tables of Logarithms*, provided a relatively short, fast solution for meridian angle, with very few rules and only one interpolation. Martelli abandoned the inspection table and provided five short tables for a four-place logarithmic solution by the formula

$$\text{hav } t = \frac{\cos (L \sim d) - \cos z}{2 \cos L \cos d}.$$

Solution required six book openings, six table entries, and four mathematical steps. Hour angles were given only to eight hours, and no provision was made for azimuth.

This method proved very popular, and is still used among navigators of several countries. A 1932 edition was published in Glasgow, Scotland, with explanations in French, Dutch, Italian, and Spanish, as well as in English. A 1944 edition added provision for finding azimuth angle, and for solution by the altitude method.

Thomson. A table of only nine pages by Sir William Thomson, better known as Lord Kelvin, was published in London in 1876 to provide a solution for the longitude method. This very thin volume, called *Tables for Facilitating Sumner's Method at Sea*, contains the first known solution by dividing the navigational triangle into two right triangles. In 1849 Towson (art. 2126) had divided the triangle in the same manner, but his solution was for reduction to the meridian. Lord Kelvin divided the triangle by dropping a perpendicular from the celestial body to the celestial meridian of the

observer, as shown in figure 2111. He used a for the length of the perpendicular v, b for x, and b' for w (of fig. 2111). His solution uses the formulas

$$\sin \mathrm{t}=\frac{\sin a}{\cos \mathrm{d}},$$

$$\cos b=\frac{\sin \mathrm{d}}{\cos a},$$

$$\sin \mathrm{h}=\cos a \cos b',$$

$$\sin \mathrm{z}=\frac{\sin a}{\cos \mathrm{h}}.$$

The tables are entered with *half* the colatitude (using colatitude to the nearest whole degree) in column b. With a pair of dividers, search is made in the "cohypo" column for two numbers, one agreeing with the altitude, and the other with the declination. The number in column A opposite the altitude in the cohypo column is the azimuth angle, and that opposite the declination is the meridian angle, interpolation being used if needed. The line of position is adjusted for the difference between the interpolated altitude and the observed altitude.

Although the tables are among the shortest of the various methods, their manipulation is difficult. In 1880 Kortazzi, a Russian astronomer, attempted to modify the tables to provide an easier solution, but without great success.

Davis' *Chronometer Tables,* providing a solution for the longitude method, were published in 1897 in London. They are similar to Lynn's tables, using his values but providing assistance in interpolation by adding values of change with latitude, declination, and altitude. As with Lynn, a separate volume is given for azimuth angle, in which there is no interpolation. Originally Davis' tables were limited to latitude 50° and declination 24°, but later tables were published for declinations 23° to 64°. A limited number of altitude entries is given.

Blackburne. Tables by H. S. Blackburne, a New Zealander, were published in London in 1914 under the title *The Excelsior Azimuth and Position Finding Table.* The tables, providing a solution by the longitude method, are similar to *Lynn Horary Tables* and Davis' *Chronometer Tables* but with a new determination of azimuth based upon the ratio of variation of latitude to variation of meridian angle. Azimuth angles (ten pages) are given in a separate tabulation in the same volume with meridian angles (242 pages).

Blackburne's arrangement is more modern than that of Davis. This was the first publication to include columns for variations of t for 1′ of declination, latitude, and altitude. Meridian angles are given to 0ˢ1. Latitude is limited to 30°, and declination to 23°.

Rust. In 1918 the *Practical Tables for Navigators and Aviators,* by Captain Armistead Rust, USN, were published in Philadelphia. This small volume of 37 pages of tables reverted to a logarithmic solution, as did Martelli's, using the following formula for determining meridian angle:

$$\log \mathrm{hav}\ \mathrm{t}=\log \sec \mathrm{L}+\log \sec \mathrm{d}+\log \tfrac{1}{2}\,[\cos (\mathrm{L}\sim\mathrm{d})-\sin \mathrm{h}].$$

The volume has three tables. Table A tabulates log secants for obtaining the first two terms of the formula. Table B is a double-entry table giving log ½[cos (L∼d) −sin h]. Table C gives log haversines. Values are given to four places.

Azimuth angle is obtained from an original diagram computed from the well-known formula

$$\sin \mathrm{Z}=\sin \mathrm{t} \cos \mathrm{d} \sec \mathrm{h}.$$

This diagram had been given in a volume of ex-meridian tables by Rust published in 1908. In the *Practical Tables* an auxiliary diagram was added to indicate the meridian angle when the celestial body is on the prime vertical. The purpose of the diagram is to resolve possible ambiguities when the azimuth angle is near 90°. The Rust azimuth diagram was used later by Goodwin and Weems, and in the Italian *Tavole H* (art. 2110).

Goodwin. *The Alpha, Beta, Gamma Navigation Tables* of H. B. Goodwin, an Englishman, were first published in London in 1921. This is a small volume having two tables with a total of 34 pages. Meridian angle is found from the formula

$$\text{ver } t = \frac{\cos (L \sim d) - \cos z}{\cos L \cos d}.$$

Table I has two values, α being the angle in seconds of arc, and β being four-place natural cosines multiplied by 1,000 to eliminate the decimal. Table II provides γ, the logarithms for the values of versine t.

The Rust diagram is used for determining azimuth angle.

Instructions are included for use of the tables for altitude method of solution, and for reduction to the meridian.

H.O. Pubs. Nos. 203 and 204 (Littlehales), *The Sumner Line of Position of Celestial Bodies*, were published by the U. S. Navy Hydrographic Office in 1923. These tables, prepared by George W. Littlehales, provide in two large volumes (847 and 675 pages, respectively) tabulated solutions of the meridian angle and azimuth angle, using the general time sight formulas. The arrangement is similar to that of Davis and Blackburne, but t and Z are tabulated together in consecutive columns. Latitude is limited to 60°, and declination to 27° in H.O. Pub. No. 203 and to 64° in H.O. Pub. No. 204. Interpolation for latitude is avoided by using the nearest whole degree, and shifting the line of position for the difference between the altitude at this latitude and the observed altitude.

These publications are no longer in print.

Soule and Dreisonstok. In 1932 these two Americans prepared a small volume providing a logarithmic solution of the longitude method, using the formulas

$$\frac{1}{\text{hav } t} = \frac{\sec s \csc (s-h)}{\sec L \csc p}$$

and

$$\frac{1}{\text{hav } (180° - Z)} = \frac{\sec s \sec (s-p)}{\sec L \sec h},$$

where $s = \frac{1}{2}(h+L+p)$ and $p = 90° \pm d$.

The "azimuth" determined in this way is the direction of the line of position ($Z \pm 90°$) rather than that of the celestial body.

Weems' ***Secant Time Sight*** was published in 1944 by Captain P. V. H. Weems, USN (Ret.), to provide a short solution based entirely upon secants and cosecants, using the formulas

$$\csc^2 \tfrac{1}{2} t = \frac{\sec s \csc (s-h)}{\sec L \sec d}$$

and

$$\csc Z = \frac{\csc t \sec d}{\sec h},$$

where $s = \frac{1}{2}(h+L+p)$. A Rust azimuth diagram is included for those who prefer a diagrammatic solution.

2107. Finding time on prime vertical.—Best results by time sight are obtained when the celestial body is on the prime vertical. As explained in article 1432, a celestial

body having a declination of opposite name to the latitude crosses the prime vertical below the horizon. Its nearest visible approach is at the time of rising and setting.

If a celestial body has a declination of the same name as the latitude, but is numerically *greater*, it does not cross the prime vertical. Its nearest approach (in azimuth) is at the point at which its azimuth angle is maximum. At this point the meridian angle is given by the formula

$$\sec t = \tan d \cot L,$$

and its altitude by the formula

$$\csc h = \sin d \csc L.$$

A celestial body having a declination of the same name as the latitude, and numerically *smaller*, crosses the prime vertical at some point before it reaches the celestial meridian, and again after meridian transit. At these two crossings of the prime vertical, the meridian angles are equal and are always less than 90°. They are given by the formula

$$\cos t = \tan d \cot L.$$

The altitudes are also equal, and are given by the formula

$$\sin h = \sin d \csc L.$$

Meridian angle and altitude of bodies on the prime vertical, and similar data for the nearest approach (in azimuth) of those bodies of same name which do not cross the prime vertical, are given in table 25 for various latitudes, and for declinations from 0° to 23°, inclusive. Similar information can be determined by means of H.O. Pub. No. 214, entering with latitude and declination, and finding the meridian angle and altitude corresponding to an azimuth angle of 90° (or the maximum azimuth angle for nearest approach). Since this information is generally not required to great accuracy, interpolation is not needed.

To find the *time* of crossing the prime vertical, convert t to LHA, and add west longitude or subtract east longitude to find GHA. The GMT at which this GHA occurs can be found, as explained in article 2104, and converted to any other time desired.

Example.—Determine (1) the approximate zone time, and (2) the approximate altitude of the sun when it crosses the prime vertical during the afternoon of May 30, 1958, at lat. 51°32′.3 N, long. 160°21′.7 W, using table 25 and the *Nautical Almanac.*

Solution.—

	May 30	
t	71°.6 W	(from table 25)
LHA	71°.6	
λ	160°.4 W	
GHA	232°.0	
3^h	225°.6	
26^m	6°.4	
GMT	0326	May 31
ZD (+)	11	(rev.)
(1) ZT	1626	May 30
(2) h	28°.4	(from table 25)

At the time of crossing the prime vertical, or at nearest approach (in azimuth), a celestial body is changing azimuth slowly, and therefore this is considered a good time to check compass deviation or to swing ship.

The prime vertical at any place is the celestial horizon of a point 90° away, on the same meridian. Therefore, a celestial body crosses the prime vertical at approximately

the same time it rises and sets at the point 90° away. Thus, if one is at latitude 35° N, the sun crosses his prime vertical at about the same time it rises or sets at latitude 55° S. If time of sunrise and sunset are to be obtained accurately by this method, corrections must be applied for semidiameter and refraction.

2108. Altitude methods, like longitude methods, require an accurately timed observed altitude of a celestial body. Usually, in both types of solution, the navigational triangle is solved, but in the altitude method, t, d, and L are used in solving for altitude. The method is based upon the concept of circles of equal altitude explained by Commander Marcq St.-Hilaire, a Frenchman, in 1875 (art. 131). For this reason it is often called the **Marcq St.-Hilaire method.** It may also be called the **altitude intercept method** because it uses the difference between computed and observed altitudes, a value sometimes called an **altitude intercept.**

The altitude method has largely replaced the latitude and longitude methods, although some navigators still prefer the older methods. The principal advantage of the altitude method is that it provides a universal solution that is equally reliable in all latitudes, with all values of declination, and with all values of meridian angle. Even for observations of celestial bodies near the zenith the altitude method is applicable, although in this case an arc of the circle itself is plotted, without the use of the altitude difference (art. 2011). However, the formulas selected for some of the "short methods" do impose some limitations when those methods are used.

For many years following introduction of the altitude method, the concept was termed the "new navigation," an expression now seldom heard. At first, an attempt was made to adapt existing tables to the altitude method. Some were more readily adaptable than others. In due course, various methods designed for use with the altitude method made their appearance. These methods may be grouped in six classifications: those which do not divide the triangle, those which divide it by dropping a perpendicular from each of the three vertices, those which do not use the navigational triangle, and the modern "inspection table." However, not all inspection tables are for altitude methods. In practice, the dropping of a perpendicular from the pole has not been used except in great-circle sailing (art. 822). This would result in dividing both the meridian angle and zenith distance into two parts, a condition that has not proved attractive.

2109. Altitude methods, triangle not divided.—The basic formula for solution of the undivided navigational triangle is

$$\sin h = \sin L \sin d + \cos L \cos d \cos t,$$

derived from the law of cosines. A number of special tables have been prepared for solution of the undivided triangle:

Davis' *Requisite Tables*, published in London in 1905, introduced the **cosine-haversine formula** to navigation, although it had been used previously by astronomers. This formula is

$$\text{hav } z = \text{hav } (L \sim d) + \cos L \cos d \text{ hav } t,$$

in which z is zenith distance $(90° - h)$. This is sometimes written

$$\text{hav } z = \text{hav } (L \sim d) + \text{hav } \theta,$$

in which hav $\theta = \cos L \cos d$ hav t. It might also be written entirely in haversines:

$$\text{hav } z = \text{hav } (d - L) + \text{hav } t \, [\text{hav } (180° - L - d) - \text{hav } (d - L)].$$

In this formula the sign of d is reversed if L and d are of contrary name. The haversine of an angle is positive whether the angle is positive or negative.

These tables were the first to give log haversines and natural haversines in one table. The method was little used at first, but later proved very popular, and as haversines became available from additional sources, the formula was used even more widely. Davis' original tables made no provision for azimuth.

Since the cosine-haversine formula can be used for solution with tables 33 and 34, an example is given below, with solution of azimuth by the formula

$$\sin Z = \sin t \cos d \sec h.$$

Example.—A celestial body a little to the south of west is observed, with the following results: t 80°45′.9 W, *a*L 41°12′.3 S, d 21°50′.7 S.

Required.—The Hc and Zn by the formulas given above.

Solution.—

t 80°45′.9 W	*l* hav 9.62300		*l* sin 9.99434
*a*L 41°12′.3 S	*l* cos 9.87643		
d 21°50′.7 S	*l* cos 9.96764		*l* cos 9.96764
θ —	*l* hav 9.46707	*n* hav 0.29313	
L∼d 19°21′.6		*n* hav 0.02827	
z 69°04′.3		*n* hav 0.32140	
Hc 20°55′.7			*l* sec 10.02964
Zn 258°.8		Z S 78°47′.0 W	*l* sin 9.99162

This is typical of logarithmic solutions, except that there are no "rules" for the altitude computation. In this example the coordinates are the same as those of example 3, article 2008, where solution is by H.O. Pub. No. 214, using Δd, Δt, ΔL. The slight differences are due to the interpolation and rounding off of different quantities. As pointed out in article 2125, the formula used for azimuth angle does not indicate whether the body is north or south of the prime vertical.

Ball. In 1907 Rev. Frederick Ball's *Altitude or Position Line Tables* were published in London. There are two volumes of 244 and 240 (later 313) pages, respectively, the first volume having tables for latitude 0° to 30°, and the second, 31° to 60° (later editions 24° to 60°). These were the first inspection tables for the altitude method. The tabulated altitudes were computed by the haversine formula. The assumed position is selected so that latitude and meridian angle are the nearest whole degree, but no assistance is given for interpolation of altitude for declination.

Azimuth angle is not tabulated, being found by the altitude tables, interchanging altitude and declination, and finding azimuth angle (in hours and minutes) in the meridian angle columns. Since declination is limited to 24° in the first edition and 60° in later editions, this method is not available for azimuth if altitude is greater than this amount. In this case azimuth angle is found by the formula

$$\sin Z = \frac{\sec L \times \Delta h \text{ (for } 8^{m})}{120}.$$

This formula had not previously been used in navigation.

Davis' ***Alt-Azimuth Tables*** were published in London in 1917. This volume lists both altitude and azimuth together for the first time. Latitudes included are from 30° to 64°, and declinations from 0° to 24°. In 1921 a second volume was published for latitudes 0° to 30°. Entries are for each whole degree of latitude and declination, and for each 4^{m} (1°) of meridian angle. However, for each meridian angle, altitude *or* azimuth angle is given alternately. Thus, azimuth angle is given for meridian angles of 0^{m}, 8^{m}, 16^{m}, 24^{m}, etc., and altitude for meridian angles of 4^{m}, 12^{m}, 20^{m}, 28^{m}, etc. Altitudes are given in bold type. All declination entries (0° to 24°) are given on facing pages. Tables for latitude and declination of the same name are

given in the first part of the book and those for contrary names in the last part, the two parts being separated by several auxiliary tables. Altitude is given to the nearest 1′, and azimuth angle to the nearest 0°1. Altitudes are carried down to the horizon, and the local apparent times of sunrise and sunset are also given, with the azimuth angle at these times. Because of the 8^m interval between altitude entries, and the use of an assumed position to avoid interpolation for change in meridian angle, large altitude differences sometimes arise.

H.O. Pub. No. 201, *Simultaneous Altitudes and Azimuths of Celestial Bodies*, was published by the U. S. Navy Hydrographic Office in 1919. In this volume of 606 pages, altitudes and azimuths were tabulated in parallel columns for the first time. Latitude is limited to 60° and declination to 24°. Virtually all altitudes above the horizon are included. The tables are well arranged and very legible, but no assistance is given for interpolation of altitude or azimuth angle for a change of declination. Meridian angles are given at intervals of 10^m (2°5). Since the assumed position is selected to avoid interpolation of altitude or azimuth for meridian angle, large altitude differences result in some instances. This publication is no longer in print.

Yonemura. In 1920 S. Yonemura's *Tables for Calculating Altitude and Azimuth of Celestial Bodies* were published in Japan. This small table of 39 pages contains logarithms of haversines and secants, arranged for convenient solution of the formulas

$$\text{hav }(90°-h)-\text{hav }(L\sim d)=\text{hav }\theta,$$

$$\log\frac{1}{\text{hav }\theta}-(\log\sec L+\log\sec d)=\log\frac{1}{\text{hav } t},$$

$$\log\csc Z=\log\csc t+\log\sec d-\log\sec h.$$

The method is similar to that of Davis' *Requisite Tables* but includes solution for azimuth angle. The table is included in the book of Ogura's tables (art. 2110).

Braga. The *Táboas de Alturas* by Romêo Braga, a Brazilian, were published in 1924 in Paris. This is a table of natural haversines arranged for solution of the formula

$$\text{hav } h=A+B,$$

in which $$A=\text{hav } t-[\text{hav }(L+d)\text{ hav } t]$$

and $$B=\text{hav }(L-d)-[\text{hav }(L-d)\text{ hav } t].$$

The first table of 108 pages is for solution for A and B. The second table of nine pages is for finding h.

The assumed latitude is selected so that (L+d) is a whole degree. The assumed longitude is selected so that t is a whole degree.

No provision is made for azimuth.

Japanese H.O. Pub. No. 601, *Celestial Navigation Computation Tables*, was published in 1942. The method is similar to that of Yonemura, the triangle not being divided and a modification of the cosine-haversine formula being used for altitude.

Waller. In 1946 George W. D. Waller, a naval officer on duty as a navigation instructor at the U. S. Naval Academy, proposed a solution by means of Gaussian logarithms, commonly called "addition and subtraction logs." The formula

$$\csc h=\frac{\csc d\csc L}{1+\dfrac{\csc d\csc L}{\sec d\sec L\sec t}}$$

was derived from the basic formula given above,

and $$\csc Z=\frac{\csc t\sec d}{\sec h}$$

was derived from the time and altitude azimuth formula given in article 2125.

A single table of 30 pages would contain in consecutive columns the following values:

$$\begin{aligned}
A\ &= \log \text{secant} \\
B\ &= \log \text{cosecant} \\
C- &= \log(\text{cosecant}+1) - \log \text{cosecant} \\
C+ &= \log \text{cosecant} - \log(\text{cosecant}-1).
\end{aligned}$$

All values would be multiplied by 100,000 to eliminate decimals. One additional page would contain A and B values for all whole degrees from 0° to 180°. The values C+ and C− are the Gaussian logs.

The method is reasonably short and simple. Its publication as the "A, B, C Method," with suitable explanation, was prevented by the untimely death of its originator.

Hugon. *Nouvelles Tables Pour le Calcul de la Droite de Hauteur a Partir du Point Estimé*, by the French hydrographic engineer, Professor P. Hugon, were published in 1947. This logarithmic solution is based upon the fundamental formula

$$\sin h = \sin L \sin d + \cos L \cos d \cos t,$$

from which the following is derived:

$$\text{hav } z = Xy + Yx$$

in which

$$\begin{aligned}
X &= \text{hav } (180° - t) = \text{cohav } t \\
y &= \text{hav } (d - L) \\
Y &= \text{hav } t \\
x &= \text{hav } [180° - (d + L)] = \text{cohav } (d + L).
\end{aligned}$$

The formula for z may then be written

$$\text{hav } z = A + B$$

in which

$$\begin{aligned}
\log A &= \log X + \log y \\
\log B &= \log Y + \log x.
\end{aligned}$$

Solution is by means of a table of 90 pages which lists in parallel columns values of log cohav, log hav, and natural hav for every minute of arc from 0° to 180°. The solution requires six book openings, seven table entries, and five mathematical steps.

Azimuth is found from a diagram in a pocket on the inside back cover. This diagram is designed to solve the formula

$$M = \alpha X + \beta Y,$$

in which

$$\begin{aligned}
M &= \cos h \cos Z \\
\alpha &= \sin (d - L) \\
X &= \cos^2 \frac{t}{2} \\
\beta &= \sin (d + L) \\
Y &= \sin^2 \frac{t}{2}.
\end{aligned}$$

Chiesa. About 1948 the *Tavole nautiche e Tavole dei Semisenoversi* of the Italian Stefano Chiesa were published in Genova, Italy. These include tables for computation of altitude by the cosine-haversine formula, and "A, B, C" tables for computation of azimuth angle by the formula

$$\text{hav } Z = [\text{hav } p - \text{hav}(L - h)] \sec L \sec h.$$

Rose. In 1952 the *Nautische Tafeln* of G. Rose were published in Germany. This volume has a convenient table for computation of the altitude by the cosine-haversine formula. It also includes the "A, B, C" azimuth tables of Lecky (art. 2126). Various other tables are included, a number of them having been taken from an earlier work of the same name by Dr. Otto Fulst, published in numerous editions since 1860.

Doniol. The *Miniature Navigation Table for Altitude and Azimuth*, by R. Doniol, a Frenchman, was published in 1955. This is undoubtedly the shortest of all sight reduction tables, consisting of only two pages. The formula for altitude was derived from the basic formula given above. The formula used is

$$\sin h = n - (n + m)\, a,$$

in which $n = \cos (L - d)$, $m = \cos (L + d)$, and $a = \text{hav } t$.
The formula for Z was derived from the formula

$$\cot Z = \frac{\tan d \cos L - \cos t \sin L}{\sin t}.$$

The formula used is

$$\tan Z = \frac{\cos d}{\gamma},$$

in which $\gamma = f\Delta_M + f'\Delta_N$. In this expression, $f = \frac{\tan \frac{1}{2} t}{2 \sin 1'}$, $f' = \frac{\cot \frac{1}{2} t}{2 \sin 1'}$, $\Delta_M = \sin (d + L) \sin 1'$, and $\Delta_N = \sin (d - L) \sin 1'$.

The first of the two tables gives sines and cosines for each half degree, and tangents for half degrees of 45° and more. Interpolation is performed by means of a tabulated Δ value which is the change of sine or cosine for 1′. Interpolation is minimized by selecting an assumed position so that t and either (L+d) or (L−d) are an exact half degree.

The second table gives the value of t in degrees, minutes, and seconds, and the values of f and f′ corresponding to selected values of *a* (natural haversines). The interval between consecutive tabulated values of haversine varies from 0.0002 to 0.005.

The solution is generally accurate to 0′.1 of altitude and 0°.1 of azimuth, but the method requires a number of relatively simple mathematical steps, making it somewhat longer than most "short" solutions.

2110. Altitude methods, perpendicular from zenith.—In figure 2110 the navigational triangle is shown in heavy lines on a diagram on the plane of the celestial meridian (art. 1432). The broken line is a perpendicular from the zenith to the hour circle of the celestial body. This perpendicular may fall outside the triangle. In figure 2110 it divides both the azimuth angle (at Z) and the codeclination side into two parts. The length of

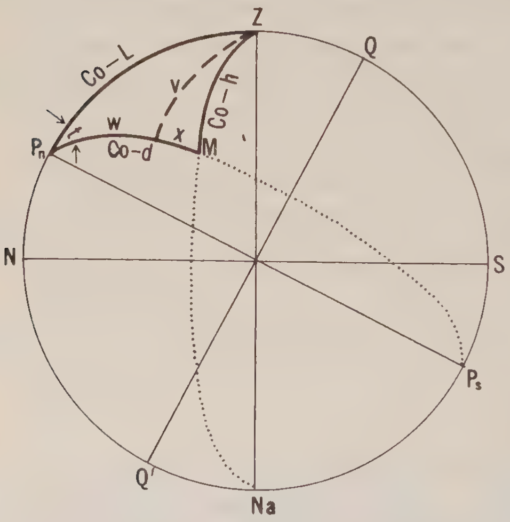

FIGURE 2110.—Navigational triangle with perpendicular from zenith to hour circle.

the perpendicular is designated v and the two parts of the codeclination are designated w and x. By means of Napier's rules (art. O42), the following basic formulas can be derived:

$$\sin v = \cos L \sin t \tag{1}$$

$$\cos w = \sin L \sec v, \text{ or } \tan w = \cot L \cos t \tag{2}$$

$$\sin Z' = \sin w \sec L, \text{ or } \cot Z' = \sin L \tan t \tag{3}$$

$$\sin h = \cos v \cos x \tag{4}$$

$$\sin Z'' = \sin x \sec h, \text{ or } \cos Z'' = \tan v \tan h, \tag{5}$$

in which $x = 90° - (d + w)$.

This basic method has been modified in a number of ways, having proved the most popular altitude method.

Souillagouet, a French professor of hydrography, was the first to divide the navigational triangle by dropping a perpendicular from the zenith. His *Tables du Point Auxiliare* were published in France in 1891. He designates various parts of the diagram of figure 2110 as follows:

v is designated a

w is designated b

x is designated $90° - (d \sim b)$.

His formulas for altitude are

$$\tan b = \cot L \cos t$$

$$\sin a = \cos L \sin t$$

$$\sin h = \cos a \sin (d \sim b).$$

For azimuth angle, the perpendicular is dropped from the celestial body to the celestial meridian, a being the perpendicular and b that part of the celestial meridian from the pole to the foot of the perpendicular. The following formulas are used:

$$\tan b = \cos t \cot d$$

$$\sin a = \sin t \cos d$$

$$\cot Z = \cos (L + b) \cot a.$$

The assumed position is selected so that latitude is the nearest 15′ and meridian angle is the nearest 1^m or 15′ (2^m or 30′ for latitudes greater than 60°). There are four separate tables with a total of 408 pages. The method requires five book openings, seven table entries, and six mathematical steps. Interpolation is not needed.

Bertin. A French professor of hydrography, Charles Bertin, devised tables similar to those of Souillagouet, which were published in Paris in 1919 under the title *Tablette de Point Sphérique*. Bertin used Souillagouet's formulas for altitude, but for azimuth angle he dropped the perpendicular from the zenith, as for altitude, and used the following formulas:

$$\sin Z_1 = \sin c \sec L$$

$$\cot Z_2 = \sin b \tan (c \sim d)$$

$$Z = Z_1 + Z_2.$$

In these formulas, b and c are substituted for the a and b, respectively, of Souillagouet. This is the first method in which Z is divided into two parts, found separately.

The assumed position is selected so that latitude and meridian angle are each to the nearest 20′. The tables are shorter than those of Souillagouet, having 324 pages, but still bulky for this type solution. The method has fewer steps and requires only two book openings, but interpolation is needed in two steps.

Ogura. In 1920 the *New Altitude and Azimuth Tables* by Sinkiti Ogura, Japanese hydrographic engineer, were published in Tokyo. The solution for altitude is generally similar to that of Souillagouet, a perpendicular being dropped from the zenith, but Ogura introduced secants and cosecants for the first time in this type solution. His solution for azimuth is similar to that of Blackburne (art. 2106) and Lecky (art. 2126).

The assumed position is selected so that latitude and meridian angle are each to the nearest whole degree. The altitude is determined by means of two tables (A and B-C) of a total of 27 pages, and azimuth by means of three additional tables (D, E, F) of a total of 29 pages. The altitude can be obtained to an accuracy of 0′.6 without interpolation. Latitude and declination are limited to 65°. The rules are numerous and complicated.

Both the Ogura and Yonemura (art. 2109) tables are given in the same book, the Japanese Hydrographic Office Pub. No. 225. An English edition, with slight modifications in the Ogura method, was published in 1924.

The Ogura tables have been widely copied.

Smart and Shearme's *Position Line Tables* were published in London in 1922, based upon a division of the triangle by a perpendicular from the zenith. The altitude formulas of Souillagouet were used, but the arrangement of the earlier tables was improved. It is somewhat similar to that of Ogura, but with the positions of meridian angle and latitude interchanged, providing a better arrangement when solutions of several observations are made simultaneously. Solution requires a log sine table which is not provided. There is no solution for azimuth. The assumed position is selected so that the meridian angle and latitude are each the nearest whole degree. No interpolation is needed.

Newton and Pinto. The *Navegação Moderna* of J. A. Newton and J. C. Pinto was published in Lisboa, Portugal, in 1924, providing a solution by dropping a perpendicular from the zenith. The method is based upon ideas expressed by Newton in 1912 and 1913. The formulas for altitude are almost the same as those of Souillagouet. The method of finding azimuth angle resembles somewhat the method of Bertin, but with the use of auxiliary angles. There are only two tables, the first occupying 120 pages, and the second two pages. The assumed position is selected so that latitude and meridian angle are each to the nearest 30′. No interpolation is needed, but the rules are somewhat complicated.

Weems' *Line of Position Book,* published in 1927, combines the Ogura altitude tables and the Rust azimuth diagram (art. 2106).

H.O. Pub. No. 208 (Dreisonstok), *Navigation Tables for Mariners and Aviators,* was published by the U. S. Navy Hydrographic Office in 1928 to provide a solution by the method of dropping a perpendicular from the zenith. The method, devised by Lieutenant Commander J. Y. Dreisonstok, USN, is similar to Ogura's. For altitude, it uses the Souillagouet formula inverted so as to be in secants and cosecants. For azimuth angle the formula is similar to that of Newton and Pinto, except that it does not use the parallactic angle at the celestial body. In the first edition the latitude was limited to 65°. There were two tables, one of 45 pages and the other of 18 pages. Later, a 23-page addition to the first table extended the coverage to the poles.

The assumed position is selected so that the latitude and meridian angle are each the nearest whole degree. The method requires four book openings, eight table entries, and six mathematical steps. Although values are usually obtained by relatively easy interpolation, altitude accuracy of 0′.5 can be obtained without interpolation.

As with H.O. Pub. No. 211 (art. 2111), the rules for this method were made on the assumption that only bodies above the celestial horizon would be observed. The rules may be restated to allow for both positive and negative altitudes, as follows:

If t is less than 90°, give b same name as latitude.

If t is greater than 90°, give b opposite name to latitude, and mark Z′ minus.

If (d+b) is numerically greater than 90°, mark Z″ minus.

If (d+b) is contrary name to latitude, the altitude is negative; use the supplement of Z″.

If Z is minus, subtract from 360° and mark plus.

The value labeled "t" in the tables is actually LHA. If t, east or west, is used, as in modern practice, the printed values greater than 180° can be ignored. The rules can be stated in abbreviated form on alternate pages, as follows:

At the top of each left-hand page of table I:

$$t < 90°, \text{ b same name as L.}$$

At the top of each right-hand page of table I:

$$t > 90°, \text{ b contrary name to L, Z}' \ (-).$$

At the top of each left-hand page of table II:

$$(d+b) > 90°, \ Z'' \ (-).$$

At the top of each right-hand page of table II:

$$Z \ (-), \text{ use } 360° - Z.$$

At the bottom of each page of table II (if desired):

$$(d+b) \text{ contrary name to L, Hc } (-)\text{: use } 180° - Z''.$$

If the D+B value used for finding Z″ exceeds 10,000, it is reduced by this amount, the remainder being used for entering table II. If desired, this can be stated in abbreviated form at the bottom of alternate pages of table II, as follows:

$$(C+D) > 10{,}000, \text{ use } (C+D) - 10{,}000.$$

Like H.O. Pub. No. 211 (art. 2111), H.O. Pub. No. 208 has been largely superseded by H.O. Pub. No. 214 (art. 2113).

Gingrich. The *Aerial and Marine Navigation Tables*, by Lieutenant John E. Gingrich, USN, were published in 1931 to provide another solution by the method of dropping a perpendicular from the zenith. The formulas for altitude are similar to those of Ogura, and the formulas for azimuth are similar to those of Perrin (art. 2126). The first two tables, of 31 and seven pages, respectively, are similar to those of Ogura. A single third table of 13 pages is given for azimuth. The general arrangement is in many respects similar to that of H.O. Pub. No. 208, and as with the earlier method, the assumed position is selected so that latitude and meridian angle are each to the nearest whole degree. The precision of tabulation of K, an auxiliary function, is not consistent. Consequently, if the tables are used without interpolation, errors as great as 0′.5 can arise in the computed altitude.

Weems' ***New Line of Position Tables*** are sometimes called the *Manuscript Tables* because they were in manuscript form from 1932 until they were published in 1943. They are similar to his earlier tables but arranged with the position of latitude and meridian angle values interchanged so that values for several observations can be taken from the tables with a single book opening. The latitude values are extended from the 65° given in earlier tables to 90°. As in the earlier edition, the Rust azimuth diagram (art. 2106) is included, but provision is also made for computation of azimuth angle. One part is found in terms of latitude and meridian angle, using the formula of H.O. Pub. No. 208, and the other part is found in terms of altitude and the perpendicular from the zenith. If the azimuth is required to a greater precision than 0°.5, interpolation is needed. The assumed position is selected so that the latitude and meridian angle are each the nearest whole degree.

Collins. The *I. C. S. Altitude and Azimuth Tables for Air and Sea Navigation*, by Elmer B. Collins, formerly of the U. S. Navy Hydrographic Office, were published by the International Correspondence Schools in 1934. The tables and method of solution are generally similar to those of H.O. Pub. No. 208.

F-Tafel, published by the German Oberkommandos der Kriegsmarine about 1937, divides the triangle by a perpendicular from the zenith. The formulas of Souillagouet are used for altitude. Azimuth is found by the familiar formula

$$\sin Z = \sin t \cos d \sec h.$$

There are four tables. Latitude, declination, and altitude are limited to 70°. The assumed position is selected so that latitude and meridian angle are each to the nearest whole degree.

Comrie. In 1938 the *Hughes' Tables for Sea and Air Navigation*, by L. J. Comrie, former Superintendent, H. M. Nautical Almanac Office, were published in London. These tables are similar to those of H.O. Pub. No. 208, but arranged with the positions of latitude and meridian angle interchanged as in the Weems' *New Line of Position Tables*.

Myerscough and Hamilton. The *Rapid Navigation Tables*, by W. Myerscough and W. Hamilton, were published in London in 1939. A perpendicular is dropped from the zenith to the hour circle of the celestial body. With slight modification, the altitude formulas of Souillagouet and the azimuth formula of Gingrich are used. Six quantities are tabulated in a single table of 90 pages. Both altitude and latitude are limited to 70°.

Ageton's ***Manual of Celestial Navigation,*** published in 1942, combines the first table of Weems' *New Line of Position Tables* as table I, and H.O. Pub. No. 211 (art. 2111) as table II. The basic formulas are restated in terms of secants and cosecants. The result is a short, easy solution without interpolation, involving four book openings, eight table entries, and four mathematical steps. Since the H.O. Pub. No. 211 table is included, the book can be used for Ageton's earlier method.

Benest and Timberlake. The *Astro-Navigation Tables for the Common Tangent Method* by two British professors, E. E. Benest and E. M. Timberlake, were published in 1945. In three tables of 61, 18, and 12 pages is given a logarithmic solution for altitude only, by dropping a perpendicular from the zenith. The formulas are slight modifications of those of Ogura.

The location of the line of position is somewhat similar to the method sometimes used in longitude method solutions such as H.O. Pubs. Nos. 203 and 204 (art. 2106). Two assumed positions are selected, usually 1° apart on the same meridian. The altitude difference at each position is determined, and a circle, or arc of a circle, is drawn with the assumed position as the center, and the altitude difference as the radius.

The line of position is the common tangent to the two circles. Since there are four common tangents, the general direction of the body is required. Where doubt exists as to which of two or more answers is the correct one, additional solutions from other assumed positions may resolve the ambiguity. If the celestial body is near the meridian, the two assumed positions are better taken on the same parallel of latitude. Even with these precautions, there is danger of selection of the wrong line.

Tavole H (*I. I. 3113*), published by the Istituto Idrografico della Marina of Italy in 1947, combines table I of Ogura and table II of Weems' *New Line of Position Tables*, including, also, the Rust azimuth diagram (art. 2106). This table is a modification of an earlier *Tavole F*.

2111. Altitude methods, perpendicular from body.—Figure 2111 is a diagram on the plane of the celestial meridian (art. 1432), with the navigational triangle shown in heavy lines. A perpendicular from the celestial body, *M*, to the celestial meridian divides the triangle into two right spherical triangles. In figure 2111 the length of the perpendicular is designated v and the two parts of the colatitude are designated w and x. By means of Napier's rules (art. O42), the following basic formulas can be derived:

$$\sin v = \cos \mathrm{d} \sin \mathrm{t} \qquad (1)$$
$$\cos w = \sin \mathrm{d} \sec v, \text{ or } \sin w = \cot \mathrm{t} \tan v \qquad (2)$$
$$\sin \mathrm{h} = \cos v \cos x \qquad (3)$$
$$\sin \mathrm{Z} = \sin v \sec \mathrm{h}, \text{ or } \cos \mathrm{Z} = \tan x \tan \mathrm{h} \qquad (4)$$

Since $x = 90° - (w + \mathrm{L})$, formula (3) can be written in terms of latitude, and w found from equation (2). Thus, both h and Z can be determined by means of t, d, and L and auxiliary functions found from them.

William Thomson (Lord Kelvin) was the first to divide the navigational triangle as shown in figure 2111 for sight reduction, but his method (art. 2106) was for determination of longitude. Various later methods made such a division for determination of altitude.

Fuss. The *Tables to Find Altitudes and Azimuths*, devised by V. E. Fuss, an astronomer at the Kronstadt (Russia) Naval Observatory, were published in 1901. In these tables a perpendicular is dropped from the celestial body, the following notation being used (fig. 2111):

v is designated a
w is designated 90°–b
x is designated B–90°
$\mathrm{B} = 90° - \mathrm{L} + \mathrm{b}$ (if v falls between Z and Q).

Solution is by the following formulas:

$$\sin \mathrm{a} = \cos \mathrm{d} \sin \mathrm{t}$$
$$\cot \mathrm{b} = \cot \mathrm{d} \cos \mathrm{t}$$
$$\sin \mathrm{h} = \cos \mathrm{a} \sin \mathrm{B}$$
$$\cot \mathrm{Z} = \cot \mathrm{a} \cos \mathrm{B}.$$

The assumed latitude is selected to provide the nearest 15′ value of B. The assumed longitude is selected so that t will be the nearest whole 1^m (0°25). The tables are entered twice, first with t and d to find a and b, interpolating for d, and then with B and a to find h and Z, interpolating for a. The method involves two book openings, eight table entries, four interpolations, and ten mathematical steps. There are 144 pages of tables.

Aquino. The *Altitude and Azimuth Tables* of Radler de Aquino, a Brazilian naval officer, were first published in 1909. These were followed the next year by his *Sea and*

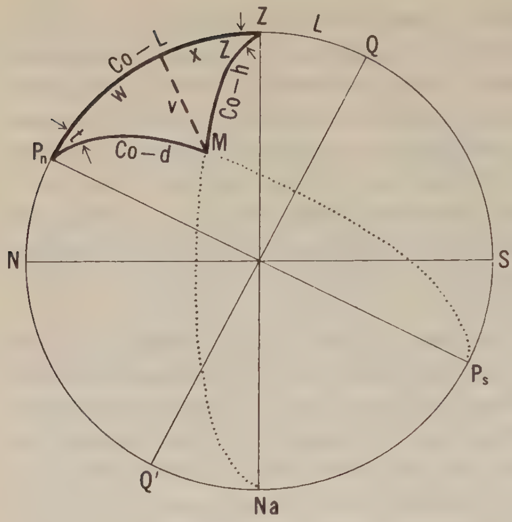

FIGURE 2111.—Navigational triangle with perpendicular from celestial body to celestial meridian.

Air Navigation Tables. Several later editions of both publications appeared with some modification, principally of the auxiliary material given. Aquino dropped a perpendicular from the celestial body to the celestial meridian, and used the same formulas as Fuss and generally the same arrangement, except that longitude is assumed so as to provide a meridian angle to the nearest whole degree.

H.O. Pub. No. 209 (Pierce), *Position Tables for Aerial and Surface Navigation,* was published by the U. S. Navy Hydrographic Office in 1930. These tables were devised by Commander M. R. Pierce, USN, in 1925, when he was navigator of the dirigible USS *Los Angeles.* The method is based upon a triangle divided by a perpendicular from the celestial body. It is generally similar to those designed by Fuss and Aquino, but the arrangement is somewhat different, requiring 206 pages of tables. This method was never widely used, and is now out of print.

H.O. Pub. No. 211 (Ageton), *Dead Reckoning Altitude and Azimuth Table,* was published by the U. S. Navy Hydrographic Office in 1931. This method, designed by Lieutenant Arthur A. Ageton, USN, while a student of the Post Graduate School, then at Annapolis, Maryland, is based upon a triangle divided by dropping a perpendicular from the celestial body. It is generally similar to those of Fuss and Aquino. However, Ageton modified the formulas so as to include only secants and cosecants. In terms of figure 2111, his notation is as follows:

v is designated R

w is designated 90°–K

x is designated K∼L

K=x+L.

Ageton's formulas are

$$\csc R = \csc t \sec d$$

$$\csc K = \frac{\csc d}{\sec R}$$

$$\csc h = \sec R \sec (K \sim L)$$

$$\csc Z = \frac{\csc R}{\sec h}.$$

A single table of 36 pages gives five-place log cosecants (labeled A) and log secants (labeled B), both multiplied by 100,000 to eliminate the decimal. These values are given in parallel columns for each 0'.5 of angle from 0° to 180°. The table is well arranged and indexed for quick reference. The rules are relatively simple and well presented. The method can be used for solution from the dead reckoning or any other assumed position. The method is intended for use without interpolation. These

features combined to make this a popular method, although solution is somewhat tedious, and large errors may be encountered if t is near 90°. The method has been largely superseded by H.O. Pub. No. 214 (art. 2113).

If a celestial body near the visible horizon is observed, it may be *below* the celestial horizon (zenith distance greater than 90°), because of refraction and dip. Under these conditions the *computed* altitude, Hc, is negative (art. 2010). In the solution by H.O. Pub. No. 211, Hc is negative if K is of the same name as L and greater than (90°+L), *or* if K is of contrary name to L and greater than (90°−L). Under the second of these conditions, Z is less than 90° and should be taken from the top of the table *if* K is greater than (180°−L).

Fontoura da Costa and Penteado's *Tabuas de Altura e Azimute* were published in Lisboa, Portugal, in 1936. These consist of 26 pages of log secant and log cosecant tables similar to those of H.O. Pub. No. 211. The method and formulas are slight modifications of those of H.O. Pub. No. 211.

Tillman. The *Altitude Tables for Mariners and Aviators*, by E. Tillman, were published in 1936 in Sweden. Solution is by three tables using the basic formulas given above.

USSR tables. About 1940 the USSR replaced the Fuss tables with a method that is similar but uses a much shorter table. However, the solution is about the same length as with the Fuss tables, requiring six book openings, nine table entries, and five mathematical steps. Visual interpolation is used.

Japanese H.O. Pub. No. 602, *Brief Celestial Navigation Table*, was published in 1942. A perpendicular is dropped from the celestial body, as in figure 2111. Side *w* is designated K, and the following formulas are derived from the basic formulas given above:

$$\log \tan K = \log \cot d + \log \cos t$$

$$\log \cot Z = \log \cot t + \log \csc K + \log \cos (K+L)$$

$$\log \cot h = \log \cot (K+L) + \log \sec Z.$$

These formulas result in a simple solution, at the expense of some duplication in the three tables of 49 pages.

Hickerson. In 1944 Thomas F. Hickerson, professor of applied mathematics at the University of North Carolina, published a small volume called *Navigational Handbook with Tables*, in which the tables of H.O. Pub. No. 211 are given with the interval between entries reduced to 0.′2. All values are given on 45 pages, by tabulating values only to 45° and interchanging the A and B values for angles between 45° and 90°. In 1947 a second edition was published under the title *Latitude, Longitude and Azimuth by the Sun or Stars.*

2112. Altitude methods without use of navigational triangle.—The navigational triangle is composed of arcs of three great circles: the celestial meridian of the observer, the hour circle of the celestial body, and the vertical circle of the celestial body. Arcs of other great circles might also be used in forming spherical triangles that can be solved to find altitude and azimuth.

Kotlarić. In 1956 Stjepo M. Kotlarić, technical assistant, Hydrographic Institute of the Yugoslavian Navy, proposed a method based upon the solution of three right spherical triangles composed of arcs of great circles, as follows:

triangle 1—celestial horizon, hour circle, and celestial equator;
triangle 2—celestial horizon, hour circle, and vertical circle;
triangle 3—celestial horizon, hour circle, and celestial meridian (lower branch).

The formulas are derived from Napier's rules:

$$\tan (Z+F) = -\sin L \tan t$$
$$\tan M = \cot L \cos t$$
$$\cos C = \cos L \sin t$$
$$\tan F = \cos C \tan (M+d)$$
$$\sin Hc = \sin C \sin (M+d)$$
$$Z = (Z+F) - F,$$

in which F, M, and C are auxiliary parts.

Four tables totaling about 200 pages would be needed with the method, although table III is not needed if the assumed position is selected so that latitude and meridian angle are the nearest whole or half degree. The size of the tables could be reduced considerably if half degrees were dropped. With an assumed position selected as indicated above, the method requires only four table entries and four mathematical steps. The rules are few and simple.

2113. Modern inspection tables may contain lists of altitude or azimuth, or both. Another type tabulates the information needed for finding longitudes. Values are taken directly from the tables, without the need for logarithms, auxiliary functions, or mathematical solutions (except interpolation). Inspection tables are not new, the horary tables of Cassini in 1770, Lalande in 1793, Lynn in 1827, and Hommey in 1863 (art. 2106) being of this type. Other inspection tables include Davis' *Chronometer Tables*, Blackburne, H.O. Pubs. Nos. 203 and 204, Ball, Davis' *Alt-Azimuth Tables*, and H.O. Pub. No. 201 (arts. 2106 and 2109). None of these tables is used to any extent today, largely because interpolation is difficult, and coverage is limited. A short logarithmic solution with wide coverage has often proved more popular.

In contrast, the modern inspection table, made practicable by recent developments in computation techniques, has largely replaced the trigonometric solution. The principal modern inspection tables are:

H.O. Pub. No. 214, *Tables of Computed Altitude and Azimuth*, were published by the U. S. Navy Hydrographic Office between 1936 and 1946, in nine volumes. Between 1951 and 1953 the British Admiralty published identical tables (H.D. 486) in six volumes, with altered explanation to suit British practice. The first volume of an identical Spanish edition was published in Spain in 1953, and the second volume in 1956. Several volumes of an Italian edition based on H.O. Pub. No. 214 have also been published. The H.O. Pub. No. 214 series is described in detail in chapter XX.

British Air Pub. 1618 (H.O. Pub. No. 218), *Astronomical Navigation Tables*, were published by the British Admiralty between 1938 and 1944 in 15 volumes (lat. 0°–79°). In 1941 the first 14 volumes (lat. 0°–69°) were republished by the U. S. Navy Hydrographic Office as H.O. Pub. No. 218. The tables are intended primarily for aviators.

These tables are similar to H.O. Pub. No. 214, but with several differences. In A.P. 1618 values are given to the nearest whole minute for altitude, and the nearest whole degree for azimuth. The altitude values include allowance for refraction at a height of 5,000 feet. The minimum altitude in most cases is 10°. Provision is made for interpolation for declination only, and this always from the *next smaller* whole degree, instead of from the *nearest* whole degree. Declination is given for each whole degree from 0° to 28° only. In addition, values of altitude and azimuth are given for the declination (in 1940) of 22 stars. This part of the table is entered with the star name (or an arbitrarily-assigned number), so the declination of the body need not be

known. An auxiliary table provides a correction for changes in declination during the years following 1940 (to the year 2000).

During World War II these tables were widely used by aviators. Some marine navigators also used them. Since publication of H.O. Pub. No. 249, their use has declined.

Japanese H.O. Pub. No. 351, *Celestial Navigation Observation Table,* was published in 1940–42, in seven volumes for latitudes 0°–70°. The original printing was classified "secret." The tables are similar to British Air Pub. 1618, with several differences. In H.O. Pub. No. 218 all star-name entry tables are given first, followed by all declination entry tables. In Pub. No. 351 the declination entry table for each degree of latitude is followed by the star-name entry table. Altitudes, including refraction at 4,000 meters (13,123 feet), are tabulated to a minimum value of 2°. Declination is extended to 29°. The latitude-declination contrary-name entries are inverted so that meridian angles increase *upward* on the page as in H.O. Pub. No. 260 (art. 2126), resulting in better utilization of space on the pages having both "same name" and "contrary name" entries. Twenty stars are used, the selection differing somewhat from that of H.O. Pub. No. 218. In H.O. Pub. No. 218 the stars are listed and numbered alphabetically. In Pub. No. 351 they are given in order of declination, from Dubhe, listed as 62°03′N, to Sirius, listed as 16°38′S.

Hoehne. In October 1941 George G. Hoehne, an American, proposed a set of tables similar to the star section of H.O. Pub. No. 218, except that a value approximating LHA♈ would replace meridian angle of the star as an entering argument, and a maximum of ten stars would be given in parallel columns for each whole degree of entering value. The value used for entering the tables would be determined by adjusting LHA♈ by an amount tabulated for each year for each star used. This would prevent the tables from becoming inaccurate because of precession of the equinoxes (art. 1419). Refraction at altitude 5,000 feet would be included as in H.O. Pub. No. 218. One volume of these tables (volume II, lat. 20°N to 39°N) was published in 1943.

Japanese H.O. Pub. No. 603, *Simplified Celestial Observation Table,* was published in 1943. This publication is virtually the same as Pub. No. 351, except that eight additional stars are given, all farther south than those of Pub. No. 351. This extends the list to *α Crucis* (Acrux), given as declination 62°48′S.

Altitude and Azimuth Almanac was published by the Japanese Hydrographic Office, beginning in 1944. Originally, this was a secret publication. Several different versions were printed, and there were some modifications after the first editions. In each, however, the functions of almanac and sight reduction tables were combined. For each of several specific locations, the altitude and azimuth of one or more celestial bodies are tabulated for the date and time, usually at ten-minute intervals. In the earlier editions, the locations selected were important points in the western Pacific. From this practice, these publications are sometimes called "destination tables." Later editions used positions differing in latitude by 5°. These tables provided a quick solution for observations made at the tabulated times. On a worldwide basis such a system would involve a very voluminous tabulation each year, or cumbersome corrections. The *Altitude and Azimuth Almanac* is no longer published.

Hohentafeln nach Sternzeit, an official German table, was published in 1944 as an experimental edition with a very limited range of latitude. The tables were similar to those of Hoehne, but with six stars listed for each minute of local sidereal time.

Méneclier and Chevalier. The *Cálculo del Punto* of Víctor Méneclier and Roberto Chevalier was published in 1945–49 by Aeronáutica Argentina. There are six volumes for latitudes 0° to 59° *south.* At intervals of 4^m LST (or 1° LHA♈) the altitude,

a correction factor, and azimuth (not azimuth angle) of selected stars are tabulated. Twelve columns are provided, but a number of blank areas appear, resulting in an average of about nine altitude-azimuth entries for each time entry. In most cases, altitudes are carried to a minimum value of 5°, and azimuth to the horizon. These tables are similar to those of Hoehne and volume I of H.O. Pub. No. 249.

H.O. Pub. No. 230 (Goetz), *High Latitude Celestial Navigation Tables,* designed in 1945 by Roy F. Goetz, was published by the U. S. Navy Hydrographic Office in 1946.

The first section, called "Star Tables," is entered with the latitude to the nearest 1° from 70°N to 89°N, the name of the star (for ten selected stars), and LHA♈ at intervals of 2° for latitude 70° to 79°, 5° for 80° to 84°, and 10° for 85° to 89°. Altitude is tabulated to the nearest 1′ and azimuth (not azimuth angle) to the nearest 0°1. A "ΔH" value is given for use with an auxiliary table to interpolate for precession of the equinoxes (art. 1419).

In the second section, called "Declination Tables," declination is substituted for the name of the star. A separate table is given for each 1° declination from 0° to 28°. For each degree a "same name" section is given first, followed by a "contrary name" section (to declination 19°). The minimum altitude is 1°. The declination tables give "d" in place of "ΔH" for use with an auxiliary table to interpolate for declination.

Only 400 of these tables were published. They were intended only for use in military aircraft operating beyond the latitude range of H.O. Pub. No. 218. After H.O. Pub. No. 249 became available, H.O. Pub. No. 230 was canceled.

H.O. Pub. No. 249, *Sight Reduction Tables for Air Navigation,* in three volumes, are published by the U. S. Navy Hydrographic Office. A preliminary edition of volume I for selected stars was published in 1947 under the title *Star Tables for Air Navigation,* using the principles and features of tables proposed previously by George G. Hoehne, Commander C. H. Hutchings, USN, and others. The altitudes of this edition were adjusted for refraction at a height of 10,000 feet. By the time the "first" edition was printed in 1951, for epoch 1955.0, more than 20,000 copies of the preliminary edition had been distributed. The 1951 edition dropped the refraction adjustment feature from the altitudes, and had an improved selection of stars. It was followed in 1952 with two volumes for declination entry at 1° intervals from 0° to 29°. In 1952 and 1953 a British edition was published with identical tables (A. P. 3270) but altered explanation. The tables have been accepted as standard by the air forces of Great Britain, Canada, and the United States. They are in limited use by mariners. Extracts from these tables (1957 edition, for epoch 1960.0) are given in appendix CC.

Volume I contains tabulations of altitude (to the nearest 1′) and azimuth (to the nearest 1°) in parallel columns. For each 1° of latitude a two-page table (one-page above 69°) is given. For each 1° (2° beyond latitude 69°) of LHA♈, altitude and azimuth are given for seven stars carefully selected with regard to azimuth, magnitude, altitude, and continuity. Stars of the first magnitude are shown in capital letters, and those of second and third magnitude in lower case with initial capital. After each 15 entries a break occurs and a new listing of stars is given, whether or not there are any changes from the previous list. Stars are listed in the order of increasing azimuth at the beginning of each period. A total of 41 stars is used, 19 of which are of the first magnitude, 17 of the second magnitude, and 5 of the third magnitude. The tables are intended for use with an assumed position selected so that latitude and LHA♈ are each the nearest whole degree (nearest *even* degree of LHA♈ at latitudes higher than 69°).

Tabulation by name of star eliminates the need for finding the declination, but for strict accuracy, a correction for precession of the equinoxes (art. 1419) and nutation (art. 1417) may be needed. This is given in an auxiliary table (tab. IV). Since it is

anticipated that the tables will be recomputed at five-year intervals, it will probably be possible for aviators to ignore this correction. However, it may reach a value of as much as 3′, and should not be neglected if the tables are used by mariners. This correction is applied to the *fix*, not to each *altitude*.

Tabulation of *azimuth* (not azimuth angle) eliminates the need for conversion.

Tabulation by LHA ♈ instead of meridian angle of the star eliminates the need for finding and applying SHA. It also makes of the tables a star finder for the seven stars given, since all values given for any entry of LHA ♈ are for the same *time*. In the air it is common practice, when H.O. Pub. No. 249 is used, to observe the stars at intervals of exactly four minutes. Solution is made for only one observation (usually the middle of three), altitude and azimuth entries being found on consecutive lines (neglecting the small difference between solar and sidereal time during a four-minute period), and *all are plotted from the same assumed position*, selected so that latitude and LHA ♈ are the nearest whole degree, and adjusted as necessary for the motion of the observer between observations. If the time selected for the observation to be solved is a whole 10^m of GMT, and the navigational watch is set to GMT, the GHA ♈ can be taken directly from the *Air Almanac* without interpolation. With addition or subtraction of only one longitude, a person has all the information needed for entering H.O. Pub. No. 249 for solving *three* observations. If the navigator had a watch set to read GHA ♈ in arc, the almanac would not be needed for solving an observation. Wing Commander E. W. Anderson and Dr. D. H. Sadler, both of Great Britain, have suggested a ruler for use with a Mercator chart of certain scales, and a circular computer for use with any projection and scale, to permit quick conversion of sidereal to solar units if observations are made at greater intervals.

Example 1.—During evening twilight on June 2, 1958, the 1724 DR position of a ship is lat. 40°39′.2 S, long. 128°01′.2 E. At GMT $8^h24^m03^s$ the navigator observes Canopus with a marine sextant having no IC, from a height of eye of 38 feet. The hs is 55°57′.1.

Required.—The *a*, Zn, and AP, using H.O. Pub. No. 249 (epoch 1960.0), vol. I, and the *Air Almanac*.

Solution.—

	June 2	Canopus
GMT	$8^h24^m03^s$ June 2	
8^h20^m	15°18′	
4^m03^s	1°01′	
GHA ♈	16°19′	
*a*λ	127°41′ E	
LHA ♈	144°00′	
*a*L	41°00′ S	
Hc	55°45′	
Ho	55°50′	
a	5 T	*a*L 41°00′ S
Zn	233°	*a*λ 127°41′ E

	+	☆ −
IC	—	—
D		6′
R		1′
sum	—	7′
corr.		(−) 7′
hs		55°57′
Ho		55°50′

This problem is similar to that of example 4, article 2008. A comparison of the two indicates that the H.O. Pub. No. 249 solution reduces the number of table entries over the number required by H.O. Pub. No. 214 solution by four, and the number of mathematical steps also by four. The use of a whole 10^m of GMT would eliminate one more table entry and one mathematical step. If three observations were made at 4^m intervals, two more table entries and two mathematical steps would be eliminated from the three solutions. Whether or not these "wrinkles" are used, all values needed for a fix are together on one page, and are extracted without interpolation.

Volumes II and III are somewhat similar in many respects to H.O. Pub. No. 214. Altitude and azimuth angle are given in parallel columns for every whole degree of latitude (0° to 89°), every whole degree of declination (0° to 29°), and every whole degree (2° beyond lat. 69°) of LHA for all values at which the altitude is greater than several degrees *below* the celestial horizon (to allow for large values of dip at aircraft heights, and for considerable difference between assumed position and the position of the craft at the time of observation). The values for latitude and declination contrary name are tabulated with values of meridian angle (LHA less than 180°) increasing *upward* on the page, as in some older tables such as H.O. Pub. No. 260 (art. 2126). This permits better utilization of space where same- and contrary-name tabulations are given on the same page. It also serves to emphasize the difference between the same- and contrary-name tabulations, the contrary-name tabulation being given in a "contrary" manner on the page. A more convenient arrangement of declination entries is provided by having the "top" of each page of the tables along the left side, requiring the turning of the page through 90°.

A "d" value is tabulated between the altitude and azimuth angle to facilitate interpolation of altitude for declination. No interpolation is needed for latitude and LHA because the assumed position is selected so that these are the nearest whole degree (nearest *even* degree of LHA beyond latitude 69°). The "d" value is the difference in minutes, with sign, between the accompanying altitude and that for declination 1° *greater*, at the same latitude and LHA. It is used for entering an auxiliary table (tab. III) for determining the correction to be applied to altitude for minutes of declination, in a manner similar to using Δd and the "multiplication table" of H.O. Pub. No. 214. Interpolation is normally made in the direction of increasing declination.

Volume II covers latitudes 0° to 39°, and volume III contains similar information for latitudes 40° to 89°. Since these tables are entered with LHA of the celestial body, they do not become inaccurate in succeeding years, and no correction is needed for precession and nutation, as in volume I. These volumes are intended for solution of observations of the sun, moon, planets, and any stars within the declination range.

Example 2.—During morning twilight on June 2, 1958, the 0724 DR position of a ship is lat. 40°39′.2 S, long. 131°01′.2 E. At GMT $22^h24^m03^s$ (June 1) the navigator observes Alpheratz with a marine sextant having no IC, from a height of eye of 38 feet. The hs is 20°15′.3.

Required.—The *a*, Zn, and AP, using H.O. Pub. No. 249, vol. III, and the *Air Almanac.*

Solution.—

	June 2		Alpheratz	
GMT	$22^h24^m03^s$	June 1		
22^h20^m	224°53′			
4^m03^s	1°01′			
SHA	358°26′

hs		20°15′
Ho		20°06′

This problem is similar to those of example 4, article 2008, and example 1 above. All volumes of H.O. Pub. No. 249 are intended for use with the *Air Almanac.*

Experimental Air Navigation Tables. During the early part of World War II the British Royal Air Force felt the need for an inspection table that would be faster than Air Pub. 1618 (H.O. Pub. No. 218), but free from the limitations of the astrograph (art. 2123). Wing Commander R. C. Alabaster suggested the addition of SHA to the hour angle (measured eastward) of the stars given in Air Pub. 1618, converted to time at the sidereal rate of 15°02′.5 per hour. This would give the time interval until the next meridian transit of the vernal equinox. Before observation, the time of passage of the vernal equinox across a convenient meridian would be marked on the chart or plotting sheet. After observation, the tables would be entered with assumed latitude and the nearest tabulated altitude. The (SHA+HA) corresponding to this altitude would be added to GMT at the time of observation. The result should be close to the time marked on the chart. The difference would be converted to arc units (or a time scale would be marked on the chart or plotting sheet) and the corresponding longitude determined. This point would serve as the assumed position. The difference between the observed altitude and that used for entering the table would be the altitude difference to be used with the azimuth for plotting the line of position.

Squadron Leaders A. Potter and A. J. Hagger suggested a method of printing a time scale on the chart or plotting sheet with an auxiliary table to assist in locating the assumed position.

Various modifications and conventions were later added to avoid negative values and other complications. As the method finally emerged, a quantity known as "scale time" was adopted. This value, designated T, would be equal to 26 hours plus the GMT of the next transit of the vernal equinox occurring after 0600 during the night of the flight. The GMT of observation would be designated t. The quantity $T-t$ would be the value tabulated.

Further attempts were made to simplify the conversion of mean to sidereal time so that the single setting might be used during an entire flight. One of these, called the "Astro-Scales," was suggested by Wing Commander E. W. Anderson in 1945. In 1953 he and D. H. Sadler suggested an improved version.

Although a considerable amount of thought was given to this method, and experimental tables were published for a limited band of latitude, the limitations of a longitude method and the inconvenience of converting mean time to sidereal time resulted in the method being discarded in favor of the less restrictive H.O. Pub. No. 249 method.

Ashton. In 1943 Philip Ashton proposed a set of tables called *Astrograph-time Star Tables for Air Navigation,* based upon the principle of the *Experimental Air Navigation Tables.* A permanent table would be entered with the name of the star, latitude, and "astrograph mean time" (art. 2123), and altitude and azimuth would be taken from the table. A set of tables issued each year would list the values to be used with GMT each night to determine the astrograph mean time. Before take-off, the chart or plotting sheet would be marked to agree with the astrograph mean time, and a metal tape would then be used to convert mean time to sidereal time for finding the assumed position.

Heard. About 1950 John F. Heard, associate professor of astronomy at the University of Toronto, prepared a modification of the *Experimental Air Navigation Tables.* The tabulation would be altered so that altitude would be given in the left-hand column at intervals of 20′. A delta ("diff.") value would be tabulated and this used with the difference between entering and observed altitudes to enter an auxiliary

table to determine a correction to be applied to $T-t$ so that the altitude difference need not be plotted. A correction for 60 minus seconds of T would also be applied. The "bearing" of the line of position (azimuth plus or minus 90°) would also be tabulated. The line of position would be plotted through the assumed position, in the direction indicated by the "bearing." For any given time three stars differing in azimuth by approximately 120° would be given. The part of the table to use would be determined by a rough computation of $T-t$.

2114. Azimuth methods.—Nearly all methods proposed for obtaining a line of position are based upon the use of altitudes. The azimuth might also be used if an instrument becomes available for measuring it to the required accuracy. The accuracy needed would depend upon the acceptable error of the line of position. The error would be proportional to the cosine of the altitude. For a celestial body on the celestial horizon an error of 1′ in the azimuth would introduce an error of one mile in the line of position, the same as it does in an altitude observation. For any altitude greater than 0°, the error would be less.

Each method of determining a line of position by altitude has its counterpart in the azimuth problem. Thus, if it can be determined that a celestial body is exactly on the celestial meridian, the west longitude is the same as the GHA of the body. If the body is exactly on the prime vertical, the latitude can be computed. As a more general case, two points on a given azimuth line can be computed and joined by a straight line, by assuming two latitudes or two longitudes. However, if one such position is known, the azimuth line of position can be drawn through it in the direction of the azimuth. If the celestial body is sufficiently high, or if a small scale is acceptable and allowance is made for chart distortion, the azimuth line can be plotted directly, just as the circle of position can be drawn if the altitude is known. The difference between the observed azimuth and that computed for an assumed position can be used in a manner similar to the altitude difference. The azimuth difference in minutes multiplied by the cosine of the altitude would be the "intercept" measured off from the assumed position in a direction perpendicular to the computed azimuth. Through the point thus determined, a line would be drawn in the direction of the observed azimuth. For small differences, the line could be drawn perpendicular to the line from the assumed position. The relative values of the observed and computed azimuths would indicate the direction (right or left) to draw the line from the assumed position.

If the altitude and azimuth were both known to sufficient accuracy, a single celestial body would suffice for determining position by any combination of altitude and azimuth methods or by direct computation of latitude and longitude. The two lines of position would always be perpendicular to each other.

Double altitudes. For a stationary observer the longitude can be determined by observing the altitude shortly before meridian transit (either upper or lower), and noting the time when the altitude has returned to exactly the same value after meridian transit. If there has been no change in declination between observations, the mid time represents the moment of meridian transit, at which time the azimuth is 000° or 180°. The GHA (or 360°−GHA for east longitude) is the longitude of the observer. This method might be considered as either a longitude or an azimuth method. A variation is to observe a number of altitudes shortly before and after meridian transit. These are then plotted against time on cross-section paper and a smooth curve plotted through them. The time corresponding to the maximum altitude (minimum altitude for lower transit) is the moment of meridian transit.

Quilter. In 1950 Commander E. S. Quilter, USN, suggested a method based upon azimuth difference. He would measure and compute azimuth to the nearest 0°.01 (when the means for doing so became available) and express the azimuth difference to the

same precision. A table would be provided to list values of K, a constant by which the azimuth difference would be multiplied for any given altitude to determine the "intercept" to measure off from the assumed position.

2115. Determination of latitude and longitude.—Most methods provide information needed for plotting a line of position. The fix is at the common intersection of two or more such lines. A line of position might be plotted in one of several ways. In the latitude and longitude methods, the lines are plotted at the computed coordinate. When one coordinate has been determined, the other can be computed without plotting. Thus, the longitude determined by time sight is generally correct only for the latitude used in its solution, and the plotting of a longitude line is misleading, unless the celestial body is on the prime vertical. A better procedure is to compute two points, using different latitudes (or longitudes, if latitude is being computed). These two points are on the line of position. A straight line connecting them is a good approximation of the circle of equal altitude. This was the method used by Captain Sumner when he discovered the line of position (art. 131), and the method of H.O. Pubs. Nos. 203 and 204 (art. 2106).

Another method is to compute one point and the azimuth (or Zn$\pm$90°), and plot the line of position through the point. This is the method used by Soule and Dreisonstok (art. 2106).

If only the altitude difference is computed for two points, the line of position is a common tangent of circles of radius equal to the altitude difference at these two points. This is the method of Benest and Timberlake (art. 2110).

The most common modern method of plotting the line of position is by means of the assumed position, altitude difference, and azimuth. If this information is available for two observations solved for the same assumed position, the position of the fix can be determined by computation instead of by plot, using the following formulas:

$$\tan B = \frac{a_2 - a_1 \cos A}{a_1 \sin A},$$

and

$$a' = a_1 \sec B,$$

in which A is the difference in azimuth of the two celestial bodies, B is the difference between the azimuth of the first celestial body and the direction of the "position vector" (the line connecting the common assumed position with the fix), a_1 is the altitude difference of the first celestial body, a_2 is the altitude difference of the second celestial body, and a' is the length of the position vector.

If A is greater than 90°, the minus sign in the numerator of the first formula is replaced with a plus sign. The common intersection of the two lines of position (the fix) is a' miles from the common assumed position, in a direction B degrees from the azimuth of the first observation. Since B is always between the azimuths of the two celestial bodies observed, it will always be *added* to the first azimuth if the left-hand body is considered the "first" one.

With the information a' and B one can find the latitude and longitude of the fix by (1) plot, (2) table 3, or (3) computation. If method (2) or (3) is used, the problem is the same as that encountered when course and distance from a known position is given, and point of arrival is desired. This can be solved by a combination of plane and parallel sailing, as explained in articles 813 and 815.

It is possible, too, to plot circles of position by using the geographical position of each body as the center of its circle, and the zenith distance as its radius. This is the method used for high-altitude observations (art. 2011), but is generally not practical for ordinary altitudes because of the small scale that would be needed, and the error that would be introduced by chart distortion, unless plotting were done on the surface of a sphere (art. 2124).

The use of a circle of equal altitude is similar to the use of a circle of position around a landmark of known range. The bearing of such a landmark also furnishes a line of position. Similarly, a line of position can be obtained by plotting the azimuth line of a celestial body, and a fix by plotting two such lines. This is generally not done because of the scale and chart limitations mentioned above, and also because the needed accuracy in observation is beyond the capability of equipment generally available to the navigator. Errors in both compass and measurement of azimuth are involved.

Various methods of determining position by computation from observations of two or more celestial bodies or four observations of a single celestial body are discussed in articles 2116 and 2117.

2116. Computed position from observation of two or more bodies.—Several methods have been proposed for computing the position directly from the observation of two or more celestial bodies. These generally consist of some combination of latitude and time sight methods. One form of automatic celestial navigation, proposed by Collins Radio Company, uses the principle of the planetarium in reverse, two bodies serving to position a horizontal-stabilized sphere (in principle) for latitude and local sidereal time. If the device is accurately set to Greenwich sidereal time, longitude is indicated.

Fox. In 1951 Charles Fox, associate professor of mathematics at McGill University, Montreal, proposed formulas for computing latitude and longitude if certain star pairs are observed, the two stars of each pair having almost the same SHA. Presumably, simultaneous observations would be needed. Five such star pairs are listed. Four of the stars in three of these pairs are dimmer than the third magnitude, and are not listed in the almanacs, either in the main tabulation or among the additional stars. More involved formulas are suggested for use of the method with any three celestial bodies.

de Jonge. In 1945 Joost H. Kiewiet de Jonge, a lieutenant in the Netherlands East Indies Army Air Force, proposed a method of determining position from the observation of three stars. The U. S. Navy Hydrographic Office published experimental tables for several star pairs for latitudes 20° to 30° under the title *Three Star Position Tables for Aerial Navigation.* It was anticipated that if the method proved popular, all possible three-star combinations (of the stars in the main tabulation of the almanacs) would be given, so that the navigator would not be limited in his selection.

No assumed position is needed with the method. Three stars are observed at intervals of three minutes, the stars being observed in the order of listing in the main table. Table I is entered with the three altitudes, h_1, h_2, and h_3, and for each a value is taken from the table. These values are labeled H_1, H_2, and H_3, respectively. They are combined to form $H_1+H_2=H_{12}$, and $H_2+H_3=H_{23}$. These combined values, H_{12} and H_{23}, are then used to enter the main table, from which local sidereal time (in arc units) and latitude are obtained. Greenwich sidereal time minus local sidereal time equals longitude (measured westward). Delta values and auxiliary tables provide corrections for motion of the observer and observation intervals differing from three minutes. Mean corrections for both atmospheric refraction and Coriolis are included in the tables, which are limited to altitudes between 20° and 75°, and azimuth difference between consecutive stars to 165°.

Dozier. In 1949 Charles T. Dozier proposed a method based upon the simultaneous observation of two celestial bodies and the solution of two spherical triangles, with vertices as follows:

triangle 1—the two celestial bodies and the elevated pole,
triangle 2—the two celestial bodies and the zenith.

The method involves the successive solution of seven formulas:

$$\cos D = \sin d_1 \sin d_2 + \cos d_1 \cos d_2 \cos S \tag{1}$$

$$\sin (X_1 \pm A_1) = \frac{\sin S \cos d_2}{\sin D} \tag{2}$$

$$\cos A_1 = \frac{\sin h_2}{\cos h_1 \sin D} \pm \frac{\tan h_1}{\tan D} \tag{3}$$

$$X_1 = (X_1 \pm A_1) \mp A_1 \tag{4}$$

$$\sin L = \sin d_1 \sin h_1 + \cos d_1 \cos h_1 \cos X_1 \tag{5}$$

$$\sin t_1 = \frac{\sin X_1 \cos h_1}{\cos L} \tag{6}$$

$$\lambda = GHA_1 \pm t_1 \tag{7}$$

in which D is the great-circle distance (angular) between the two celestial bodies, d_1 is the declination of the first body, d_2 is the declination of the second body, S is the difference of SHA of the two bodies, X_1 is the parallactic angle of the first body, A_1 is the angle at the first body between its vertical circle and the great circle between it and the second body, h_1 is the altitude of the first body (Ho is used), h_2 is the altitude (Ho) of the second body, L is the latitude of the observer, t_1 is the meridian angle of the first body, λ is the longitude of the observer, and GHA is the Greenwich hour angle of the first body.

If the great circle joining the two celestial bodies is on that side of the zenith opposite the elevated pole (if Z is within the angle formed by the vertical circle and hour circle of the first body), (X_1+A_1) is used in formulas (2) and (4), the sign in formula (3) is positive (+), and the sign of A_1 in formula (4) is negative (−). These signs are all reversed if the line adjoining the celestial bodies is on the opposite side of the zenith (Z outside the angle). If the great circle joining the two bodies passes almost through the zenith, an error might be made in the selection of the sign, and it is well to select another star pair. In formula (7) the sign is positive if the first celestial body is east of the observer's celestial meridian, and negative if it is west. The answer is in longitude measured westward from the Greenwich meridian. If the value exceeds 180°, it is subtracted from 360°, and the longitude is east.

If the quadrant of angle $(X_1 \pm A_1)$ or if t_1 is in doubt, the following formulas are suggested to replace (2) or (6):

$$\cot (X_1 \pm A_1) = \frac{\cos d_1 \tan d_2 - \sin d_1 \cos S}{\sin S} \tag{2A}$$

$$\cot t_1 = \frac{\cos d_1 \tan h_1 - \sin d_1 \cos X_1}{\sin X_1} \tag{6A}$$

In the presentation of the method it was suggested that simultaneous observations be obtained by a two-star tracker mounted on a stable platform, or by a double sextant. Several such sextants have been proposed, but none is in common use. Other possibilities would be to have two observers or to adjust the value of one observation for the change in altitude due to its apparent motion and the motion of the observer between observations.

It was proposed that values obtained by solution of formula (1) be published in a permanent table, since these values for various star pairs would be constant except for the very slight change due to proper motion (art. 1418). Since the values obtained by formula (2) change slowly with precession of the equinoxes (art. 1419), it was proposed that the angle (X_1+A_1) for a number of star pairs be published annually, perhaps in the almanacs. The other formulas would be solved after observation of the celestial bodies.

Kotlarić. In 1956 Stjepo M. Kotlarić (art. 2112), of Yugoslavia, proposed a method based upon computation of the same quantities suggested by Dozier. In the Kotlarić method most of the computation would be done in advance and published in tables divided into volumes for different latitude bands. This would generally eliminate the need for two answers for each set of altitudes, for the two intersections of the two circles of position would ordinarily be so far apart that only one solution would fall in the tabulated latitude band. Each volume would have a two-page index listing the stars used for each 5° latitude band and 15° LHA ♈ band, based upon the selection used in H.O. Pub. No. 249, Vol. I (art. 2113).

Similar tables were proposed for use with two observations of the sun or moon taken 45° of GHA apart. In this case, the first observation would be corrected (before the tables were entered) for the change in altitude due to motion of the craft between observations.

A separate table would be provided for each pair of observations. The tables would be entered with the altitudes, to the nearest 0°5, and the latitude of the observer; and the meridian angle of the second celestial body would be taken directly from the table. The meridian angle and GHA (from the almanac) would then be combined to find longitude. Delta values and a "multiplication table" would provide corrections for (1) the differences between observed and tabulated altitudes, (2) the difference between actual and tabulated declinations, and (3) the difference between the actual and tabulated SHA (or GHA) difference of the two celestial bodies. In the case of stars, the corrections for (2) and (3) are primarily due to precession of the equinoxes (art. 1419). If star observations were not taken simultaneously, a correction would be applied (before the tables were entered) to the first altitude to obtain the value it would have if made at the time of the second observation.

Uribe-White. A unique method of using two stars was suggested in 1952 by Enrique Uribe-White, of Colombia. A bubble sextant would be used to measure the altitude of one star, while a small, marine-type sextant attached to the bubble sextant would be used to measure simultaneously the angle at the star between the vertical circle and the great circle through this star and a second one. Prepared tables would give the great-circle distance between the two stars and also the angle between the great circle joining them and the hour circle of the first star. This angle, combined with the inclined angle which would be measured, constitute the parallactic angle (art. 1433). With this value, the observed altitude, and the declination of the first body, the latitude of the observer and the meridian angle of the first star could be computed by relatively simple formulas or by a mechanical computer proposed by the originator of the method. Meridian angle could be compared with GHA to determine longitude.

2117. Position from observation of single body.—If azimuth could be determined and plotted to sufficient accuracy, the altitude and azimuth of a single body could be used for establishing a fix. Any combination of altitude and azimuth methods (arts. 2108 and 2114) might be used, or the position could be computed without plotting. The following formulas might be used:

$$\sin t = \sin Z \cos h \sec d$$
$$\tan K_1 = \cos t \cot d$$
$$\tan K_2 = \cos Z \cot h$$
$$L = 90° - (K_1 \pm K_2) \qquad \text{(Approximate latitude must be known)}$$

A single body can be used for a running fix, of course, and if the body is near the zenith, a relatively short time might be needed. This is the case for high-altitude

observations (art. 2011) and has been used by a submarine measuring azimuth through its periscope when the sun is near the zenith (art. 2404).

Willis. Another method of determining position by a single body is by the use of altitude and rate of change of altitude. Three methods of doing this were suggested by Edward J. Willis in 1928.

Prime vertical observation. It can be shown by the use of differential calculus (art. O44) that

$$\cos L = \frac{dh}{dt} \csc Z \tag{1}$$

when $\frac{dh}{dt}$ is the rate of change of altitude with respect to time, specifically the change of altitude in minutes of arc during a one-minute-of-arc (four-seconds-of-time) change of hour angle of the body. However, to obtain latitude accurately in this way it is necessary to determine $\frac{dh}{dt}$ to an accuracy of perhaps four decimal places, and Z to an accuracy of perhaps one minute of arc. Two possible methods of obtaining $\frac{dh}{dt}$ are given below, but present instrument limitations do not permit measurement of azimuth to the required accuracy. However, the cosecant of 90° is unity, so that if the observation is made when the celestial body is on the prime vertical, the formula becomes

$$\cos L = \frac{dh}{dt} \tag{2}$$

Relatively little error is introduced if the body is within 1° of the prime vertical. The determination of position consists of the following steps:

1. Observe the altitude (h) and rate of change of altitude $\left(\frac{dh}{dt}\right)$ when the celestial body is within 1° of the prime vertical.
2. Compute latitude (L) by formula (2).
3. Determine longitude by any standard method, such as H.O. Pub. No. 214 or other line of position method, or by time sight (art. 2106).

Perpendicular lines of position. The great circle through the zenith and the celestial body (the vertical circle or azimuth line) furnishes an azimuth line of position that can be established if rate of change of altitude can be accurately determined. This line is perpendicular to the circle of equal altitude and therefore nearly perpendicular to the line of position determined in the usual manner. The intersection of the two lines is the position of the observer. The method involves the following steps:

1. Observe the altitude (h) and rate of change of altitude $\left(\frac{dh}{dt}\right)$.
2. Compute the direction of the great circle through the zenith and the celestial body (the vertical circle) at the point where the great circle crosses the celestial equator. This is the complement of the latitude of the vertex and so can be found from a modification of formula (2), which gives the latitude of the vertex:

$$\sin Z_0 = \frac{dh}{dt} \tag{3}$$

3. Compute the longitude (λ_0) at which the vertical circle crosses the celestial equator, using the formula

$$\sin (\lambda_0 \sim \lambda_b) = \tan Z_0 \tan d \tag{4}$$

The value λ_b is the longitude of the geographical position of the celestial body.

4. Solve for the latitude (L) at which the azimuth line of position crosses the meridian of the dead reckoning position, or for longitude (λ) at which the line crosses the parallel of latitude of the dead reckoning position, using one of the following formulas:

$$\tan L = \cot Z_0 \sin (\lambda_0 \sim \lambda_{DR}) \tag{5}$$

or

$$\sin (\lambda_0 \sim \lambda) = \tan Z_0 \tan L_{DR} \tag{6}$$

in which L_{DR} and λ_{DR} are the DR latitude and longitude, respectively. Any assumed position in the vicinity can be used in place of the DR. In general, it is preferable to use (5) if azimuth angle is between 45° and 135°, and (6) if it is outside these limits.

5. Solve for the direction (Z) of the azimuth line of position at the point determined in step (4), using the formula

$$\sin Z = \sin Z_0 \sec L \tag{7}$$

If the DR position or the AP is near the actual position, the azimuth can be considered the same at both without appreciable error.

6. Plot the azimuth line of position through the point found in step (4), in the direction found in step (5).

7. Compute *a* and Zn by any method and plot the resulting line of position. The intersection of the two lines of position is the fix.

Latitude and longitude by computation. This method is independent of a dead reckoning position, and requires no plotting. It is free from limitations except that observations near meridian transit should be avoided. At this time the rate of change of altitude decreases to zero and then reverses, introducing a possible error. The steps by this method are:

1. Observe the altitude (h) and rate of change of altitude $\left(\frac{dh}{dt}\right)$.
2. Compute Z_0, using formula (3).
3. Compute the latitude (L) of the observer by the formula

$$\sin L = \cos Z_0 \cos \left[h \pm \sin^{-1} \left(\frac{\sin d}{\cos Z_0} \right) \right] \tag{8}$$

In the solution of this equation, the angle whose sine is $\frac{\sin d}{\cos Z_0}$ is added to or subtracted from h. The cosine of this angle is then multiplied by $\cos Z_0$, and the result is the sine of the latitude of the observer. The sign is positive (+) unless L is greater than d and has the same name, when it is negative (−). However, if d is of the same name and greater, the angle to be added may be greater than 90°.

4. Compute the meridian angle of the observer by the formula

$$\sin t = \sin Z_0 \cos h \sec d \sec L \tag{9}$$

5. Determine GHA for the time of observation.
6. Convert t to LHA, and compute longitude (λ) by the formula

$$\lambda = GHA - LHA \tag{10}$$

If λ is greater than 180°, subtract it from 360° and label it E (east).

Formulas (8) and (10) yield a position on the circle of equal altitude regardless of the value of Z_0 used. The correct position is given only if the correct value of Z_0 is used.

Any of the three methods requires determination of $\frac{dh}{dt}$. Two methods are proposed:

In the first, the time needed for the sun (or moon) to change altitude an amount equal to its own diameter is measured. If the body is rising, the upper limb of the reflected image is brought a short distance below the horizon. As it makes contact with the horizon, a stop watch is started. When the lower limb makes contact with the

horizon (usually between 127.8 seconds, the minimum for a stationary observer, and ten minutes after the first contact) the watch is stopped, and the time is read to the nearest tenth of a second, if possible. If the body is setting, the lower limb of the reflected image is brought a short distance above the horizon and the watch started when the lower limb makes contact and stopped when the upper limb makes contact with the horizon. At sunrise or sunset no sextant is needed. Any lag in starting or stopping the watch will not affect the result if it is the same at both ends of the period. The diameter of the body, in minutes of arc, divided by one-fourth the number of seconds is $\frac{dh}{dt}$. Since semidiameter is tabulated, the most convenient procedure for determining $\frac{dh}{dt}$ is probably to solve the equation

$$\frac{dh}{dt}=\frac{8\,SD}{T},$$

where SD is the semidiameter of the body in minutes and T is the time interval in seconds. The semidiameter is given to the nearest 0'.1 in the *Nautical Almanac*. More accurate results will be obtained if the value is taken from the *Ephemeris*, where semidiameter is given to the nearest 0".01.

The motion of the observer introduces an error which can be corrected as follows: multiply *half* the run of the vessel between upper and lower limb contacts, expressed in nautical miles, by the cosine of the angle between the course of the vessel and the azimuth of the celestial body at the mid time of observation. If this angle is *less* than 90°, the correction is *added* to the tabulated semidiameter if the body is setting, and *subtracted* if it is rising. If the angle is *greater* than 90°, the correction is *added* if the body is rising and *subtracted* if it is setting.

Some practice may be needed to obtain an accurate measurement of the time interval. This practice might be obtained by making a number of observations at a known position and comparing these with values obtained by computation, using the formula

$$T=8\,SD\cos h\sec d\sec L\csc t,$$

using Hc for h.

The time of an observation is at the middle of the interval between contacts. In correcting hs, the reading of the sextant, to obtain Ho, omit the correction for semidiameter. This might be done by correcting in the usual manner, with an additional correction equal to the semidiameter. The additional correction is negative (−) if the lower limb correction is applied, and positive (+) if the upper limb correction is applied. Another way is to apply neither the lower nor upper limb correction, but a value equal to the algebraic average of both.

The second method of determining $\frac{dh}{dt}$ is given as the more accurate of the two. It consists of observing three altitudes of the celestial body at exactly equal intervals of from 15 to 30 minutes. A shorter interval may result in too great an error in rate, while a longer one increases the time without advantage. If h_1, h_2, and h_3 are the three altitudes and t_1 and t_3 are the meridian angles at the times of the first and third observations, respectively, $\frac{dh}{dt}$ can be computed by means of the formula

$$\frac{dh}{dt}=\sin \tfrac{1}{2}(h_1-h_3)\cos \tfrac{1}{2}(h_1+h_3)\csc \tfrac{1}{2}(t_1-t_3)\sec h_2.$$

If difficulty is experienced in making an accurate observation at a given time, better results might be obtained by computing the time for the third observation, by adding the interval between the first two observations to the time of the second observation, and then making several observations starting shortly before the computed

time. These can then be plotted on cross-section paper with altitude as one coordinate and time as the other. The altitude indicated by the intersection of the line representing the required time and a line faired through the plotted points is used as the third altitude. A similar procedure might increase the accuracy of the first two observations. A quicker but less accurate way of determining the third altitude is to take one observation shortly before the required time and another shortly after it, and interpolating to find the altitude at the required time. Another variation is to take an altitude at *about* the required time and adjust the second altitude to the corresponding value midway between the first and third observations, using the mean value found by interpolating from the first or third observation and extrapolating (art. P6) from the other. The time and altitude are those of the second observation.

This method assumes no change of declination between observations, and no change in the position of the observer. When the observer is not stationary, a correction is applied to h_1 and h_3 to convert them to the equivalent values at the position of the second observation. Assuming constant course and speed, this correction in minutes of arc is equal to the vessel's run between consecutive observations multiplied by the cosine of the angle between the course of the vessel and the average azimuth of the body. If the angle is *less* than 90°, the correction is *added* to h_1 and *subtracted* from h_3. If the angle is *greater* than 90°, the correction is *subtracted* from h_1 and *added* to h_3.

A possible variation of either method of determining $\frac{dh}{dt}$ would be to make a comparatively large number of observations (10 to 15) at short intervals and plot the altitudes versus time on cross-section paper. A point near each end of the line faired through the plotted points would then be corrected for the run of the vessel, as in the second method. Two points might then be selected, one near each end of the altitude-time line. The change in altitude, in minutes, divided by the number of seconds between the two points is $\frac{dh}{dt}$. If preferred, three points might be selected at equal intervals and the formula of the second method used.

Rate determined by two individual observations a few minutes apart would not be sufficiently accurate for practical navigation.

None of the methods employing rate of change of altitude have proved popular, probably because of the difficulty of obtaining an accurate value of $\frac{dh}{dt}$. The use of azimuth and rate of change of azimuth, altitude and rate of change of azimuth, or azimuth and rate of change of altitude have been even less attractive because of the even greater difficulty of obtaining accurate measurements of azimuth or rate of change of azimuth. With the further development of automatic devices for continuously measuring altitude or azimuth, with allowance for motion of the observer, such methods might prove more attractive.

2118. Use of unique situations.—Various unique situations might be used for determining position or a line of position. As a general rule these have not been attractive because they could be used only when the conditions were met. As an example, if a celestial body of known coordinates were known to be in the zenith, the declination of the body would be the same as the latitude of the observer. His longitude would be the same as GHA of the body (360°−GHA in east longitude).

Near the geographical poles, the poles can be used as the assumed position. Here the declination of the body is the same as the computed altitude, and GHA replaces azimuth.

Meridian altitudes (art. 2103) and latitude by Polaris (art. 2105) are examples of methods depending upon unique situations. These have both been used extensively,

but are decreasing in popularity because of their reliance upon unique conditions, without adequately compensating advantages.

Shchetkin. In 1899 N. O. Shchetkin proposed a method of computing latitude and meridian angle from measurement of the times at which two or more pairs of stars have the same altitude. Each star pair would provide, in effect, a single great-circle line of position. Variations of the method were proposed by Zinger, Pewzow, and W. W. Kawraisky, a Russian. The necessary tables for latitude 60° N to 80° N were published by the Astronomical Institute of Russia in 1936. A similar method was prepared by Simon Swahn in 1943.

Collins. In 1946 Oliver C. Collins, an astronomer at the University of Nebraska, proposed a variation of the method of Shchetkin, and extended it to include observations when two celestial bodies have the same azimuth.

McKee. In 1951 Lieutenant Merlin A. McKee, USMS, proposed a graphical solution of the same-altitude method of Collins.

Pierce. About 1951 Rear Admiral M. R. Pierce, USN (Ret.), suggested a method of establishing a line of position perpendicular to the course line when the altitude of a celestial body is observed at the moment it crosses the great circle through the observer and his destination.

2119. Graphical and mechanical solutions.—All of the methods described above require tables, either for a mathematical solution or to extract computed values of altitude and azimuth. The total number of possible tabular solutions must be very great. The number of graphical and mechanical solutions is almost endless. The ones selected for mention below are representative of the types that have been prepared or made available.

Graphical solutions are almost as old as tabular ones, having existed at least since 1790, when *Margetts' Horary Tables* appeared in graphical form. These were intended "for shewing by Inspection the Apparent Diurnal Motion of the Sun, Moon, and Stars, the Latitude of a Ship and the Azimuth, Time, or Altitude corresponding with any Celestial Object." They were intended primarily for use with the longitude method of laying down a line of position.

In general, graphical and mechanical solutions have not proved popular, for several reasons: First, they generally involve a small scale, yielding results of less accuracy than desired, even with careful work. Second, some of the methods must be used as a whole, and cannot be divided into parts to increase the scale. Third, such methods usually do not provide a record of the solution, and it is often difficult to check the results. Fourth, solutions requiring instruments are subject to errors due to lack of proper adjustment or mechanical damage which may not be apparent. Fifth, the required diagrams or instruments may be quite bulky, requiring considerable space for stowage and manipulation. Finally, in some cases the necessary instruments are expensive.

2120. Altitude and azimuth angle by graph.—One type of graphical solution is by means of a diagram that solves an equation.

d'Ocagne. Typical of such diagrams is that prepared by Maurice d'Ocagne, a Frenchman. Both altitude and azimuth angle can be found by means of this diagram, which is based upon the following formulas:

$$\text{hav } z = \text{hav } (L-d) + \{\text{hav } [180° - (L+d)] - \text{hav } (L-d)\} \text{ hav } t,$$

$$\text{hav } (90° \pm d) = \text{hav } (L-h) + \{\text{hav } [180° - (L+h)] - \text{hav } (L-h)\} \text{ hav } Z,$$

in which $z = 90° - h$.

The sides of a square are divided according to the haversines of angles, from 0° to 180°, and the corresponding graduations of opposite sides are connected with straight lines, forming a diagram as shown in figure 2120a. The graduations on the two sides run in opposite directions. To find the zenith distance, locate the value corresponding to (L−d) along the left of the diagram, and the value corresponding to (L+d) along the right of the diagram. Draw a straight line through these points. Locate the intersection of this line with the vertical line corresponding to meridian angle. A horizontal line from this intersection to the left edge indicates the zenith distance.

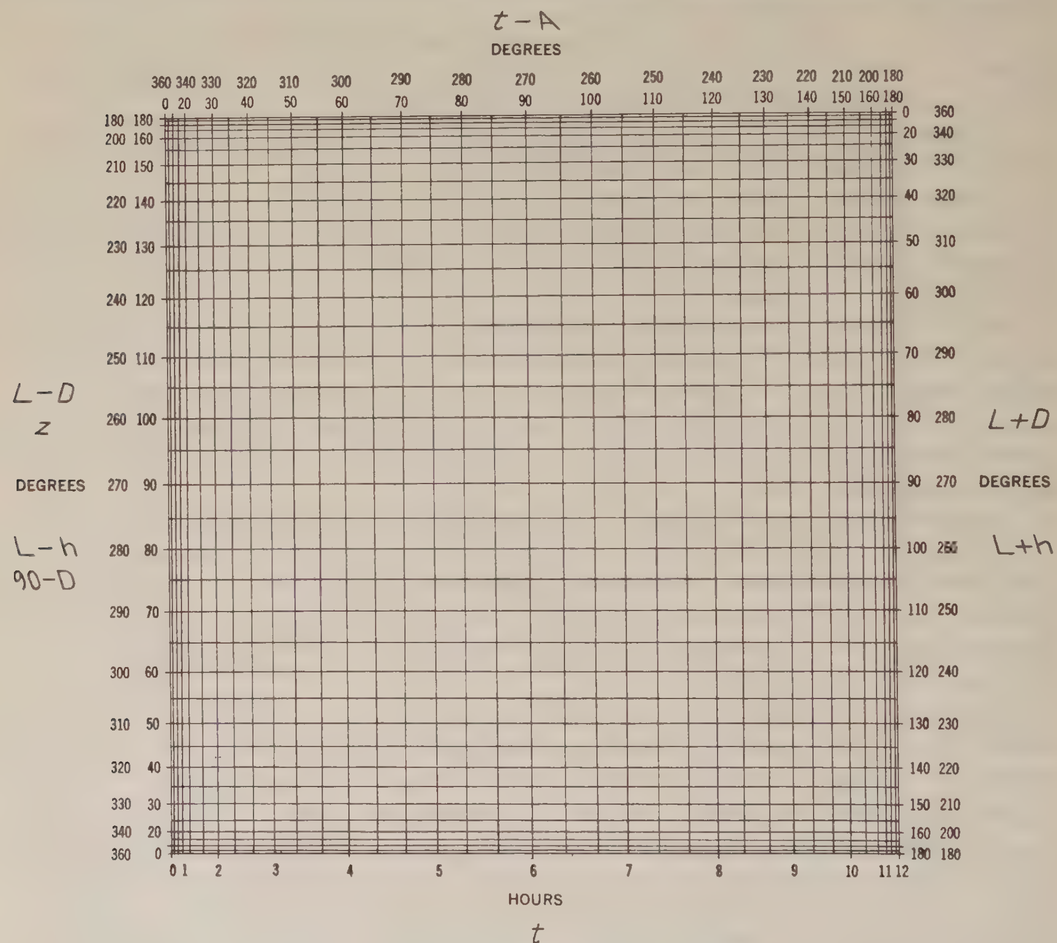

Figure 2120a.—The d'Ocagne diagram as H.O. Chart No. 2776.

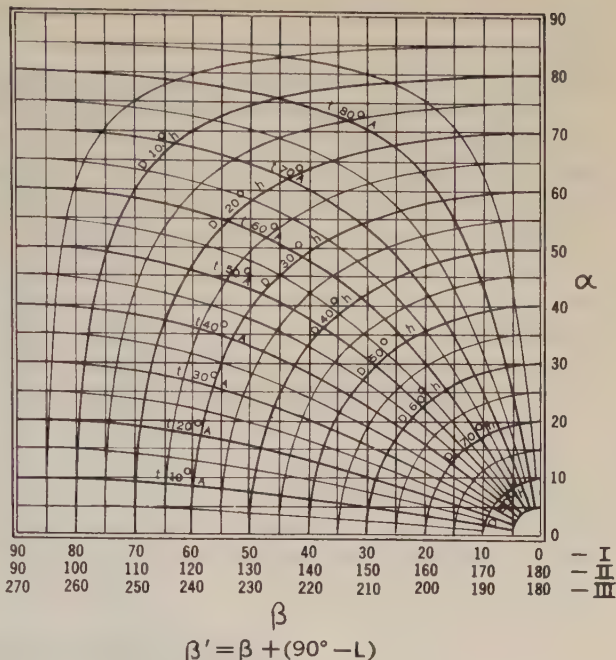
To find azimuth angle, draw a straight line between (L−h) at the left and (L+h) at the right. Locate the intersection of this line and the *horizontal* line corresponding to (90°−d). A *vertical* line from this intersection to the top of the diagram indicates the azimuth angle.

If the altitude, latitude, and declination are known, the first solution can be made in reverse for meridian angle, for a longitude method solution.

The diagram was first published in 1899 in *Traité de Nomographie* by d'Ocagne. Similar diagrams have since been published under the name *Spherical Triangle Nomo-*

gram by Wimperis, and under the title *Altitude, Azimuth, and Hour Angle Diagram* by Littlehales in 1906, and by the U. S. Navy Hydrographic Office in 1917.

Favé and Rollet de l'Isle.—If a perpendicular is dropped from the celestial body to the celestial meridian, a diagram can be prepared to solve the basic formulas given in article 2111, or others derived from these. Such a diagram is shown in figure 2120b. This diagram was devised by the French engineers Favé and Rollet de l'Isle in 1892. The diagram represents only one-eighth of a sphere, additional sections being needed. An alternative is to show additional labels, as in figure 2120b. This results in three "cases" and several rules similar to those used with some logarithmic solutions. Solutions for both altitude and azimuth angle are made in two steps, plus one addition or subtraction. This diagram was reproduced by the Frenchman M. E. Pereire in 1894 and by another Frenchman, P. Constan, in 1906 as a method of finding azimuth.



Case 1. L and D same Name —t<90°
Read β on scale II
Azimuth from upper pole, E or W as star is E or W of meridian

Case 2. L and D same name —t>90°
Read (180°—t) instead of t
Read β on scale I
Azimuth from upper pole, E or W as star is E or W of meridian

Case 3. L and D opposite names
Read β on scale I
Azimuth from lower pole, E or W as star is E or W of meridian

FIGURE 2120b.—The Favé diagram.

Jernæs.—In 1953 Leiv Jernæs, a Norwegian, invented a device he called a "Nauticator," which consists of various scales in a semicircle with radial scales on a plastic arm pivoted at the center of curvature of the semicircle. The device is used with a pair of dividers to solve various problems of spherical trigonometry to an accuracy of about 15′.

Bertin. In 1955 Rev. Maurice Bertin, a Frenchman, devised a graphical solution for the longitude method, using the formulas:

$$\tan^2 \tfrac{1}{2} t = \tan \tfrac{1}{2} (90° - \alpha) \tan \tfrac{1}{2} (90° - \beta) \quad (1)$$

and

$$\tan^2 \tfrac{1}{2} Z = \frac{\tan \tfrac{1}{2} (90° - \alpha)}{\tan \tfrac{1}{2} (90° - \beta)} \quad (2)$$

in which

$$\tan \tfrac{1}{2} \alpha = \tan \tfrac{1}{2} (h + d) \tan \tfrac{1}{2} (90° - L)$$

and

$$\tan \tfrac{1}{2} \beta = \frac{\tan \tfrac{1}{2} (h - d)}{\tan \tfrac{1}{2} (90° - L)}.$$

The diagram consists of three families of straight lines, one vertical, one horizontal, and the third at an angle of 45° to the others. The accuracy depends upon the scale of the diagram, but a large one is needed for navigational accuracy.

2121. Altitude and azimuth angle by computer.—Slide rules, like diagrams, have been devised to solve formulas. In the case of the navigational triangle, both suffer from the need for a scale that can be read to a subdivision at least as small as 1′. A number of such slide rules have been devised for use in reducing celestial observations.

Richer. In 1791 Jean Francisco Richer, a Frenchman, constructed a device composed of six arms, some hinged and some sliding, which won a prize offered by the Paris Academy of Science for a simple method of "clearing" lunar distances (art. 131) in the solution for longitude. The device solved a formula devised by the French mathematician Joseph Louis Lagrange, and was capable also of solving other problems involving spherical triangles, such as those related to time sight solution (art. 2106), computation of altitude, and great-circle sailing problems (art. 819).

Poor. A slide rule invented by Professor Charles L. Poor is shown in figure 2121a. This device, called the "Line of Position Computer," was designed to solve the cosine-haversine formula (art. 2109). Eight concentric circular scales are engraved on a metal disk about 15 inches in diameter. A plastic arm and circular sheet are pivoted at the center of the disk. The arm may be clamped to the plastic sheet. The seven

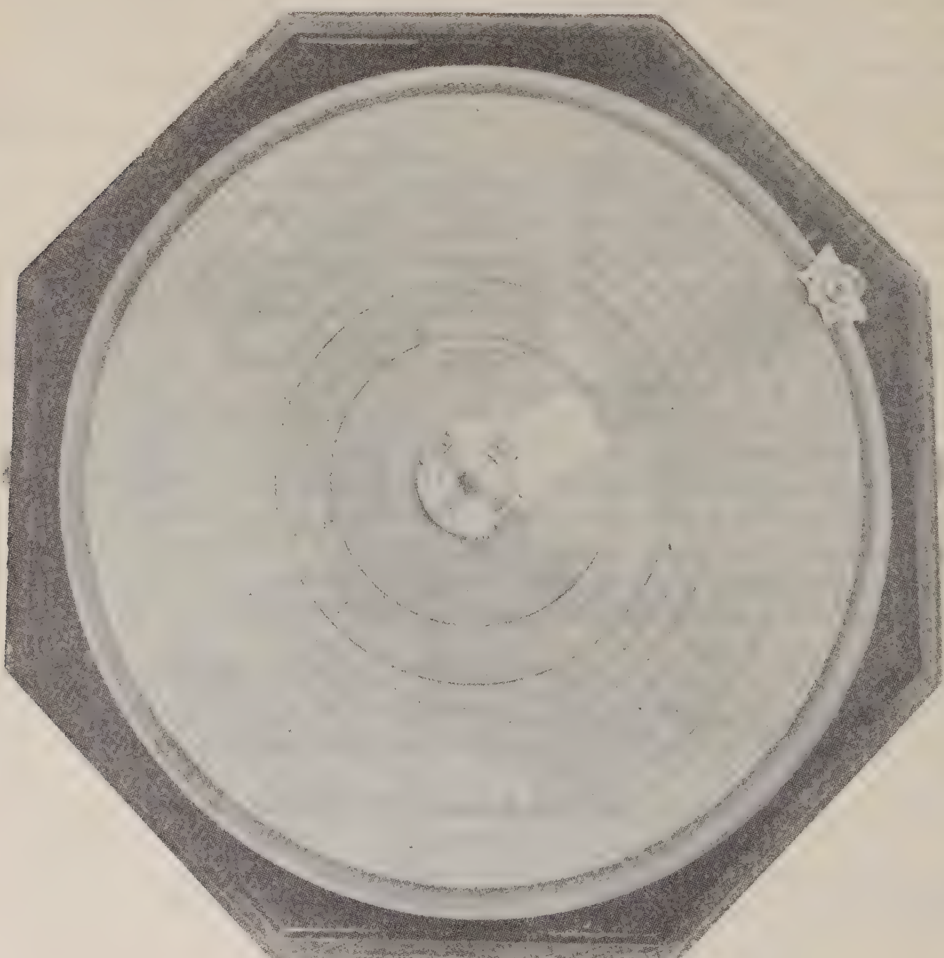


Figure 2121a.—The Poor Line of Position Computer.

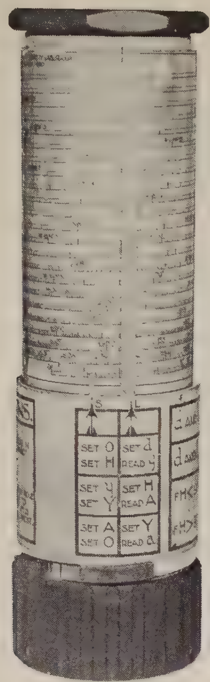

FIGURE 2121b.—The Bygrave slide rule.

outer scales are used in solving for altitude. The altitude scale is graduated at intervals of 10′, and further subdivisions can be estimated. The inner scale is used for determining azimuth angle. Several rules are needed, and the number of scales adds to the possibility of error.

Bygrave. A cylindrical slide rule was designed by the Englishman Bygrave to solve the navigational triangle divided by dropping a perpendicular from the celestial body to the celestial meridian (fig. 2111). This device, shown in figure 2121b, consists of three concentric tubes. The inner one has a spiral scale of logarithmic tangents, the middle one a spiral scale of logarithmic cosines, and the outer one a pointer for each scale. Solution is simple and relatively fast, but altered procedures are required if the azimuth angle is near 90°, or the meridian angle or declination is very small. The overall dimensions are about 2½ inches in diameter by nine inches long. An accuracy of about 1′ or 2′ is generally attainable.

Bertin. In 1955 Rev. Maurice Bertin devised an 18-inch slide rule to provide a solution of the longitude method to an accuracy of about 1°, using the formulas upon which his graphical solution (art. 2120) is based. He also devised a solution of the same formulas by a circular slide rule consisting essentially of two spirals. The inner one is on a disk 23 centimeters (9.2 inches) in diameter, and the outer one is on an annular ring 39 centimeters (15.6 inches) in outside diameter. The graduations are proportional to the log cotangents of half-angles. A window on a cover is provided with a radial line to serve as an index. Solution is facilitated if an approximation of the answer is known in advance. An accuracy of better than 3′ is claimed for this device. Still another solution proposed at the same time is by a computer consisting

of a strip four centimeters (1.6 inches) wide and 12 meters (nearly 40 feet) long, wound on two rollers and engraved with three sets of graduations. An accuracy of better than 1′ is claimed, but several arithmetical steps are required.

LeSort. A computing device based upon solution of formulas for a divided navigational triangle was designed by Commander LeSort of the French Navy. Logarithmic scales are placed on eight films wound on rollers. The films operate in pairs so arranged that the two films of any pair can be locked together at any point. Alternate films carry log cosine and log tangent scales. Although an accuracy of about 0′.2 can be obtained, the method is comparatively long and has no apparent advantage over modern inspection tables.

Desk computers. Several desk-type computers have been designed to solve the navigational triangle, but none has proved popular.

2122. Altitude and azimuth angle by map projection.—If the observer were to move along his meridian to the nearer pole, and the navigational triangle were to move with him without its proportions being changed, his zenith would coincide with the pole, and the vertical circle would coincide with some celestial meridian. Zenith distance or altitude could be read directly. Since both great circles forming the azimuth angle would now coincide with celestial meridians, the azimuth angle could also be determined directly.

Littlehales. To accomplish this with a sphere, to a useful accuracy, would require a sphere of impractical size for use by the navigator. However, the solution can be made by means of a map projection. George Littlehales, of the U. S. Navy Hydrographic Office, used the stereographic projection (art. 318) and a 12-foot sphere for this purpose. The projection is divided into 368 overlapping sheets which, with a key diagram, are bound together. An accuracy of about 1′ or 2′ can be obtained by a rapid and simple process, but the volume is bulky and not particularly convenient.

Veater. Commander Veater of the British Royal Navy used the transverse Mercator projection (art. 309), with the observer's meridian as the fictitious equator.

Hyatt. A similar principle is utilized in the diagram on the plane of the celestial meridian (art. 1432). A mechanical device based upon this diagram can be made by drawing a hemisphere by equatorial orthographic (art. 319) or stereographic projection and pivoting at its center an identical hemisphere on transparent material. If the top hemisphere is rotated until the arc between poles of the two hemispheres is equal to the colatitude of the observer, the lines of one hemisphere represent coordinates of the celestial equator system (art. 1426), and those of the other, coordinates of the horizon system (art. 1428). Thus, if a body is located by meridian angle and declination on one set of lines, its altitude and azimuth angle can be read from the other set. If altitude and declination are used to locate the body, meridian angle can be read from the diagram. In the United States such a device, on both the orthographic and stereographic projections, has been prepared by Commander Delwyn Hyatt, USN, under the titles "Celestial Coordinator" and "Coordinate Transformer." It has also been produced in other countries, notably in Germany, France, and Russia, where, in addition to such a device, precision instruments based upon the same principle have been constructed. The scale of the German instrument is so small that an accuracy of about 5′ is about the best that can be expected. The Bastien-Morin (French) and Kavroyskyy (Russian) instruments might yield results of slightly greater accuracy. The plastic device, if carefully made, might be generally accurate to half a degree. It has been used primarily for instructional purposes.

Brown-Nassau. The Brown-Nassau "Navigational Computer" utilizes the same principle, but uses the azimuthal equidistant projection (art. 320) and increases the

scale by limiting the device to an octant of the sphere, with separate solutions for altitude and azimuth, and various rules.

True. In his *Celestial Navigator for Aviators*, printed about 1943, Clarence H. True, of the Canal Zone, uses a single diagram on the orthographic projection. This serves as the basis for a solution by construction, claimed to be of sufficient accuracy for use in lifeboats. Various rules are needed.

Pierce. A series of diagrams on the azimuthal equidistant projection have been devised by Rear Admiral M. R. Pierce, USN (Ret.). The method is based upon the principle that angles are correctly represented at the point of tangency of this projection, and radial lines from this point represent great circles along which distances are represented by a uniform scale. A protractor is used for measuring the azimuth angle. Attached to the protractor is an arm with a linear scale graduated so that altitude can be read directly. The whole device is called a "Cadameter." The method is easy to use, and about as fast as modern inspection tables. With great care an accuracy of 1′ can be obtained. The method suffers from the need for a number of diagrams which are somewhat bulky and more susceptible to damage than a book.

2123. Latitude and longitude by diagram.—A number of graphical and mechanical solutions have been devised to yield latitude and longitude directly.

Beij. One proposed in 1924 by K. Hilding Beij, of the U. S. Bureau of Standards, was based upon the fact that latitude and local sidereal time are completely defined by the simultaneous altitudes of two celestial bodies whose declination and SHA are known. A page of his proposed diagrams is shown in figure 2123a, in which latitude is the abscissa, and LST is the ordinate. Position on the graph is located by the intersection of the curves representing the altitude of the two celestial bodies observed. The vertical line through the intersection indicates the latitude, and the horizontal line the LST. The difference between GST and LST is the longitude. If a timepiece keeping GST is available, not even an almanac is needed.

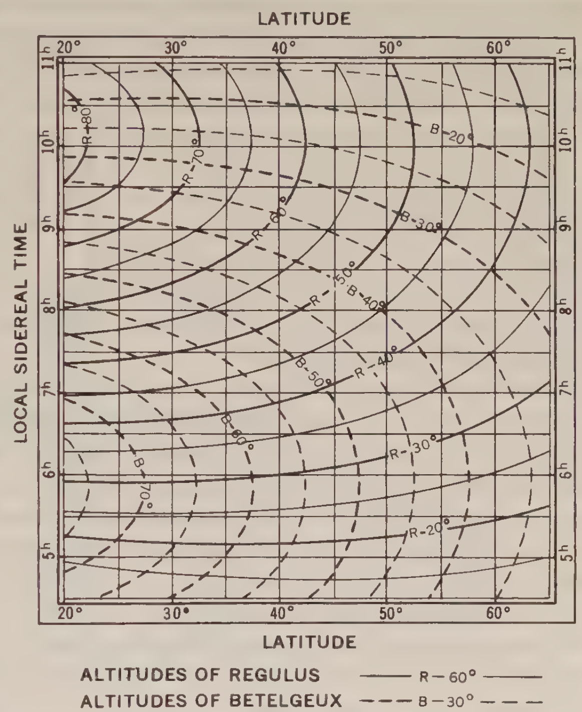

FIGURE 2123a.—The Beij two-star diagram.

The method is accurate, fast, and direct. The individual sheets can be drawn to any scale and cut to any size desired. For a large scale with sheets of a convenient size, a great many diagrams would be needed, but these might be bound together in convenient-size volumes, or placed on a tape wound around rollers, as originally proposed. A weakness of the method is the requirement for simultaneous observations. For nonsimultaneous observations a table might be provided to indicate the change in altitude during the interval between observations. Since the positions of the curves depend upon the declination and SHA of the body, the method is limited to celestial

bodies whose coordinates are nearly constant, unless the curves are intended only for a particular time. Even for stars, the diagrams become out-of-date in a few years. The method is limited to the particular bodies for which curves are shown, although the number of curves need not be limited to two. This is a form of precomputation, since the computation is performed in locating the curves, rather than by the navigator. In a sense, it might be considered a graphical form of H.O. Pub. No. 249 (art. 2113).

Weems. If the Beij diagram is rotated through 90°, the parallels of latitude become horizontal, as customary on a chart. If they are spaced according to the Mercator projection, azimuth is indicated by the normal to a curve. This is the arrangement used by Captain P. V. H. Weems, USN (Ret.), in his *Star Altitude Curves*, the first volume of which was published in 1928. Later he added a third star, using a different color for each star, and included a correction for refraction at sea level. A separate volume is used for each 10° of latitude, and a correction is provided for precession of the equinoxes. Coverage extends from latitude 50° S to 70° N, with a separate volume for latitude 70°–90° N. The curves for 80°–90° N are on the polar stereographic projection. Any orthomorphic projection (art. 302) could be used at any latitude.

Lines representing observations at different times can be advanced or retired as on any chart of the same projection. In addition to the adjustment due to motion of the craft between observations, the lines are shifted right or left for the elapsed time between observations. An accuracy of about 1′ is attainable by interpolation between curves for each 10′ of altitude.

The star altitude curves are undoubtedly the most widely used of all the graphical and mechanical methods. Two-star curves similar to Weems' first edition were published in Germany in 1940.

Pritchard and Lamplough. In 1940 H. C. Pritchard and F. E. Lamplough, of the British Royal Aircraft Establishment, devised a method of reducing the work involved in the adjustment for elapsed time between observations. They placed the star altitude curves on film which is used in a projector called an **astrograph.** The curves are projected onto a Mercator plotting sheet and can be moved across it to allow for rotation of the earth. The adjustment is critical, the setting of the projector somewhat involved (a special "astrograph mean time" being needed), and a bulky and expensive projector is needed to prevent distortion. Because of these disadvantages and the fact that any advantage over short tabular methods is slight, the astrograph decreased in popularity following World War II.

Longley. In 1943 Flight Lieutenant C. D. N. Longley, RAF, suggested a "Star Computer" based upon the principle of the astrograph. A circular disk serving as a base plate would have a mean time scale around its circumference. Altitude curves of a limited number of stars would be printed on a template for each latitude. The circumference of each template would also carry a mean time scale. A radial cursor would aid in reading the device, which is set by means of the GMT at which LHA ♈ is 0° at some convenient longitude, the time of observation, and observed altitude. Longitude is determined within a 10° band, the ambiguity being resolved by means of the dead reckoning position. With a modification of the procedure, the device can be used with the altitude method.

Baker. As early as 1919 Commander T. Y. Baker, RN, prepared altitude curves and their orthogonals (normals) on transparent tape which is wound on rollers in the "Baker Navigating Machine" (fig. 2123b). The transparent tape is moved across a Mercator plotting sheet, being oriented by means of a time scale set with respect to a meridian. The line of position is transferred to the plotting sheet by means of carbon paper. A single tape has curves for several stars, and a separate tape for each 4° of declination from 24° N to 24° S permits use of the device with the sun and other

bodies of the solar system. A rule attached to the machine (shown at the top of fig. 2123b) provides a correction for declination differing from that of the curves.

Davies. The principle of the Baker Navigating Machine was used by Commander T. D. Davies, USN, in 1947 in a device for use in the antarctic. A chart on the polar azimuthal equidistant projection (art. 320) is printed on plastic material. A set of altitude curves is printed on a second sheet and placed under the chart, being pivoted at the south pole. A slot in the material bearing the altitude curves permits adjustment for any declination between 8°S and 18°S, the values the sun was to have had during the original period of use. Additional sets of curves could be provided for other declination ranges, or the slot increased in length. In the use of the device, the curves are oriented for GHA and declination, and a short segment of the curve representing the observed altitude is traced on the chart.

Weems. In 1955 Captain P. V. H. Weems, USN (Ret.), prepared a somewhat similar device called a "Polar Computer," using his star altitude curves.

Leick. In 1911 Dr. A. Leick, a German, prepared a diagram by which latitude and LST could be obtained by altitudes of Polaris and one other star. The diagram can be used for finding the correction to apply to the altitude of Polaris to determine the latitude, and then to find the LST in a second step.

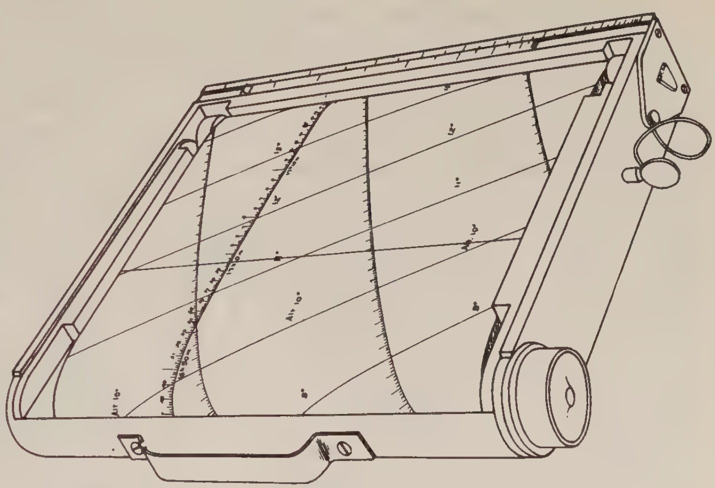

FIGURE 2123b.—The Baker Navigating Machine.

Favé. In 1901 Favé devised a graphical solution based upon the Marcq St.-Hilaire principle (art. 2108). A chart on the stereographic projection (art. 318) is used. Tables of computed altitude and azimuth for the point of tangency are needed. The chart is on transparent material. An additional sheet has a set of arcs of circles, with a straight azimuth line drawn normal to them. The chart is placed over the curves with the straight azimuth line through the point of tangency and oriented in the direction of the celestial body. A large circle on the chart assists in this orientation. The chart is then moved along the azimuth line until the curve representing the computed altitude at the point of tangency is under that point. The curve representing the observed altitude is then correctly placed and a segment of it can be traced on the chart. However, due to chart distortion, error is introduced in this way. It can be removed by means of a nomogram which indicates the correct curve to use. A mark is placed on the chart at the intersection of the azimuth line and the curve representing the observed altitude. The chart is then moved along the azimuth line a second time until the correct curve is in place, and the arc is traced. This process is repeated for each celestial body observed. For stars, a one-page set of curves can be used instead of tables for determining altitude and azimuth at the point of tangency. Favé recommended use of five separate charts with points of tangency at 0°, 30°, 45°, 75°, and 90°, respectively. Each chart could be used as a plotting sheet for any longitude at the same latitude, requiring computed altitude and azimuth for only five places. Favé

later put his method into instrumental form and used a special protractor and curved ruler.

Brill. In 1909 Dr. Alfred Brill, a German, invented a device based upon the same principle used by Favé, as shown in figure 2123c. In this device the plotting sheet is on the azimuthal equidistant projection (art. 320) and covers about 10° of latitude. Two sets of curves on separate sheets of tracing cloth are mounted below the plotting sheet. A handle turns the plotting sheet to the correct azimuth.

Voigt. The same principle used by Favé and Brill was used in the Voigt "Orion" instrument constructed in Germany in 1911. A plotting sheet on the azimuthal equidistant projection is engraved on aluminum. Each of the three plotting sheets, centered on latitudes 42°, 50°, and 55°, respectively, covers a spread of 10° of latitude. The line of position is drawn by means of a flexible ruler mounted on a bridge that can be clamped at any position over the plotting sheet. The curvature is controlled by means of gears, a scale being provided to indicate the correct value.

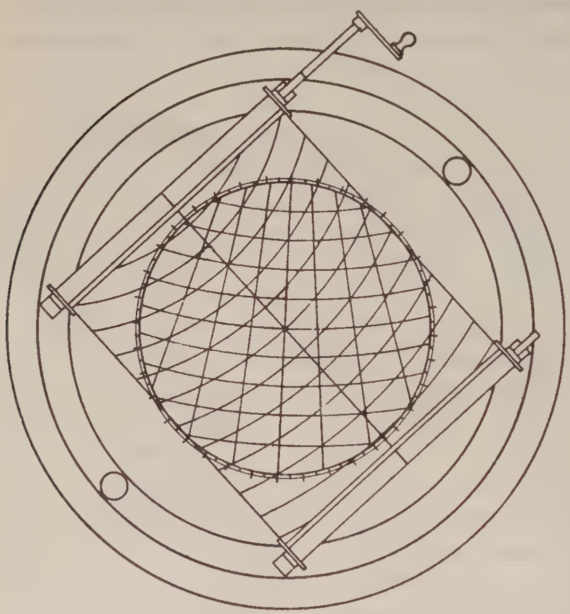

FIGURE 2123c.—The Brill device.

Vucetic. In 1921 a device called a "Toposcope" was prepared by Vucetic, a Frenchman. The device is identical with the Brill instrument except that a single set of curves is prepared and these are cut through the material as slots, and placed over the top of the plotting sheet.

Littlehales in 1918 suggested a method similar to that of Favé, but with a polyconic projection (art. 315).

Kahn. In 1928 Louis Kahn, a French naval architect, proposed that a set of navigational charts be prepared on the oblique Mercator projection (art. 310), a separate chart being provided for the great circle between various places on the earth. On each chart the small circles on the earth directly below the parallels of declination (that is, the daily paths of the geographical positions) of various navigational stars would be shown. These circles would be graduated in Greenwich sidereal time, so that the GP at any GST would be indicated. The distance from any assumed position to the GP at the instant of observation would be the zenith distance, and the direction of the line would be the azimuth. By comparing the observed zenith distance with that at the assumed position, the navigator could obtain the altitude difference, and plot the line of position. The common intersection of two or more such lines of position, advanced or retired to a common time if necessary, would define the position of the observer. The method would be limited to zenith distance within the range of the chart. A later version would produce greater accuracy, but with a little more trouble in making the measurements, by substituting the gnomonic projection (art. 317) for the oblique Mercator projection.

Dusinberre. In 1944 Lieutenant Commander H. W. Dusinberre, USN, suggested a method using star diagrams. A diagram for each 1° of latitude and 1° of LHA♈ would be provided. Each diagram would consist of a series of radial lines extending in the directions of the prominent stars favorable for observation. The 22 stars of

H.O. Pub. No. 218 (art. 2113) were suggested. Until changed by precession of the equinoxes (art. 1419) the common origin of these lines would represent a definite altitude for each star. The altitude at the next higher whole degree or half degree, adjusted for refraction, would be indicated by a tick on the appropriate azimuth line. After observation, a transparent plotting board would be properly oriented over the appropriate star diagram, using LHA ♈ and adjusting for the run between observations. The line of position would then be drawn at the correct point, perpendicular to the azimuth line, using the tick as a guide. An LHA ♈ computer was proposed for determining LHA ♈ at the time of each observation from a single LHA ♈ for a time near the start of each set of observations. When all lines of position were plotted, the fix would be transferred to the chart or plotting sheet.

2124. Solution by sphere.—Solution of a spherical triangle directly on a spherical surface, or by means of arcs representing great circles on the surface of an imaginary sphere, must have occurred to man quite early. Pictures of ancient navigators surrounded by their instruments and accessories invariably show a sphere. Solution by sphere is still suggested from time to time. Although this method is relatively simple and easy, the problem of scale is even more acute than in the graphical solutions.

Spherical methods can be classified in three groups: (1) those which solve the navigational triangle for a single line of position, (2) those which solve two or more observations for a fix, and (3) those which combine observation and solution for a fix.

The first group constructs the navigational triangle with arcs of great circles. Essentially, such a device consists of three arcs. The one representing the celestial meridian is usually fixed and a part of the frame. The base to which it is attached usually carries the azimuth scale. Movable arcs are provided for the vertical circle and the hour circle. If the latitude, meridian angle, and declination are properly set, the three arcs form the navigational triangle, and altitude and azimuth angle can be read from their scales. If altitude is used for constructing the triangle, meridian angle can be read from the instrument for a longitude solution.

Willis. A large number of teaching aids has been based upon this design or one of the many possible variations of it. Several precision instruments have been proposed or actually constructed. In 1932 such an instrument designed by Edward J. Willis, an American engineer, was constructed in Scotland. The marine version, weighing about 27 pounds, is graduated to 1′; and the aeronautical version, weighing between seven and eight pounds, is graduated to 5′. The longest dimension of either version is 11 inches.

Japanese Navy. During World War II, the Japanese Navy used an instrument virtually in the form described above. Results were accurate to approximately 1′.

McMillen. Of the various methods of determining a fix by sphere, the most obvious is that of providing an actual sphere as a plotting surface, with provision for striking arcs equal to the zenith distances, using the geographical positions of the celestial bodies as centers. In 1943 such a method was proposed by D. A. McMillen, a United States businessman in São Paulo, Brazil. His sphere, of a little more than 14 inches in diameter, had a scale of 8° (480 nautical miles) per inch along a great circle.

Hiltner. In 1945 Dr. W. F. Hiltner, a professor at Lehigh University, suggested a similar method using arcs of spheres and a billiard ball. This, in effect, sets up two navigational triangles, locating the observer at the common zenith of both triangles. Simultaneous observations are needed.

U. S. Navy Training Device Center. About the same time, the Training Device Center of the U. S. Navy prepared a device called the "Sphereman Craft Positioner," combining the functions of the devices of both McMillen and Hiltner, and providing a

plotting surface for dead reckoning. A line of position from a single observation can be drawn on the 17-inch aluminum globe, or the triangle of position from the observation of three stars can be mechanically set up. Provision is made for advancement or retirement of lines due to motion of the craft. The device was intended for training purposes.

Zerbee. In 1951 Louis J. Zerbee, of Bellfontaine, Ohio, proposed a device similar to that of Hiltner, but without the billiard ball. His instrument was called the "Zerbee Celestial Fix Finder." Like the Hiltner device, that of Zerbee makes no provision for nonsimultaneous observations (unless one of them is corrected to the value it would have if observed simultaneously with the other) or for a check by observation of additional bodies. Observations of bodies near the meridian or taken from high latitudes cannot be accommodated.

Combined sextant and computer. At least as early as 1895 an attempt was made to combine in a single instrument the functions of sextant and computer. Such instruments are fundamentally the same as those described above, except that they are set by alignment with one or more celestial bodies. If the instrument is level and accurately aligned with the meridian at the time of observation, the miniature sphere is oriented to the celestial sphere and the earth. If both the altitude and azimuth are used, a fix can be obtained by means of a single celestial body. If two bodies are observed simultaneously, accurate directional reference by compass is not needed.

The weakness of such methods is the need for a stable platform and either accurate directional reference or the need for observing two bodies simultaneously.

Beehler. In 1895 Lieutenant W. H. Beehler, USN, invented an instrument he called the "Solarometer," which was designed to furnish a position from observation of the sun. It requires a heavy cast iron base rigidly attached to the ship, with a bowl set in gimbals and filled with mercury. A float resting on the mercury carries the sighting instrument.

Hagner. In 1936 Fred Hagner, of San Antonio, Tex., invented a similar instrument he called the "Hagner Position Finder." This is a portable instrument operating on the same principle as the Solarometer, but obtaining the vertical by being hung from a suitable support, and therefore acting as a pendulum. This is reminiscent of the ancient astrolabe (art. 124).

Bedell. In 1953 A. L. Bedell, of St. Louis, Mo., proposed an instrument based upon simultaneous observation of two celestial bodies. The horizontal would be defined by spirit level.

Zenith photography. A number of suggestions have been made for eliminating a miniature sphere and locating the zenith among the stars. Several methods of doing this have been proposed, but the usual suggestion is to use a stabilized camera to photograph a portion of the sky in the vicinity of the zenith, which would be marked by a small cross within the camera. Use of a quick-developing method would reduce the delay. The position of the craft would be determined by comparison of the developed picture with a graduated star chart. Another suggestion is to reverse this process by comparing a previously made photograph with the actual sky.

Automatic celestial navigation. The principal weakness of methods requiring stabilization is the high order of accuracy needed. An error of 1′ introduces an error of one mile in the position. Such accuracy aboard a moving craft subject to various accelerations has been elusive. If stabilization of the required accuracy is available, it can be utilized with automatic star trackers to provide automatic celestial navigation. Such a system has been proposed. By means of the star trackers, the device would be continually oriented to two celestial bodies, and if the device were set for sidereal time, latitude and longitude would be indicated continuously on dials. The only setting

required would be the shifting from one star to another when the altitude of the first one became too low for convenient use of the body.

What would seem to be the "final" step in the development of such methods would be the scheduling of a voyage or flight in advance and the automatic comparison of preset values with automatically observed values, any discrepancy being used to actuate controls to change the heading or speed of the craft so that it would be automatically guided along the prescribed track on a preselected schedule. Several such methods, either singly or in combination with inertial or Doppler methods (art. 809), have been proposed for use in guided missiles. They could be adapted for use aboard ship, but are very expensive.

2125. Azimuth.—Most of the methods described above provide for determination of both altitude and azimuth angle. Several provide only for altitude. The number of tables, diagrams, and devices providing solution for azimuth only is very great, approaching the number providing solution for both altitude and azimuth. The reason for this is that azimuth is needed for other purposes than sight reduction. One common use is for checking the compass. Since modern inspection tables have provided parallel columns of computed altitude and azimuth or azimuth angle, separate azimuth tables have decreased in popularity.

Azimuth can be determined by computation or by amplitudes (tab. 27, 28), as well as by azimuth table. The method of computation depends somewhat upon the information available. There are three general approaches:

Time azimuth is the name given an azimuth or azimuth angle computed with meridian angle (a function of time), latitude, and polar distance (or declination) as the known quantities. Solution can be made by the following formula:

$$Z=X+Y,\ Z=X\sim Y,\ \text{or}\ Z=180°-(X\sim Y),$$

in which $\tan X=\sin D \csc S \cot \tfrac{1}{2} t$

and $\tan Y=\cos D \sec S \cot \tfrac{1}{2} t.$

Further, $D=\tfrac{1}{2}[p\sim(90°-L)]$

and $S=\tfrac{1}{2}[p+(90°-L)].$

If S is less than 90°, use $Z=X+Y$ if p is greater than $(90°-L)$, or $Z=X\sim Y$ if p is less than $(90°-L)$.

If S is greater than 90°, use $Z=180°-(X\sim Y)$.

To convert Z to Zn, label Z north or south to agree with the latitude, and east or west to agree with the meridian angle.

Altitude azimuth is an azimuth or azimuth angle computed with altitude, latitude, and polar distance as the known quantities. Solution can be made by the formula:

$$\text{hav } Z=\sin (s-L) \sin (s-h) \sec h \sec L,$$

in which $s=\tfrac{1}{2}(h+L+p).$

Azimuth angle is labeled N or S to agree with the latitude, and E or W as the celestial body is east or west of the celestial meridian.

Time and altitude azimuth is computed with meridian angle, declination, and altitude as the known quantities, the most common formula being

$$\sin Z=\sin t \cos d \sec h.$$

The weakness of this method is that it does not indicate whether the celestial body is north or south of the prime vertical. Usually there is no question on this point, but if Z is near 90°, the quadrant may be in doubt. If this occurs, either the meridian angle or altitude when on the prime vertical can be determined from table 25 or by computation, using the formula

$$\cos t = \tan d \cot L$$

or

$$\sin h = \sin d \csc L.$$

If the altitude is *less*, or the meridian angle is *greater* than the value when the body is on the prime vertical, the azimuth angle should be labeled N or S to agree with the latitude. If h is *greater* or t is *less* than when on the prime vertical, Z should be given the contrary name (N or S) to that of the latitude.

Amplitudes. For checking the compass, a low altitude is desirable because it can be measured easiest and most accurately. If a celestial body is observed when its center is on the *celestial* horizon, the amplitude (art. 1428) can be taken directly from table 27. It is given a prefix E (east) if rising or W (west) if setting. It is given a suffix N or S to agree with the *declination* of the body. When the center of the sun is on the celestial horizon, its *lower limb* is about two-thirds of a diameter above the visible horizon. When the center of the moon is on the celestial horizon, its *upper limb* is on the visible horizon. When planets and stars are on the celestial horizon, they are a little more than one sun diameter above the visible horizon.

If the body is observed when its center is on the *visible horizon*, the *observed* value should be corrected by the value from table 28, using the rules given with the table, before comparison with the value taken from table 27. If preferred, the correction can be applied with reversed sign to the value taken from table 27 and compared with the uncorrected observed value. This is the procedure used if amplitude or azimuth is desired when the celestial body is on the visible horizon.

Example.—The DR latitude of a ship is 51°24′.6 N, at a time when the declination of the sun is 19°40′.4 N.

Required.—(1) The amplitude (A) when the center of the setting sun is on the celestial horizon.

(2) The amplitude when the center of the setting sun is on the visible horizon.

(3) The azimuth when the center of the setting sun is on the visible horizon.

Solution.—

(1)	A	W 32°.6 N	(tab. 27)
	T 28	1°.1 S	(Rev.)—applied to *tabulated* amplitude
(2)	A	W 33°.7 N	
(3)	Zn	303°.7	

2126. Azimuth tables are numerous. Originally, they were designed primarily for use in determining compass error. Since the sun was the celestial body customarily used for this purpose, most of the tables were designed with the sun in mind. Meridian angle is commonly expressed in terms of local apparent time, in intervals varying from about one to 20 minutes. In many of the tables, meridian angle increases *upward* from the bottom of the page.

The following are some of the principal azimuth tables:

Wakeley. The first known azimuth tables for use of the navigator were *The Regiment of the Pole Star* by Andrew Wakeley. These tables were part of the author's *The Mariner's Compass Rectified*, published in London in 1665. These tables show the "true hour of the day" at which the sun is at the various points of the compass.

Lynn Azimuth Tables, by Thomas Lynn (art. 2106), were published in 1829. This 364-page table gives azimuth angle computed by the haversine formula of article 2106.

Towson and Atherton. The *Tables to Facilitate the Practice of Great Circle Sailing,* by the Englishmen John Thomas Towson and J. W. Atherton, were designed primarily for great-circle sailing, but since they indicate the course, they were easily adapted to finding azimuth angle. They were published in England in 1847.

Burdwood. The *Tables of Sun's True Bearing or Azimuth,* by Staff Commander John Burdwood, RN, were first published in 1852, with additional parts being added in 1858, 1862, 1864, and 1866. Captain John E. Davis, RN, and Percy L. H. Davis, of the British Nautical Almanac Office, later added to the tables, making them complete for all values of altitude and for declination between 64°N and 64°S. These tables were standard in Great Britain for more than a century. They have now been largely replaced by H.D. 486 (H.O. Pub. No. 214) for mariners and A.P. 3270 (H.O. Pub. No. 249) for aviators. Burdwood used modifications of the time azimuth formula.

Labrosse. Azimuth tables by the Frenchman F. Labrosse were published in London in 1868, and later in Paris. In 275 pages this *Table des Azimuts du Soleil* covers latitudes from 61°N to 61°S, and declinations from 0° to 30°N or S. The following formula was used:

$$\cot Z = \frac{\tan d \cos L}{\sin t} - \sin L \cot t.$$

Fifteen editions had been published by 1920.

Shortrede. In 1869 Captain Robert Shortrede's *Azimuth and Hour Angle for Latitude and Declination* and *Tables for Finding Azimuth at Sea* were published in London.

John E. Davis. The first azimuth tables by Captain John E. Davis were published in 1875. These were published as an extension of the Burdwood tables.

Perrin. In Paris the *Nouvelles Tables Destinées à Abréger les Calculs Nautiques,* by Ensign de Vaisseau E. Perrin, French Navy, were published first in 1876. These consist of three tables of nine, seven, and six pages, respectively, providing elements for determination of azimuth by a short computation. Several editions were published.

Kortazzi, a Russian, produced a volume appropriately called *Modification des Tables d'Azimuth de Thomson* (art. 2106). These were published in Paris in 1880.

H.O. Pub. No. 66 (Schroeder and Wainwright), *Arctic Azimuth Tables.* Lieutenants Seaton Schroeder and Richard Wainwright, USN, prepared azimuth tables for use of the USS *Rodgers* in her search for the arctic steamer *Jeanette.* These were published in 1881. Azimuths to the nearest 1′ are given for each 10^m meridian angle between 4^h and 7^h, for latitudes between 70° and 88°, declination 0° to 23°, same name.

Decante. In 1882 Lieutenant de Vaisseau E. Decante, of the French Navy, prepared *Table du Cadran Solaire Azimutal,* which was published in 1904, in eight volumes for latitudes 1° to 66° and declinations 0° to 48°.

H.O. Pub. No. 260 (Schroeder and Southerland). The *Azimuths of the Sun* were prepared in 1882 by Lieutenant Seaton Schroeder, USN, and Master W. H. H. Southerland, USN. These are popularly called "Red Azimuth Tables," because of the red binding used for most printings. This designation distinguishes them from the "Blue Azimuth Tables" (H.O. Pub. No. 261). After 15 editions, these tables are still in use. Azimuth angles are given to the nearest 1′, at 10^m intervals of local apparent time from "sunrise" to "sunset" (middle of the sun on the *celestial* horizon), with the LAT and the azimuth angle of these phenomena given at the bottom of each column. A separate table is given for each 1° of latitude from 0° to 70°. The first part of the

book is a table for latitude 0°. The second part is devoted to tables of latitude and declination "same name." The third part gives "contrary name" tables. Declination entries are given at 1° intervals from 0° to 23°, with the approximate dates on which this is the declination of the sun. Extracts from these tables are given in appendix Y. Values are customarily taken by triple interpolation, using the right-hand "PM" LAT column as meridian angle, as shown in the following example:

Example 1.—Find the azimuth of a celestial body when its meridian angle is 71°24.'3 W and its declination is 18°23.'2 N, if the latitude is 23°16.'1 N.

Solution.—

		diff. for	diff.	corr. for	+	−
t	$4^h45^m.6$ W	10^m	(+) 48′	$4^m.4$	21′	
d	18°.4 N	1°	(−) 62′	0°.4		25′
L	23°.3 N	1°	(+) 25′	0°.3	8′	
tab.	79°13′			sum	29′	25′
corr.	(+) 4′			corr.		(+) 4′
Z	N 79°17′ W					
Zn	280°.7					

In the solution, the meridian angle is expressed in time units to the nearest $0^m.1$, and the declination and latitude in arc to the nearest 0°.1. The "diff. for" is the unit of the entering argument. The "diff." is the difference in minutes of arc between the tabulated value for the *nearest* values of t, d, and L, and the next value for the t, d, or L on the opposite side of the actual value. The "corr. for" is the difference between the actual value of t, d, and L and that used for entering the table. The correction for each element is found from this tabulation. For instance, the correction for t is $\frac{48' \times 4^m.4}{10^m} = 21'$. The total net correction is applied to the tabulated value to find Z, labeled N or S to agree with the latitude, and E or W to agree with the meridian angle. In entering the table, one should keep in mind that values of t increase *upward* from the bottom of the page. Care should be used in locating meridian angle, for the manner of labeling the values can easily be misunderstood. For latitude 0°, Z is labeled N or S to agree with declination. Interpolation is made for t and d only, and the value converted to Zn. The Zn at latitude 1° is then computed, and interpolation for latitude is made between the two values of Zn.

Blackburne. The New Zealand nautical almanac for 1883 carried the 177-page "A and B" azimuth tables, by H. S. Blackburne. By 1911, after several modifications, these emerged as *"A, B, C" Tables for Azimuth, Great Circle Sailing, and Reduction to the Meridian.* The range of both the latitude and declination is from 90° N to 90° S.

Lecky. In 1892 Captain S. T. S. Lecky, an Englishman, modified the Blackburne tables and produced another set of "A, B, C" tables which have been widely used.

Ebsen. The *Azimut-Tabellen* of Julius Ebsen, published in Germany in 1896, uses the same formula as Labrosse, and is arranged like H.O. Pub. No. 260, except that azimuth angles are given to the nearest 0°.1, and the time and azimuth angle of sunrise and sunset are given at the top of the table, in place of the dates of H.O. Pub. No. 260. In two volumes, coverage is for latitudes 72° N to 72° S, and declinations 0° to 29°. Tables are for same name only, contrary-name situations being handled by using the supplement of meridian angle, and using the supplement of the value taken from the table, as in H.O. Pub. No. 261.

Johnson. A *Combined Time and Altitude Azimuth Table* for latitudes and declinations from 0° to 80°, by A. C. Johnson of the British Royal Navy, was published in London in 1900. In the same year, his *Short, Accurate, and Comprehensive Altitude-*

Azimuth Tables were published. This publication consists of three tables for computation of azimuth for each degree of latitude and altitude from 0° to 75°, and each degree of declination from 30° N to 30° S.

Zhdanko. The Russian *Tables of Azimuth of the Sun*, by M. Zhdanko, published in 1900, supplied computed azimuth angles for latitudes between 61° and 75°. These were later expanded by Yustchenko.

Percy L. H. Davis. In 1900 Percy L. H. Davis took over the work previously done by Burdwood and John E. Davis, continuing to improve and extend the tables.

H.O. Pub. No. 261, *Azimuths of Celestial Bodies*, published by the U. S. Navy Hydrographic Office in 1902, extend the H.O. Pub. No. 260 tables by providing information in similar form (but with meridian angle increasing *downward* on the page) for declinations 24° to 70°. These are popularly called "Blue Azimuth Tables," from their blue binding. Tables for "same name" only are given. If latitude and declination are of contrary name, the tables are entered with the supplement of the meridian angle. The value taken from the table is then the supplement of the azimuth angle, which is labeled N or S to agree with the latitude and E or W to agree with the meridian angle. Extracts from H.O. Pub. No. 261 are given in appendix Z.

Example 2.—Find the azimuth of a celestial body when its meridian angle is 49°31′.6 E and its declination is 57°41′.4 N, if the latitude is 51°25′.5 S.

Solution.—

		diff. for	diff.	corr. for		+	−
t	$3^h18^m.1$ E						
180°−t	$8^h41^m.9$	10^m	(−) 75′	$1^m.9$			14′
d	57°.7 N	1°	(+) 36′	0°.3		11′	
L	51°.4 S	1°	(+) 14′	0°.4		6′	
tab.	26°57′				sum	17′	14′
corr.	(+) 3′				corr.		(+) 3′
180°−Z	27°00′						
Z	S 153°00′ E						
Zn	027°.0						

One step can be eliminated by considering the corrected value Z instead of 180°−Z, and labeling it N or S to agree with the *declination*. In this example the body is below the horizon, showing that a solution is no assurance that a body is visible.

Symonds. The *Nautical Astronomy, with New Tables*, by W. P. Symonds, British Survey Commissioner, Bombay, includes azimuth tables. It was published in 1912.

Goodwin. *An Equatorial Azimuth-Table*, by H. B. Goodwin, was published in 1921.

Purey-Cust. *Azimuth by Logs*, by Admiral Sir H. E. Purey-Cust, RN, was published in England in 1929. It consists of a three-page table of the logarithms of the six principal trigonometric functions at 10′ intervals (5′ below 10°) for solution of the time azimuth and altitude azimuth formulas.

Yustchenko. In 1935 A. Yustchenko, a Russian, extended the Zhdanko tables to all latitudes, in the work entitled *Azimuty Svetil* (Azimuths of Celestial Bodies). For each 10° of latitude (5°, 15°, 25°, etc., to 85°) complete azimuth tables (to the nearest 0°.1) are given for each 1^m of meridian angle and each 30′ of declination from 0° to 30°. At the bottom of each page are given corrections for 1° of latitude. This value is multiplied by the number of degrees between the actual latitude and the latitude for which the table was computed.

Cugle. *Cugle's Two-Minute Azimuths*, by Charles H. Cugle, were printed in 1935 in two large volumes. Coverage is for latitude 0° to 65° and declination 0° to 23°. The arrangement is almost identical with that of H.O. Pub. No. 260, except that

meridian angle increases *downward* on the page. The number of entries is multiplied by *five*, values being given for each 2^m of meridian angle.

Table 902. *Azimuts*, published in Paris in 1953, with the concurrence of the Marine Hydrographic Service, contains azimuth angles to the nearest 0°1 for each whole degree of latitude from 70° N to 70° S, each whole degree of declination from 0° to 30°, and each 10^m of meridian angle. The arrangement is similar to that of H.O. Pub. No. 260, except that meridian angle increases *downward* on the page.

2127. Azimuth diagrams have appeared in various forms, in addition to the general graphical and mechanical solutions discussed above. A graphical solution is generally more acceptable for azimuth than for altitude, because the accuracy requirement for azimuth is usually less.

Godfrey. A graphical solution has been available at least since 1858 when the *Time Azimuth Diagram* of Hugh Godfrey was published in London.

Weir. The *Azimuth Diagram* devised by Captain Patrick Weir, of the British Merchant Navy, was published in London in 1890, and by the U. S. Navy Hydrographic Office in 1891, under the title *Time Azimuth Diagram*.

Molfino. In 1901 the *Nomograma degli Azimut del Sole* of Molfino was published.

Constan. In 1906 P. Constan's *Tables Graphiques d'Azimut* were published in Paris. This was a reproduction of the graph of Favé and Rollet de l'Isle (art. 2120).

Alessio. The *Diagrammi Altazimutali* of A. Alessio was published in 1908 in Italy.

Rust. In 1908 the diagram of Lieutenant Commander Armistead Rust, USN, (art. 2106) was published. This diagram was later used by Goodwin (art. 2106) and Weems (arts. 2106 and 2110), and in the Italian *Tavole H* (art. 2110).

Cornet. The *Graphique d'Azimut* of Cornet was published in 1927.

Romanovsky. About 1933 A. A. Romanovsky, a Russian, devised a simple nomogram for determining azimuth.

German Oberkommandos der Kriegsmarine. A large volume called *Azimutdiagramme*, containing sets of diagrams for each whole degree of latitude (2° beyond 80°) for all azimuth angles and for all altitudes to 80°, was published by the German Oberkommandos der Kriegsmarine in 1944.

Hugon. The azimuth diagram of Professor P. Hugon (art. 2109) was published in 1947.

Hilsenrath. About 1948 Joseph Hilsenrath, of the University of Maryland, produced a mechanical device for solving azimuth angle by the method of Weir's diagram.

2128. Summary.—The methods of sight reduction discussed in this chapter are undoubtedly only a small fraction of the number of methods that have been proposed. They are considered representative of the effort that has been made to reduce the work of the navigator. Individual preferences have largely dictated the use of the various methods. Presentation and description of a method have been important factors in the relative popularity of various methods.

There is no single "best" method for all circumstances and all navigators. The one which produces the desired results easiest and with least possibility of mistake is the one that should be selected. However, two practical precautions should be observed. First, one should be thoroughly familiar with the *limitations* or *weaknesses* of the method he selects. Second, a prudent navigator will never limit himself to a single method, particularly one requiring a special table that might some day be unavailable, or a device that is subject to mechanical damage or loss. The slight bending of an arc might be too insignificant to be noticed, yet might introduce intolerably large errors in the result. A wise practice is to memorize, or write on something always carried, fundamental formulas that can be used when no "special" tables are available.

Problems

2103a. At GMT $10^h25^m22^s$ on June 1, 1958, the navigator observes the lower limb of the sun on the celestial meridian, bearing south. He makes the observation with a marine sextant having no IC, from a height of eye of 50 feet. The hs is 41°58′.7.

Required.—The latitude by meridian altitude.

Answer.—L 69°54′.1 N.

2103b. At GMT $14^h15^m21^s$ on June 1, 1958, the sun is estimated to be on the upper branch of the celestial meridian. At this time the sun is obscured by clouds, but several minutes later it breaks out, and at GMT $14^h24^m22^s$ the navigator observes the lower limb, facing in a northerly direction. He makes the observation with a marine sextant having an IC of (−) 2′.5, from a height of eye of 33 feet. The hs is 70°46′.9. The approximate latitude is 3° N.

Required.—(1) The latitude by reduction to the meridian. (2) The latitude if the navigator learns that his ship was 1′.2 of longitude farther *west* than assumed for computation of the time of meridian transit, and the azimuth angle at the time of observation was N 6°.0 W. Use table 26.

Answers.—(1) L 3°04′.1 N, (2) L 3°04′.0 N.

2103c. On June 1, 1958, the 1225 DR position of a ship is lat. 40°45′.7 N, long. 142°01′.9 W. At GMT $21^h25^m36^s$ the navigator observes the lower limb of the sun with a marine sextant having an IC of (+) 3′.3, from a height of eye of 29 feet. The hs is 71°06′.8.

Required.—(1) The *a*, Zn, and AP, using H.O. Pub. No. 214 (Δd, Δt, ΔL, and interpolating for Z) and the *Nautical Almanac.*

(2) The approximate latitude at the time of observation.

Answers.—(1) *a* 1.8 T, Zn 179°.8, *a*L 40°45′.7 N, *a*λ 142°01′.9 W; (2) L 40°43′.9 N.

2104a. Find the watch time of meridian transit of the sun at longitude 68°08′.4 E on June 1, 1958, if the watch is 27^s fast on zone time.

Answer.—W $12^h25^m31^s$.

2104b. Find the zone time of meridian transit of the moon at longitude 166°23′.2 E on June 13, 1958, using the *Nautical Almanac,* GHA method.

Answer.—ZT $8^h25^m42^s$.

2104c. Find the GMT of meridian transit of Nunki at longitude 157°52′.2 W on June 1, 1958, using the *Air Almanac.*

Answer.—GMT $12^h46^m11^s$.

2104d. On June 1, 1958, the 1200 DR position of a ship is lat. 57°21′.9 N, long. 21°53′.2 W. The ship is on course 065°, speed 22 knots. Find the zone time of meridian transit of the sun at the ship.

Answer.—ZT $12^h24^m10^s$.

2104e. Find the zone time of transit of the sun at longitude 47°23′.4 E on June 2, 1958, using apparent time and the *Nautical Almanac.*

Answer.—ZT $11^h48^m13^s$.

2105. During evening twilight on May 31, 1958, the 2325 EP of a ship is lat. 58°38′.4 N, long. 165°34′.3 W. At watch time $11^h25^m01^s$ PM the navigator observes Polaris with a marine sextant having no IC, from a height of eye of 42 feet. The watch is 6^s fast on zone time. The hs is 57°54′.4.

Required.—(1) The latitude, (2) the azimuth of Polaris.

Answers.—(1) L 58°35′.6 N, (2) Zn 001°.0.

2106. On June 2, 1958, the 0725 EP of a ship is lat. 7°31′.2 S, long. 22°35′.7 W. At GMT $9^h24^m42^s$ the navigator observes the lower limb of the sun with a marine sextant having an IC of (+) 2′.0, from a height of eye of 47 feet. The hs is 23°15′.0.

Required.—(1) The longitude by time sight.

(2) The longitude if the navigator learns that his ship was 2.1 miles farther *north* than assumed for computation, and the azimuth at the time of observation was 062°0. Use table 26.

Answers.—(1) λ 22°38′1 W, (2) λ 22°39′2 W.

2107a. Determine (1) the approximate zone time, and (2) the approximate altitude of the sun at its nearest approach to the prime vertical during the morning of June 1, 1958, at lat. 12°14′7 N, long. 35°16′1 W, using table 25 and the *Nautical Almanac.*

Answers.—(1) ZT 0826, (2) h 33°7.

2107b. Determine (1) the approximate zone time, and (2) the approximate altitude of the sun when it crosses the prime vertical during the afternoon of May 31, 1958, at lat. 41°17′2 N, long. 154°37′4 W, using H.O. Pub. No. 214 and the *Nautical Almanac.*

Answers.—(1) ZT 1625, (2) h 34°8.

2109. The dead reckoning latitude of a vessel is 10°23′8 S. The navigator observes a star having a declination of 28°51′5 N and a meridian angle of 27°17′4 E. He notes that it is in the northeast quadrant of the sky.

Required.—The (1) Hc by cosine-haversine formula and (2) azimuth by the formula sin Z=sin t cos d sec h.

Answers.—(1) Hc 42°43′4, (2) 033°1.

2113a. During evening twilight on June 1, 1958, the 1740 DR position of a ship is lat. 41°28′5 S, long. 82°17′6 W. At ZT $17^h41^m08^s$ the navigator observes Rigel Kent. with a marine sextant having an IC of (−)1′2, from a height of eye of 55 feet. The hs is 44°05′2.

Required.—The *a*, Zn, and AP, using H.O. Pub. No. 249, vol. I (epoch 1960.0), and the *Air Almanac.*

Answers.—*a* 13 T, Zn 140°, *a*L 41°00′ S, *a*λ 82°11′ W.

2113b. During morning twilight on June 2, 1958, the DR position of a ship is lat. 41°08′2 N, long. 5°11′5 E. At GMT $3^h45^m11^s$ the navigator observes Fomalhaut with a marine sextant having an IC of (+)0′8, from a height of eye of 49 feet. The hs is 13°13′7.

Required.—The *a*, Zn, and AP, using H.O. Pub. No. 249, vol. III, and the *Air Almanac.*

Answers.—*a* 10 A, Zn 152°, *a*L 41°00′ N, *a*λ 5°27′ E.

2125. The DR latitude of a ship is 15°11′3 S when the declination of the sun is 18°36′5 N.

Required.—(1) The amplitude (A) when the center of the rising sun is on the celestial horizon.

(2) The amplitude and azimuth when the center of the rising sun is on the visible horizon.

Answers.—(1) A E 19°3 N; (2) A E 19°1 N, Zn 070°9.

2126a. The dead reckoning latitude of a vessel is 23°53′6 S. The navigator observes a celestial body having a declination of 20°26′2 S and a meridian angle of 18°37′4 E.

Required.—Azimuth by H.O. Pub. No. 260.

Answer.—Zn 082°2.

2126b. The dead reckoning latitude of a vessel is 51°46′5 N. The navigator observes a celestial body having a declination of 49°42′7 N and a meridian angle of 115°37′2 W.

Required. Azimuth by H.O. Pub. No. 261.

Answer.—Zn 319°9.

CHAPTER XXII

IDENTIFICATION OF CELESTIAL BODIES

2201. Introduction.—A basic requirement of celestial navigation is the ability to identify the bodies observed. This is not difficult because relatively few celestial bodies are commonly used for navigation, and various aids are available to assist in their identification, as explained in this chapter.

Many navigators consider it a matter of professional pride to have a more extensive acquaintance with the heavens than required by the relatively simple demands of navigation.

2202. Bodies of the solar system.—No problem is encountered in the identification of the sun and moon. However, the planets can be mistaken for stars. A person working continually with the night sky recognizes a planet by its changing position among the relatively fixed stars. He identifies the planets by noting their positions relative to each other, the sun, the moon, and the stars. He knows that they remain within the narrow limits of the zodiac (art. 1420) but are in almost constant motion relative to the stars. The magnitude and color may be helpful. The information he needs is found in the *Nautical Almanac*. The "Planet Notes" near the front of that volume are particularly useful.

Sometimes the light from a planet seems steadier than that from a star. This is because fluctuation of the unsteady atmosphere causes **scintillation** or **twinkling** of a star, which has no measurable diameter with even the most powerful telescopes. The navigational planets are less susceptible to twinkling because of the broader apparent area giving light.

Planets can also be identified by the *Air Almanac* ecliptic diagram (art. 2209), star finder (art. 2210), sky diagram (art. 2212), or by computation (art. 2213).

2203. Stars.—The average navigator regularly uses not more than perhaps 20 or 30 stars. The *Nautical Almanac* gives full navigational information on 19 first magnitude stars and 38 second magnitude stars, in addition to Polaris. Abbreviated information is given for 115 more. Additional stars are listed in *The American Ephemeris and Nautical Almanac* and in various star catalogs. About 6,000 stars of the sixth magnitude or brighter (on the entire celestial sphere) are visible to the unaided eye on a clear, dark night.

Stars are designated by one or more of the following:

Name. Most names of stars, as now used, were given by the ancient Arabs and some by the Greeks or Romans. One of the stars of the *Nautical Almanac*, Nunki, was named by the Babylonians. Only a relatively few stars have names. Several of the stars on the daily pages of the almanacs had no name prior to the 1953 edition, and were given coined names so that all stars listed on the daily pages might have names. The pronunciation, meaning, and other information of general interest regarding Polaris and the 57 stars listed on the daily pages of the *Nautical Almanac* are given in appendix H.

Bayer's name. Most bright stars, including those with names, have been given a designation consisting of a Greek letter followed by the possessive form of the name

of the constellation, as *α Cygni* (Deneb, the brightest star in the constellation *Cygnus*, the swan). Roman letters are used when there are not enough Greek letters. Usually, the letters are assigned in order of brightness within the constellation, but in some cases the letters are assigned in another order, where it seems logical to do so. An example is the big dipper, where the letters are assigned in order from the outer rim of the bowl to the end of the handle. This system of star designation was suggested by John Bayer of Augsburg, Germany, in 1603. All of the 173 stars included in the list near the back of the *Nautical Almanac* are given by Bayer's name as well as regular name, where there is one.

Flamsteed's number. A similar system, accommodating more stars, numbers them in each constellation, from west to east, the order in which they cross the celestial meridian. An example is 95 *Leonis*, the 95th star in the constellation *Leo*, the lion. This system was suggested by John Flamsteed (1646–1719), who was the first British Astronomer Royal.

Catalog number. Stars are sometimes designated by the name of a star catalog and the number of the star as given in that catalog, as A. G. Washington 632. In these catalogs stars are listed in order from west to east, without regard to constellation, starting with the hour circle of the vernal equinox. This system is used primarily for dimmer stars having no other designation. Navigators seldom have occasion to use this system.

The ability to identify stars by position relative to each other is useful to the navigator. A tabulation of the relative positions of the 57 stars given on the daily pages of the *Nautical Almanac*, and Polaris, is given in appendix G. A star chart (art. 2204) is helpful in locating these relationships and others which may be useful. This method is limited to periods of relatively clear, dark skies with little or no overcast. Stars can also be identified by the *Air Almanac* ecliptic diagram (art. 2209), star finder (art. 2210), H.O. Pub. No. 249 (art. 2211), sky diagram (art. 2212), or by computation (art. 2213).

2204. Star charts are based upon the celestial equator system of coordinates, using declination and sidereal hour angle (or right ascension). The zenith of the observer is at the intersection of the parallel of declination equal to his latitude, and the hour circle coinciding with his celestial meridian. This hour circle has an SHA equal to $360° - \text{LHA}\,♈$ (or $\text{RA} = \text{LHA}\,♈$). The horizon is everywhere 90° from the zenith. A **star globe** is similar to a terrestrial sphere, but with stars (and often constellations) shown instead of geographical positions. Star globes are used by British navigators, but not customarily by Americans. The combined *Nautical Almanac* includes instructions for using this device. On a star globe the celestial sphere is shown as it would appear to an observer *outside* the sphere. Constellations appear reversed. Star charts may show a similar view, but more often they are based upon the view from *inside* the sphere, as seen from the earth. On these charts, north is at the top, as with maps, but east is to the *left* and west to the *right*. The directions seem correct when the chart is held overhead, with the top toward the north, so that the relationship is similar to that in the sky. Any map projection (ch. III) can be used, but some are more suitable than others.

The *Nautical Almanac* has four star charts. The two principal ones are on the polar azimuthal equidistant projection (art. 320), one centered on each celestial pole. Each chart extends from its pole to declination 10° (same name as pole). Below each polar chart is an auxiliary chart on the Mercator projection, from 30° N to 30° S. On any of these charts, the zenith can be located as indicated above, to determine which stars are overhead. The horizon is 90° from the zenith. The charts can also be used

to determine the location of a star relative to surrounding stars. The *Air Almanac* has a fold-in chart at the back, on the rectangular projection (art. 311). This projection is suitable for indicating the coordinates of the stars, but excessive distortion occurs in regions of high declination. The celestial poles are represented by the top and bottom horizontal *lines* the same length as the celestial equator. To locate the horizon on this chart, first locate the zenith as indicated above, and then locate the four cardinal points. The north and south points are 90° from the zenith, along the celestial meridian. The distance to the elevated pole (having the same name as the latitude) is equal to the colatitude of the observer. The remainder of the 90° (the latitude) is measured *from* the same pole, along the *lower branch* of the celestial meridian, 180° from the upper branch containing the zenith. The east and west points are on the celestial equator at the hour circle 90° east and west (or 90° and 270° in the same direction) from the celestial meridian. The horizon is a sine curve (fig. O40b) through the four cardinal points. Directions on this projection are distorted.

The star charts shown in figures 2205–2208, on the transverse Mercator projection (art. 309), are designed to assist one in learning the stars listed on the daily pages of the *Nautical Almanac*, and Polaris. Each chart extends about 20° beyond each celestial pole, and about 60° (four hours) each side of the central hour circle (at the celestial equator). Therefore, they do not coincide exactly with that half of the celestial sphere above the horizon at any one time or place. The zenith, and hence the horizon, varies with the position of the observer on the earth, and also with the rotation of the earth (apparent rotation of the celestial sphere). The charts show all stars of fifth magnitude and brighter as they appear in the sky, but with some distortion toward the right and left edges.

The transparencies add certain information of use in locating the stars. Only Polaris and the 57 stars listed on the daily pages of the *Nautical Almanac* are named on the charts. The almanac star charts should be used for locating the additional stars given near the back of the *Nautical Almanac*. When a transparency is correctly placed over its accompanying chart, the information given is properly oriented to the chart. The broken lines connect stars of some of the more prominent constellations. The solid lines indicate the celestial equator and certain useful relationships among stars in different constellations. The celestial poles are marked by crosses, and labeled. By means of the celestial equator and the poles, one can locate his zenith approximately along the mid hour circle, when this coincides with his celestial meridian, as shown in the table below. At any time earlier than those shown in the table the zenith is to the *right* of center, and at a later time it is to the *left*, approximately one-quarter of the distance from the center to the outer edge (at the celestial equator) for each hour that the time differs from that shown. The stars in the vicinity of the north pole can be seen in proper perspective by inverting the chart, so that the zenith of an observer in the northern hemisphere is *up* from the pole.

2205. Stars in the vicinity of *Pegasus* (fig. 2205).—In autumn the evening sky has few first magnitude stars. Most of these are near the southern horizon of an observer in the latitudes of the United States. A relatively large number of second and third magnitude stars seem conspicuous, perhaps because of the small number of brighter stars. High in the southern sky three third magnitude stars and one second magnitude star form a square with sides nearly 15° of arc in length. This is *Pegasus*, the winged horse, although to many modern men it more nearly resembles a baseball diamond, complete with catcher, pitcher, batter, umpire, base umpire near second base, infield and outfield; although there does seem to be a large number of outfielders. One may even see the next batter, bat boy, and coach.

Only Markab at the southwestern corner (third base) and Alpheratz at the northeastern corner (first base) are listed on the daily pages of the *Nautical Almanac*. Alpheratz is part of the constellation *Andromeda*, the princess, extending in an arc toward the northeast and terminating at Mirfak in *Perseus*, legendary rescuer of *Andromeda*.

A line extending northward through the eastern side (first-second base line) of the square of *Pegasus* passes through the leading (western) star of M-shaped (or W-shaped) *Cassiopeia*, the legendary mother of the princess *Andromeda*. The only star of this constellation listed on the daily pages of the *Nautical Almanac* is Schedar, the second star from the leading one as the configuration circles the pole in a counterclockwise direction. If the line through the eastern side of the square of *Pegasus* is continued on toward the north, it leads to second magnitude Polaris, the north star (less than 1° from the north celestial pole) and brightest star of *Ursa Minor*, the little bear. Kochab, a second magnitude star at the other end of the little dipper, is also listed in the almanacs. At this season the big dipper is low in the northern sky, below the celestial pole. A line extending from Kochab through Polaris leads to Mirfak, assisting in its identification when *Pegasus* and *Andromeda* are near or below the horizon.

Deneb, in *Cygnus*, the swan, and Vega are bright, first magnitude stars in the northwestern sky. They are discussed in article 2208. Capella, a bright star in the northeastern sky, is discussed in article 2206.

The line through the eastern side of the square of *Pegasus* (first-second base line) approximates the hour circle of the vernal equinox, shown at ♈ on the celestial equator to the south. The sun is at ♈ on or about March 21, when it crosses the celestial equator from south to north. If the line through the eastern side of *Pegasus* is extended southward and curved slightly toward the east, it leads to second magnitude Diphda. A longer and straighter line southward through the western side (home plate-third base line) of *Pegasus* leads to first magnitude Fomalhaut. A line extending northeasterly from Fomalhaut through Diphda leads to Menkar, a third magnitude star, but the brightest in its vicinity. Ankaa, Diphda, and Fomalhaut form an isosceles triangle, with the apex at Diphda. Ankaa is near or below the southern horizon of observers in latitudes of the United States. Four stars farther south than Ankaa may be visible when on the celestial meridian, just above the horizon of observers in latitudes of the extreme southern part of the United States. These are Acamar, Achernar, Al Na'ir, and Peacock. These stars, with each other and with Ankaa, Fomalhaut, and Diphda, form a series of triangles as shown in figure 2205. Almanac stars near the bottom of figure 2205 are discussed in succeeding articles.

Two other almanac stars can be located by their positions relative to *Pegasus*. These are Hamal in the constellation *Aries*, the ram, east of *Pegasus*, and Enif, west of the southern part of the square, identified as shown in figure 2205. The line leading to Hamal, if continued, leads to the *Pleiades*, not used by navigators for celestial observations, but a prominent figure in the sky, heralding the approach of the many conspicuous stars of the winter evening sky, figure 2206.

FIGURE 2205.—Stars in the vicinity of *Pegasus*.

2206. Stars in the vicinity of *Orion* (fig. 2206).—As *Pegasus* leaves the meridian and moves into the western sky, *Orion*, the mighty hunter, rises in the east. With the possible exception of the big dipper, no other configuration of stars in the entire sky is as well known as *Orion* and its immediate surroundings. In no other part are there so many first magnitude stars.

The belt of *Orion*, being nearly on the celestial equator, is visible by an observer in virtually any latitude, rising and setting almost on the prime vertical, and dividing equally its time above and below the horizon. Of the three second magnitude stars forming the belt, only Alnilam, the middle one, is listed on the daily pages of the *Nautical Almanac.*

Four conspicuous stars form a box around the belt. To the south is Rigel, one of the hottest and bluest of the stars, in contrast with relatively cool, red, variable Betelgeuse, at approximately an equal distance to the north. Bellatrix, bright for a second magnitude star but overshadowed by its more brilliant neighbors, is a few degrees west of Betelgeuse. Neither the second magnitude star forming the southeastern corner of the box, nor any star of the dagger, is listed on the daily pages of the *Nautical Almanac.*

A line extending eastward from the belt of *Orion* and curving toward the south leads to Sirius, the brightest star in the entire heavens, having a magnitude of (−) 1.6. Only Mars and Jupiter at or near their greatest brilliance, and the sun, moon, and Venus are brighter than Sirius. This is part of the constellation *Canis Major*, the large hunting dog of *Orion.* Starting at Sirius a curved line extends northward through first magnitude Procyon, in *Canis Minor*, the small hunting dog; first magnitude Pollux and second magnitude Castor (not listed on the daily pages of the *Nautical Almanac*), the twins of *Gemini;* brilliant Capella in *Auriga*, the charioteer; and back down to first magnitude Aldebaran, the follower, which trails the *Pleiades*, the seven sisters. Aldebaran, brightest star in the head of *Taurus*, the bull, may also be found by a curved line extending northwestward from the belt of *Orion.* The V-shaped figure forming the outline of the head and horns of *Taurus* points toward third magnitude Menkar. At the summer solstice the sun is between Pollux and Aldebaran.

If the curved line from *Orion's* belt southeastward to Sirius is continued, it leads to a conspicuous, small, nearly equilateral triangle of three bright second magnitude stars of nearly equal brilliancy. This is part of *Canis Major.* Only Adhara, the westernmost of the three stars, is listed on the daily pages of the *Nautical Almanac.* Continuing on with somewhat less curvature, the line leads to Canopus, second brightest star in the heavens and one of the two stars having a negative magnitude (−0.9). With Suhail and Miaplacidus, Canopus forms a large, equilateral triangle which partly encloses the false southern cross. The brightest star within this triangle is Avior, near its center. Canopus is also at one apex of a triangle formed with Adhara to the north and Suhail to the east, another triangle with Acamar to the west and Achernar to the southwest, and another with Achernar and Miaplacidus. Acamar, Achernar, and Ankaa form still another triangle toward the west. Because of chart distortion, these triangles do not appear in the sky in exactly the relationship shown on the star chart. Other daily-page almanac stars near the bottom of figure 2206 are discussed in succeeding articles.

During the winter evening sky the big dipper is east of Polaris, the little dipper is nearly below it, and *Cassiopeia* is west of it. Mirfak is northwest of Capella, nearly midway between it and *Cassiopeia.* Hamal is in the western sky. Regulus and Alphard are low in the eastern sky, heralding the approach of the configurations associated with the evening skies of spring.

FIGURE 2206.—Stars in the vicinity of *Orion*.

2207. Stars in the vicinity of *Ursa Major* (fig. 2207).—As if to enhance the splendor of the sky in the vicinity of *Orion*, the region toward the east, like that toward the west, has few bright stars, except in the vicinity of the south celestial pole. However, as *Orion* sets in the west, leaving Capella and Pollux in the northwestern sky, a number of good navigational stars move into favorable positions for observation.

The big dipper, part of *Ursa Major*, the great bear, appears prominently *above* the north celestial pole, directly opposite *Cassiopeia* (only partly shown in fig. 2207), which appears as a W just above the northern horizon of most observers in latitudes of the United States. Of the seven stars forming the big dipper, only Dubhe, Alioth, and Alkaid are listed on the daily pages of the *Nautical Almanac*.

The two second magnitude stars forming the outer part of the bowl of the big dipper are often called the *pointers* because a line extending northward (*down* in spring evenings) through them points to Polaris. The little dipper, with Polaris at one end and Kochab at the other, is part of *Ursa Minor*, the little bear. Relative to its bowl, the handle of the little dipper curves in the opposite direction to that of the big dipper. Other almanac stars near the top of figure 2207 are discussed elsewhere.

A line extending southward through the pointers, and curving somewhat toward the west, leads to first magnitude Regulus, brightest star in *Leo*, the lion. The head, shoulders, and front legs of this constellation form a sickle, with Regulus at the end of the handle. Toward the east is second magnitude Denebola, the tail of the lion. On toward the southwest from Regulus is second magnitude Alphard, brightest star in *Hydra*, the sea serpent. A dark sky and considerable imagination are needed to trace the long, winding body of this figure.

A curved line extending the arc of the handle of the big dipper leads to first magnitude Arcturus. With Alkaid and Alphecca, brightest star in *Corona Borealis*, the northern crown, Arcturus forms a large, inconspicuous triangle. If the arc through Arcturus is continued, it leads next to first magnitude Spica and then to *Corvus*, the crow, which appears most like a gaff mainsail of a schooner. The brightest star in this constellation is Gienah, but three others are nearly as bright. At autumnal equinox the sun is on the celestial equator, about midway between Regulus and Spica.

A long, slightly curved line from Regulus east-southeasterly through Spica leads to Zubenelgenubi (zo͞o·bĕn′ĕl·jĕ·nū′bē) at the southwestern corner of an inconspicuous box-like figure called *Libra*, the (weighing) scales.

Returning to *Corvus*, a line from Gienah, extending diagonally across the figure and then curving somewhat toward the east, leads to Menkent, just beyond *Hydra*.

Far to the south, below the horizon of most northern-hemisphere observers, a group of bright stars is a prominent feature of the spring sky of the southern hemisphere. *Crux*, the southern cross, is about 40° south of *Corvus*. This is a small figure and a poor cross, and hence disappointing to many who view it for the first time. The "false cross" to the west is a better but less conspicuous cross. Acrux at the southern end of the southern cross, and Gacrux at the northern end, are listed on the daily pages of the *Nautical Almanac*.

The triangles formed by Suhail, Miaplacidus, and Canopus, and by Suhail, Adhara, and Canopus, are west of the southern cross, Suhail being in line with the horizontal arm of the southern cross at this time. A line from Canopus, through Miaplacidus, curved slightly toward the north, leads to Acrux. A line through the east-west arm of *Crux*, eastward and then curving toward the south, leads first to Hadar and then to Rigil Kentaurus, two very bright stars. Continuing on, the curved line leads to small *Triangulum Australe*, the southern triangle, the easternmost star of which is Atria.

Scorpius, the scorpion, Kaus Australis, and Peacock, in the southeastern sky of the southern hemisphere, are discussed in article 2208.

FIGURE 2207.—Stars in the vicinity of *Ursa Major.*

Scale of magnitudes: 1st 2nd 3rd 4th 5th

2208. Stars in the vicinity of *Cygnus* (fig. 2208).—As the celestial sphere continues in its apparent westward rotation, the stars familiar to a spring evening observer sink low in the western sky. By midsummer the big dipper has moved to a position to the left of the north celestial pole, and the line from the pointers to Polaris is nearly horizontal. The little dipper is standing on its handle, with Kochab above and to the left of the celestial pole. *Cassiopeia* is at the right of Polaris, opposite the handle of the big dipper.

The only first magnitude star in the western sky is Arcturus, which forms a large, inconspicuous triangle with Alkaid, the end of the handle of the big dipper, and Alphecca, the brightest star in *Corona Borealis*, the northern crown.

The eastern sky is dominated by three very bright stars. The westernmost of these is Vega, the brightest star north of the celestial equator, and third brightest star in the heavens. Its magnitude is 0.1. Having a declination of a little less than 39° N, this star passes through the zenith along a path across the central part of the United States, from Washington in the east to San Francisco on the Pacific coast. Vega forms a large but conspicuous triangle with its two bright neighbors, Deneb to the northeast and Altair to the southeast. The angle at Vega is nearly a right angle. Deneb is at the end of the tail of *Cygnus*, the swan. This configuration is sometimes called the northern cross, with Deneb at the head. To modern youth it more nearly resembles a dive bomber while it is still well toward the east, with Deneb at the nose of the fuselage. Altair has two fainter stars close by, on opposite sides. The line formed by Altair and its two fainter companions, if extended in a northwesterly direction, passes through Vega, and on to second magnitude Eltanin. The angular distance from Vega to Eltanin is about half that from Altair to Vega. Vega and Altair, with second magnitude Rasalhague to the west, form a large equilateral triangle. This is less conspicuous than the Vega-Deneb-Altair triangle because the brilliance of Rasalhague is much less than that of the three first magnitude stars, and the triangle is overshadowed by the brighter one.

Far to the south of Rasalhague, and a little toward the west, is a striking configuration called *Scorpius*, the scorpion. The brightest star, forming the head, is red Antares. At the tail is Shaula.

Antares is at the southwestern corner of an approximate parallelogram formed by Antares, Sabik, Nunki, and Kaus Australis. With the exception of Antares, these stars are only slightly brighter than a number of others nearby, and so this parallelogram is not a striking figure. At winter solstice the sun is a short distance northwest of Nunki.

Northwest of *Scorpius* is the box-like *Libra*, the (weighing) scales, in which Zubenelgenubi marks the southwest corner.

With Menkent and Rigil Kentaurus to the southwest, Antares forms a large but unimpressive triangle. For most observers in the latitudes of the United States, Antares is low in the southern sky, and the other two stars of the triangle are below the horizon. To an observer in the southern hemisphere *Crux*, the southern cross, is to the right of the south celestial pole, which is not marked by a conspicuous star. A long, curved line starting with the now-vertical arm of the southern cross and extending northward and then eastward passes successively through Hadar, Rigil Kentaurus, Peacock, and Al Na'ir.

Fomalhaut is low in the southeastern sky of the southern hemisphere observer, and Enif is low in the eastern sky at nearly any latitude. With the appearance of these stars it is not long before *Pegasus* will appear over the eastern horizon during the evening, and as the winged horse climbs evening by evening to a position higher in the sky, a new annual cycle approaches.

FIGURE 2208.—Stars in the vicinity of *Cygnus*.

Scale of magnitudes: 1st 2nd 3rd 4th 5th

2209. Ecliptic diagram.—On each right-hand page of the daily tabulations of the *Air Almanac* (app. W) an ecliptic diagram shows a band of the sky 16° wide (the zodiac, art. 1420), with the sun at the center. Shown in correct position relative to the sun (except when very close to it) are the moon, selected planets and stars, and the vernal equinox. This diagram is useful for planning purposes and for locating the planets. That part of the diagram to the left of the sun is east of it, approximately coinciding with the visible part during evening twilight. That part to the right, or west, of the sun coincides approximately with the visible portion during morning twilight. The two ends are that point in the sky 180° from the sun. These diagrams were replaced in 1965 by a single *Planet Location Diagram.*

2210. Star finders.—Various devices have been invented to help an observer locate and identify individual stars. The most widely used is the Star Finder and Identifier published by the U. S. Navy Hydrographic Office. The current model, H.O. 2102–D, as well as the previous 2102–C model patented by E. B. Collins, formerly of that Office, employs the same basic principle as that used in the Rude Star Finder, which was patented by Captain G. T. Rude, USC&GS, and later sold to the Hydrographic Office. Successive models reflect various modifications to meet changing conditions and requirements.

The *star base* of H.O. 2102–D consists of a thin, white, opaque, plastic disk about 8½ inches in diameter, with a small peg in the center. On one side the north celestial pole is shown at the center, and on the opposite side the south celestial pole is at the center. All of the stars listed on the daily pages of the *Nautical Almanac* are shown on a polar azimuthal equidistant projection (art. 320) extending to the opposite pole. The south pole side is shown in figure 2210a. Many copies of an older edition, H.O. 2102–C, showing the stars listed in the almanacs prior to 1953, and having other minor differences, are still in use. These are not rendered obsolete by the newer edition, but should be corrected by means of the current almanac. The rim of each side is graduated to half a degree of LHA♈ (or 360°−SHA).

Ten transparent *templates* of the same diameter as the star base are provided. There is one template for each 10° of latitude, labeled 5°, 15°, 25°, etc., plus a tenth (printed in red) showing meridian angle and declination. The older edition (H.O. 2102–C) did not have the red meridian angle-declination template. Each template can be used on either side of the star base, being centered by placing a small center hole in the template over the center peg of the star base. Each latitude template has a family of altitude curves at 5° intervals from the horizon (from altitude 10° on the older H.O. 2102–C) to 80°. A second family of curves, also at 5° intervals, indicates azimuth. The north-south azimuth line is the celestial meridian. The star base, templates, and a set of instructions are housed in a circular leatherette container.

Since the sun, moon, and planets continually change apparent position relative to the "fixed" stars, they are not shown on the star base. However, their positions at any time, as well as the positions of additional stars, can be plotted. To do this, determine 360°−SHA of the body. For the stars and planets, SHA is listed in the *Nautical Almanac.* For the sun and moon, 360°−SHA is found by subtracting GHA of the body from GHA♈ at the same time. Locate 360°−SHA on the scale around the rim of the star base. A straight line from this point to the center represents the hour circle of the body. From the celestial equator, shown as a circle midway between the center and the outer edge, measure the declination (from the almanac) of the body *toward* the center if the pole and declination have the *same* name (*both* N or *both* S), and *away* from the center if they are of *contrary* name. Use the scale along the north-south azimuth line of any template as a declination scale. The meridian angle-declination template (the latitude 5° template of H.O. 2102–C) has an open slot

FIGURE 2210a.—The south pole side of the star base of H.O. 2102–D.

with declination graduations along one side, to assist in plotting positions, as shown in figure 2210b. In the illustration the celestial body being located has a 360°−SHA of 285°, and a declination of 14°.5 S. It is not practical to attempt to plot to greater precision than the nearest 0°.1. Positions of Venus, Mars, Jupiter, and Saturn on June 1, 1958, are shown plotted on the star base in figure 2210c. It is sometimes desirable to plot positions of the sun and moon, to assist in planning. Plotted positions of stars need not be changed. Plotted positions of bodies of the solar system should be replotted from time to time, the more rapidly moving ones oftener than others. The satisfactory interval for each body can be determined by experience. It is good practice to record the date of each plotted position of a body of the solar system, to serve later as an indication of the interval since it was plotted.

To orient the template properly for any given time, proceed as follows: enter the almanac with GMT, and determine GHA ♈ at this time. Apply the longitude to GHA ♈, subtracting if west or adding if east, to determine LHA ♈. If LMT is substituted for GMT in entering the almanac, LHA ♈ can be taken directly from the almanac, to sufficient accuracy for orienting the star finder template. Select the tem-

FIGURE 2210b.—Plotting a celestial body on the star base of H.O. 2102–D.

plate for the latitude nearest that of the observer, and center it over the star base, being careful that the correct sides (north or south to agree with the latitude) of both template and star base are used. Rotate the template relative to the star base until the arrow on the celestial meridian (the north-south azimuth line) is over LHA ♈ on the star base graduations. The small cross at the origin of both families of curves now represents the zenith of the observer. The approximate altitude and azimuth of the celestial bodies above the horizon can be read directly from the star finder, using eye interpolation. Consider Polaris, not shown, as at the north celestial pole. For more accurate results, the template can be lifted clear of the center peg of the star base, and shifted along the celestial meridian until the latitude, on the altitude scale, is over the pole. This refinement is not needed for normal use of the device. It should not be used for a latitude differing more than 5° from that for which the curves were drawn. If the altitude and azimuth of an identified body shown on the star base are known, the template can be oriented by rotating it until it is in correct position relative to that body.

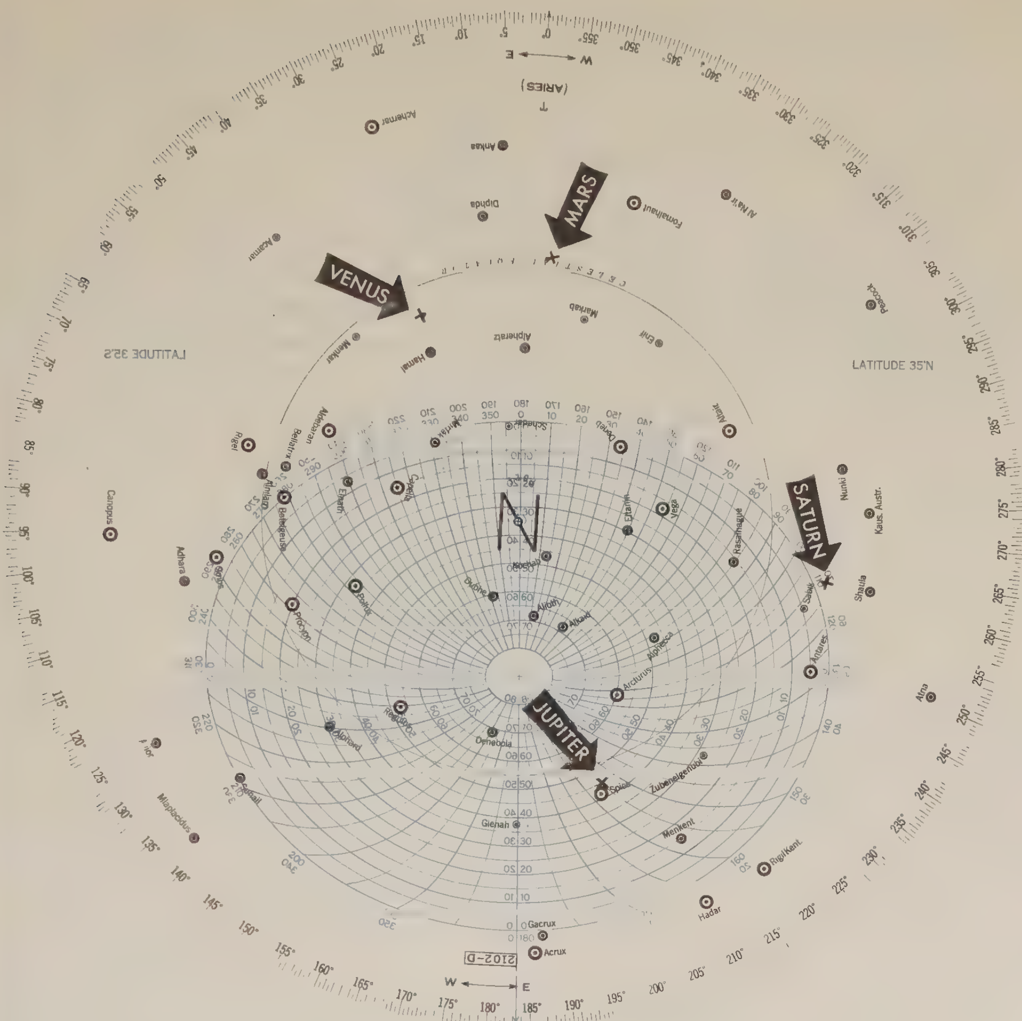

FIGURE 2210c.—A template in place over the star base of H.O. 2102–D.

Customarily, H.O. 2102–D is used in either of two ways:

1. To make an advance list of celestial bodies available for observation at a given time.

2. To identify an unknown celestial body which has been observed.

Example 1.—During evening twilight on June 1, 1958, the GMT 2324 DR position of a ship is lat. 34°12′.5 N, long. 57°46′.8 W.

Required.—The approximate altitude (h*a*) and azimuth of each first magnitude star, and any planets, between altitudes 15° and 75°.

Solution (fig. 2210c).—(1) Plot the positions of the planets, as shown. The values used are those for GMT 1200 on June 1, as follows:

Planet	*360° − SHA*	*Dec.*
Venus	28°.5	9°.6 N
Mars	356°.7	3°.5 S
Jupiter	201°.1	7°.3 S
Saturn	262°.8	21°.8 S

(2) Determine LHA ♈ by means of the *Nautical Almanac*, as follows:

GMT	2324	June 1
23^h	234°55′.0	
24^m	6°01′.0	
GHA ♈	240°56′.0	
λ	57°46′.8 W	
LHA ♈	183°09′.2	

(3) Select the template for latitude 35°, place it over the north side of the star base with "LATITUDE 35° N" appearing correctly, and orient it to 183°.2. It is customary to list the bodies in order of increasing azimuth, as follows:

Body	*ha*	*Zn*
Vega	17°	054°
Arcturus	59°	111°
Jupiter	45°	155°
Spica	42°	157°
Regulus	53°	240°
Procyon	20°	262°
Pollux	33°	284°
Capella	15°	316°

Example 2.—At the time and place of example 1, an unidentified celestial body is observed through a break in the clouds. Its sextant altitude is 15°27′.8, and its azimuth is 085°.

Required.—Identify the celestial body.

Solution (fig. 2210c).—Orient the template as in example 1. By means of its altitude and azimuth, identify the star as Rasalhague.

If no body appears at the measured altitude and azimuth, place the red meridian angle-declination template over the altitude-azimuth template and read off, by inspection, the declination and the 360°−SHA value of the body, and from this, determine its SHA. Using the SHA and declination, enter the list of stars near the back of the *Nautical Almanac*, and identify the body. If it is not found in this list, and no error has been made, one of the stars not listed in the almanac, or possibly the planet Mercury, has been observed. Unless a copy of *The American Ephemeris and Nautical Almanac* or another book containing the required information is available, the observation cannot be used. If right ascension (art. 1426) of the body is available, but not its SHA, the value taken from the star finder (360°−SHA) is converted to time units (art. 1904) and used directly, since RA=360°−SHA.

Example 3.—At the time and place of example 1 an unidentified celestial body is observed through a break in the clouds. Its altitude is 52°58′.9, and its azimuth is 170°.

Required.—Identify the celestial body.

Solution (fig. 2210c).—Orient the template as in example 1. Since no celestial body appears at the place indicated by its altitude and azimuth, the red meridian angle-declination template is placed over the altitude-azimuth template. The declination is found to be about 1° S. The 360°−SHA value is about 190°, and SHA is therefore about 170°. From the star list near the back of the *Nautical Almanac*, the star is identified as γ *Virginis*.

2211. Sight Reduction Tables for Air Navigation (H.O. Pub. No. 249).—Volume I of H.O. Pub. No. 249 can be used as a star finder for the stars tabulated at any given

time. For these bodies the altitude and azimuth are tabulated for each 1° of latitude and 1° of LHA♈ (2° beyond latitude 69°). The principal limitation is the small number of stars listed.

2212. Sky diagram.—Near the back of the *Air Almanac* are a number of **sky diagrams.** These are azimuthal equidistant projections (art. 320) of the celestial sphere on the plane of the horizon, at latitudes 70°N, 50°N, 30°N, 10°N, 10°S, and 30°S, at intervals of two hours of local mean time each month. A number of the brighter stars, the visible planets, and several positions of the moon are shown at their correct altitude and azimuth. These are of limited value because of their small scale; the large increments of latitude, time, and date; and the limited number of bodies shown. However, in the absence of other methods, particularly a star finder, these diagrams can be useful. Allowance can be made for variations from the conditions for which each diagram is constructed. Instructions for use of the diagrams are included in the *Air Almanac*.

2213. Identification by computation.—If the altitude and azimuth of the celestial body, and the approximate latitude of the observer, are known, the navigational triangle (art. 1433) can be solved for meridian angle and declination. The meridian angle can be converted to LHA, and this to GHA. With this and GHA of Aries at the time of observation, the SHA of the body can be determined. With SHA and declination, one can identify the body by reference to an almanac. Any method of solving a spherical triangle, with two sides and the included angle being given, is suitable for this purpose. "Short" methods such as H.O. Pubs. Nos. 208 and 211 include instructions for star identification by the tables provided. A large-scale, carefully-drawn diagram on the plane of the celestial meridian, using the refinement shown in figure 1432f, should yield satisfactory results. Perhaps the simplest method of actual computation is by H.O. Pub. No. 214. Following the tables of computed altitude and azimuth for each latitude, a two-page star identification table is given, as shown in appendix AA. The example given below is based upon this extract.

The steps in solution by H.O. Pub. No. 214 are:

1. Convert Zn to Z.

2. With Z and h*a* (usually the approximate value taken from the sextant, without correction) enter the H.O. Pub. No. 214 star identification pages for the nearest whole degree of latitude, and extract the declination and meridian angle, t (given as H.A. in the table). If the declination is given in roman type, above the heavy line, it has the *same* name as the latitude. If the declination is given in *italics*, below the heavy line, it has the *contrary* name to that of the latitude. When interpolating between roman and italic declinations, consider the italic value negative, using the arithmetical *sum* as the algebraic *difference* needed for interpolation. Extract values to the nearest whole degree.

3. Convert t to LHA.

4. Apply the longitude to LHA to find GHA, adding if in west longitude, and subtracting if in east longitude.

5. Enter the *Nautical Almanac* with GMT, and determine GHA♈.

6. Subtract GHA♈ from GHA☆ to find SHA (since GHA☆=GHA♈+SHA).

7. With the approximate SHA and d enter the *Nautical Almanac* star list and identify the body, checking first the SHA and then the declination. Do not overlook the possibility of having observed a planet or a star not listed in the almanac. For a planet, check first the declination. If this is approximately correct, check the GHA. It is not necessary to find the SHA of a planet.

Example.—On May 31, 1958, the 0425 DR position of a ship is lat. 41°13′.6 N, long. 140°41′.7 W. About this time the navigator observes an unknown star through a break in the clouds, as follows: GMT $13^h24^m46^s$, hs 15°01′.5, Zn 232°.

Required.—Identify the unknown celestial body, using H.O. Pub. No. 214.

Solution.—

	May 31				
GMT	$13^h24^m46^s$ May 31		Zn	232°	
13^h	83°31′.2		Z	N 128° W	
24^m46^s	6°12′.5		ha	15°	
GHA ♈	89°43′.7	(subtract)	d	16° S	(from H.O. Pub. No. 214)
GHA☆	193°		t	52° W	(from H.O. Pub. No. 214)
SHA☆	103°		LHA	52°	
d	16° S		λ	141° W	
Body	Sabik		GHA	193°	

Problems

2210a. During morning twilight on June 3, 1958, the GMT 1825 (June 2) DR position of a ship is lat. 26°21′.4 N, long. 157°10′.4 E.

Required.—The approximate altitude and azimuth of each first magnitude star, and any planets, between altitudes 10° and 80°, using H.O. 2102–D.

Answer.—

Body	*ha*	*Zn*
Venus	27°	092°
Mars	47°	128°
Fomalhaut	32°	160°
Saturn	14°	237°
Altair	59°	242°
Vega	50°	301°
Deneb	67°	334°

2210b. At the time and place of problem 2210a an unidentified celestial body is observed through a break in the clouds. Its sextant altitude is 21°04′.1 and its azimuth is 044°.

Required.—Identify the celestial body, using H.O. 2102–D.

Answer.—Mirfak.

2210c. The dead reckoning latitude of a ship is 25°06′.4 S. Two stars are observed in quick succession, as follows:

Star	*ha*	*Zn*
Antares	57°	100°
Unidentified	52°	337°

Required.—Identify the unknown celestial body, using H.O. 2102–D.

Answer.—*ε Virginis.*

2213. On June 2, 1958, the 1725 DR position of a ship is lat. 41°27′.3 S, long. 158°36′.9 E. About this time the navigator observes two unknown celestial bodies through breaks in the clouds, as follows: (1) GMT $6^h24^m15^s$, hs 16°04′.9, Zn 334°; (2) GMT $6^h25^m53^s$, hs 30°38′.1, Zn 071°. The second body appears to be of the first magnitude, with a bright but somewhat dimmer body above it and slightly to the right.

Required.—Identify the unknown celestial bodies, using H.O. Pub. No. 214.

Answers.—(1) Pollux, (2) Jupiter.

PART FIVE

THE PRACTICE OF NAVIGATION

PART FIVE

The Practice of Navigation

CHAPTER XXIII

THE PRACTICE OF MARINE NAVIGATION

2301. Introduction.—In the preceding 22 chapters, the various elements of navigation are discussed separately. In this chapter the interrelationship of the various parts is discussed. However, the most important element of successful navigation cannot be acquired from this book—nor from any book or instructor. The *science* of navigation can be taught, but the *art* of navigation must be acquired. Modern navigation is a blending of the two—a *scientific art*. The truly successful navigator is one who supplements his knowledge with judgment, utilizing every opportunity to improve his judgment through experience. Even with knowledge and judgment, the navigator cannot expect to be fully reliable unless he is alert, constantly evaluating the situation as it develops, avoiding dangerous situations before they arise, or recognizing them if they do occur, and always keeping "ahead of the vessel." The elements of successful navigation, then, are *knowledge*, *judgment*, and *alertness*. To the person possessing these, navigation can be a pleasure. A person who tries to navigate without them is at best a doubtful asset. He may be a menace to his vessel and shipmates.

It is not wise to attempt to reduce navigation to a series of steps that can be followed mechanically. The methods and techniques to be used are those which are applicable to the type of vessel, the equipment available, the training and experience of the navigator and any assistants, the local situation, etc. The navigation of a small craft proceeding up the Choptank River, for instance, might be quite different from that of an ocean liner entering New York harbor. Both might differ from the navigation of a naval vessel approaching an assigned anchorage. It is important that a navigator make an "estimate of the situation" and use the methods and techniques that are best adapted to the conditions at hand.

The discussion that follows is generally applicable to any vessel under average conditions, but is written primarily for an average ship which might be planning and executing an ocean voyage.

2302. Advance preparation.—Before starting a voyage, the navigator should familiarize himself with his equipment and the conditions to be encountered. Any defective or questionable instruments should be repaired or replaced. The necessary charts and publications should be on hand. If the voyage is to extend beyond the time range of any publication, such as an almanac or tide tables, the volume for the next period should be included, or provision should be made to acquire it before the expiration date of the current volume. Charts and light lists should be checked to see that they have been corrected through the latest *Notice to Mariners*.

When all equipment is on hand and in suitable condition, the navigator should study his charts and publications. He should determine which soundings are in feet, which in fathoms, and whether other units are used (app. L). It is good practice to underline or circle with a colored pencil the statement of units as given on each chart. The various notes on the chart should be read, and applicable ones marked. The latitude and longitude scales should be observed and the units noted. The channels, currents, shoals, aids to navigation, and natural landmarks should be studied so that the general arrangement is familiar. Useful natural ranges should be located and marked. Where needed, turning bearings, danger angles, and danger bearings should be determined.

The tides and currents to be encountered should be determined from the tables and charts. The advice and warnings given in coast pilots or sailing directions should be read and pertinent parts marked or copied out. The light list should be studied, and circles of visibility for the usual height of eye drawn in. Characteristics should be written on the chart, if not printed there, or in a notebook, to assist in identification. Useful radar targets, radiobeacons, loran rates, etc., should be noted if equipment to utilize them is available. If a danger sounding is useful, it should be drawn in. The bottom configuration should be studied for distinctive features that will prove helpful in locating the position of the vessel, or keeping it in safe water. If foreign charts are to be used, the symbols should be understood.

The extent of the preliminary study depends somewhat upon the navigator's previous knowledge of the area. But however familiar he may be with local conditions, the navigator should not overlook the need for checking his equipment to be sure it is complete and up-to-date, nor to refresh his memory regarding critical items of information. The prudent navigator leaves nothing to chance and *assumes nothing that can be verified.*

In pilot waters with limited maneuvering space, the desired track might well be plotted in advance, and the predicted time between buoys, turns, etc., determined. Where repeated runs are made over the same routes, the entire track may be plotted in ink. Courses, distances between lights, visibility circles, and other useful information might be prominently indicated. When this practice is followed, a positive routine should be set up to apply corrections and to bring these to the attention of all concerned.

2303. Getting underway.—Shortly before the ship gets underway the necessary charts, publications, and plotting equipment should be placed on the chart table. A check should be made to be sure that all marks (except those permanently plotted in ink or colored pencil) relating to a previous voyage have been erased from the charts. The navigator's binoculars should be checked to see that they are properly secured in their accustomed place on the bridge. The gyro compasses should be started sufficiently in advance to insure proper operation, and should then be compared with the repeaters and the magnetic compass on the bridge. A check should be made to see that the latest deviation tables are available, and that magnetic gear has not been left near the compass. Azimuth circles and peloruses should be in place and checked. The standard and emergency steering gear should be checked, as well as communication and signaling equipment. If practical, the mechanical log and electronic equipment such as radar, loran, radio direction finder, and echo sounder should be started and checked. The hand lead should be placed at a convenient location ready for immediate use. The anchor windlass should be tested. The sextant, chronometers, almanac, and tables should be checked to see that they are in their proper places. It is good practice for the navigator to prepare a check-off list to insure that nothing is overlooked. The checks should be made carefully by a responsible person.

Before getting underway the navigator should see that all navigational personnel are at their assigned stations and that each understands his duties. It is good practice to acquaint each person with the general plan of operation, for an informed person is less likely to make mistakes, and more likely to detect mistakes made by others.

2304. Leaving port.—In a harbor, the largest scale chart should be used for greatest accuracy and detail. The dead reckoning should be started as soon as the vessel steadies on its first course. If the desired track has not been plotted in advance, the dead reckoning is run ahead a short distance. In either event, the predicted time of arrival at the next turning bearing, or of passing the next aid to navigation is recorded on the chart. Predicted times of arrival at various points are of great importance in interpreting the information received and in avoiding dangerous situa-

tions. It is good practice to use *all* available information, and not rely solely upon a single aid. A good position should be maintained at all times. Fog may set in rapidly and without warning, obscuring landmarks before a round of bearings can be observed. Lights should be timed and identified by their characteristics. At a distance, the color and shape of buoys may not be apparent. Sometimes a sailboat can be mistaken for a buoy. Buoys may be out of position. Bearings and ranges on fixed objects are better than on floating aids which do not remain at fixed points. Soundings should be taken continuously in the vicinity of shoal water. It is good practice to check the compass at convenient opportunities, as when on a range. Ranges are of great value for checking position or keeping on the desired track, and should be used whenever available.

By skillful navigation, one may be able to save many miles of steaming. However, it is possible to allow insufficient margin of safety. The navigator should always keep in mind the possibility of failure of some item of equipment, unexpected fog, or the need for maneuvering room if another vessel approaches too close. He should remember, too, that in pilot waters currents may be strong and variable.

A detailed record should be kept in a notebook. Entries should be made showing bearings and ranges, important soundings, all changes of course and speed, the times of passing important aids to navigation, and other pertinent information. The record should leave nothing in doubt, indicating whether bearings are true or by magnetic compass, whether soundings are in feet or fathoms, etc. This record is useful in preparing the ship's log, providing guidance for future runs over the same area, establishing position if fog sets in, and in providing an acceptable record if the vessel experiences a mishap resulting in a later investigation.

The chart, also, should present a neat and intelligible record of the passage. Course lines and lines of position should be drawn lightly and neatly, and should be no longer than needed. Labels should be used wherever they contribute to an understanding of the plot. They should be so placed and worded that no doubt is left as to their applicability and meaning. If possible, lines and labels should not be drawn through chart symbols.

Outside the harbor, if the course is parallel to the coast, there may be advantages in remaining close enough to utilize major aids to navigation and other landmarks. However, a set toward the beach, particularly off the entrance to an estuary, can endanger the safety of a vessel. Many ships have grounded because a course was set too close to off-lying dangers.

2305. Taking departure.—When a vessel reaches the open sea and is about to leave the land astern, a last accurate position is obtained by means of landmarks available. This process is called **taking departure.** It marks the end of piloting and the beginning of the next phase of the navigation. The work of the navigator becomes less hurried, and fixes are obtained less frequently. Soundings become of less interest. The hand lead is secured. The position may be transferred from the chart to a plotting sheet. Courses and speeds will be maintained over relatively long periods. The sea routine begins. Even if the vessel is to follow the coast, it generally does so at such a distance that danger is some distance away, and navigation is an intermittent process rather than a continuous one.

2306. Navigation at sea, like piloting, varies somewhat from vessel to vessel depending upon the equipment available and the individual preferences of the navigator. A daily routine, called the **day's work,** is established by the navigator and carried out with such variations as dictated by circumstances. While details vary with the navigator, a typical minimum day's work is:

1. Plot of dead reckoning throughout the day.

2. Observation and reduction of celestial observations for a fix during morning twilight.

3. Winding of chronometers and determination of chronometer error.

4. Observation of the sun for a morning sun line (on or near the prime vertical if made at about the same time as 5).

5. Azimuth of the sun for a compass check. This may be an amplitude observation at sunrise, but is more commonly made at about the same time as a morning sun line observation.

6. Observation of the sun at or near noon. This is crossed with a morning sun line, advanced, or with an observation of the moon or Venus to obtain a noon (ZT 1200) position.

7. Computation of the day's run (noon to noon, or midnight to midnight).

8. Observation of the sun during the afternoon (on or near the prime vertical if made at about the same time as 9). This is primarily for use with the advanced noon sun line, or with a moon or Venus line, if the skies are overcast during evening twilight.

9. Azimuth of the sun for a compass check. This is commonly made at about the same time as an afternoon sun observation, but may be an amplitude observation at sunset.

10. Computation of the time of sunset, sunrise, and twilight, and preparation of a list of stars and any planets in favorable positions for observation during each twilight period, with the approximate altitude and azimuth of each body.

11. Observation and reduction of celestial observations for a fix during evening twilight.

12. Computation of the time of moonrise and moonset (if required).

13. Use of loran and any other available electronic aid on a regular schedule, as every hour.

The list of celestial bodies available for observation is customarily prepared with the aid of a star finder such as H.O. 2102–D (art. 2210). This list is particularly helpful during evening twilight, when one desires to know where to look for the brightest stars or planets before the general pattern of stars becomes visible. Some navigators list or make a simple plot of the *relative* azimuths of the bodies, to assist in locating them. The brightest bodies may be visible at about the time of sunset, or even a little before. In general, it is good practice to observe the brightest bodies as they appear in the evening, while the horizon is clear and sharp, and the dimmest first in the morning, before they fade from view. Several observations should be made of each body, each sight being taken quickly to avoid eye fatigue. In general, it is better to use one good observation than to average several of questionable accuracy. At least five or six bodies should be observed. If the three most favorably situated ones provide a good fix, additional sights need not be reduced, but if doubt remains, information for obtaining additional lines is available. It is better to observe bodies all around the horizon than in the same semicircle. Thus, three bodies separated by 120° are better than three separated by 60°, for in the former case any constant error in altitude will be neutralized.

If a comparing watch is used, it should be compared with the chronometer or a time tick every time celestial observations are made. The index correction should be determined each time the sextant is used. If the horizon is used for this purpose, the measurement should be made *before* evening twilight observations and *after* morning twilight observations, while the horizon is sharp. If the horizon is not equally sharp in all directions, the best part should be used.

When skies clear after a prolonged period of overcast, or when clouds threaten to obscure the heavens, additional observations should be made, if available. During

the day a series of sun lines might be obtained and advanced to a common time, or the moon or Venus might be available at a favorable azimuth. Sometimes observations can be made during the night, either by use of moonlight to illuminate the horizon, or by dark-adapting the eyes. At this time the moon, and bodies having an azimuth nearly the same as the moon, should be avoided because of the probability of false horizons on the illuminated water.

Sights may be reduced by any reliable method. The one most widely used by mariners is H.O. Pub. No. 214, used in conjunction with the *Nautical Almanac*. If a check is needed, a good practice is to use a different method and a different almanac, so that mistakes will not be repeated.

Before the development of modern sight reduction methods, celestial navigation was largely a matter of determining latitude by observation of bodies on or near the celestial meridian (including Polaris) and longitude by observation of bodies on or near the prime vertical. Longitude was computed by time sight. Frequently, this method of navigation was inconvenient. Often it produced misleading results, as when a north-south "longitude" line was used instead of the true line of position which might differ in direction by as much as 30° or more. Errors were introduced when an incorrect longitude was used for solving a reduction to the meridian, or an incorrect latitude for solving a time sight of a body some distance from the prime vertical. The use of azimuth with a time sight was an improvement, but was not well adapted to observations of celestial bodies near the celestial meridian. The modern navigator is freed from these restrictions. He is able to obtain a *line of position* extending in the correct direction almost any time a celestial body can be observed. He places no special significance upon latitude and longitude lines, and solves all sights by a common method of sight reduction.

It is good practice to use a workbook for the various solutions made at sea. This provides a valuable record which may be of inestimable value in the future. Entries should be neat, orderly, and intelligible to another navigator. All original data and computations should be included. The use of standard work forms is recommended. Those given in appendix Q are slight modifications of forms developed at the United States Naval Academy and used widely at sea. They are considered adequate but, for sight reduction of celestial observations, there is merit in using a form which uses a single column, so that several sights can be reduced in parallel columns. The *best* form for anyone to use is one he thoroughly understands and finds logical and least confusing. If an alteration in a work form reduces the number of errors made, it is a desirable change. Because of the difference of opinion among marine navigators, and the tendency to follow mechanically an established form without fully understanding the principles involved, a work form standardized for all navigators is probably undesirable, although such is widely used by air navigators, who use celestial navigation somewhat intermittently. When one has established the work forms he desires to use, he can have a rubber stamp made, or have the forms reproduced by printing. The former is probably preferable because it permits use of a bound workbook. However, printed forms can be punched for retention in a looseleaf binder.

At sea it is good practice to run the dead reckoning from fix to fix, determining set and drift of the current at each fix. The use of single lines of position and current to establish estimated positions is a matter of judgment. The ability to predict the difference between dead reckoning positions and fixes, which ability may be developed when the need is not apparent, can serve as a valuable asset when fixes are not available. In the U. S. Navy, the best position available is recorded in the log at 0800, 1200, and 2000. A typical plot of part of a day's run at sea (omitting possible loran fixes) is shown in figure 2306.

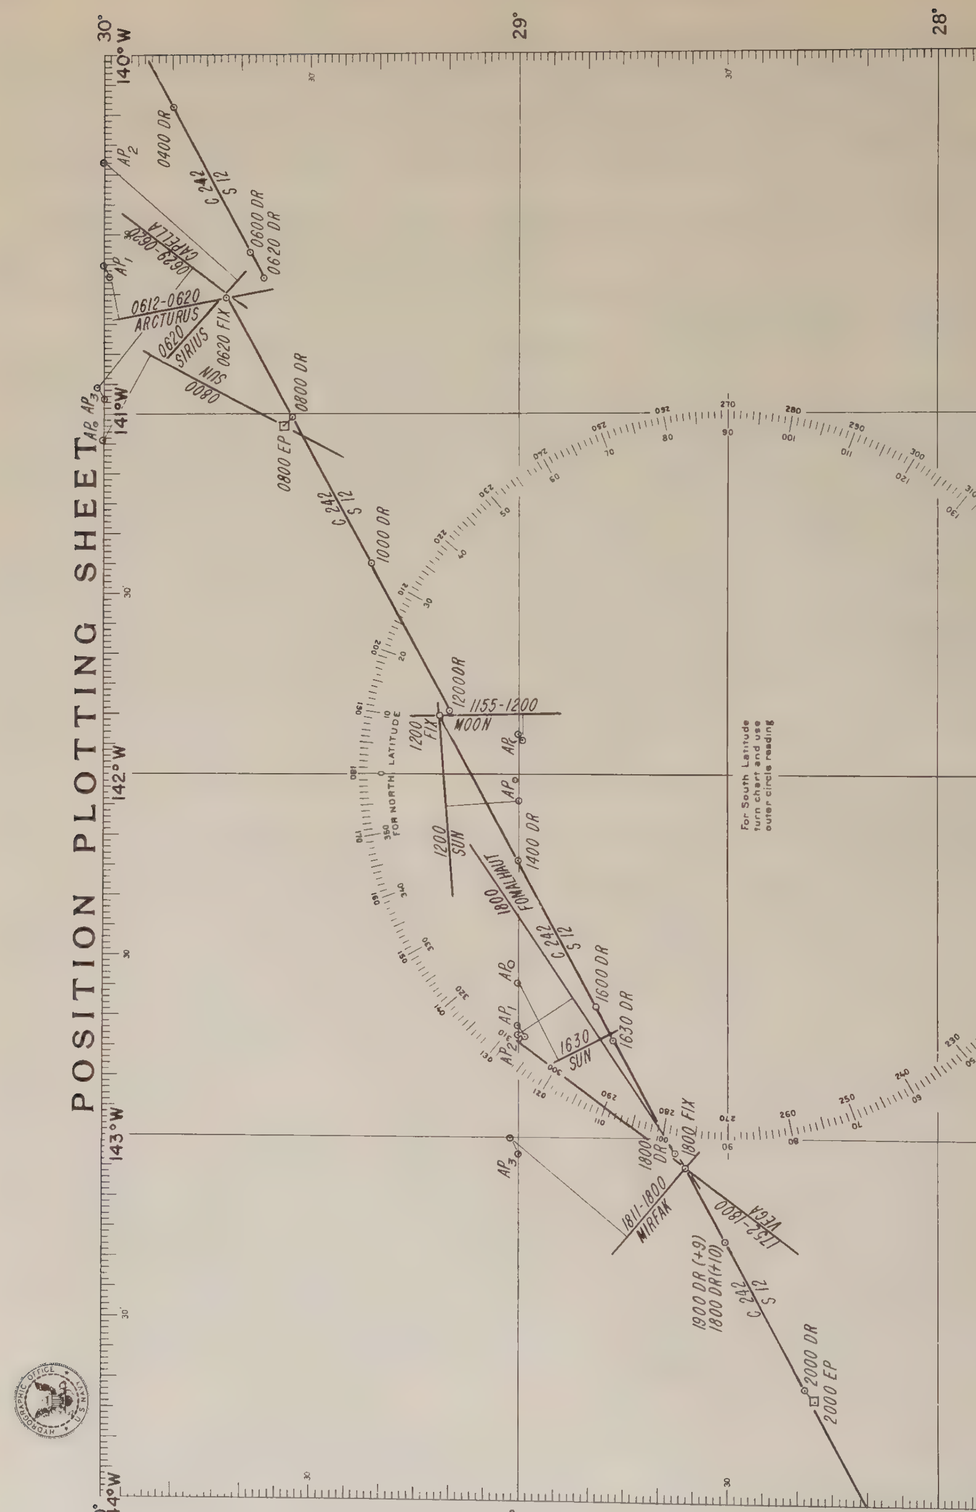

FIGURE 2306.—Typical minimum plot at sea (omitting possible loran fixes).

It is good practice to compare the gyro repeaters with the steering magnetic compass each half hour and after each change of course at sea, to detect any discrepancy which may arise through malfunction. In making the comparison, one should not overlook changes in variation and deviation. The master gyro compass should be compared with its repeaters from time to time.

One of the duties of the navigator is to inform the captain of the expected time of crossing time zone boundaries. The change of time is usually made at a convenient whole hour near the time of crossing a boundary, or during the night. Aboard some merchant ships the change is distributed equally through several watches, as 20 minutes during three consecutive watches.

It is common practice for the captain to maintain a **night order book.** Standing orders such as the conditions under which the captain is to be called, and the admonition to keep a sharp lookout, are usually given on the inside front cover. The orders for each night, if any, are recorded in order, over the captain's signature. They include items such as courses to be steered, speeds to be used, times and bearings of lights expected to be sighted, and any other pertinent navigational information. The navigator provides the captain with such information as he may require.

2307. Landfall.—After a voyage at sea, the first contact with land is of considerable importance. The accuracy with which one predicts the time and place of sighting land depends upon the accuracy of navigation. If consistent loran fixes have been obtained at frequent intervals, and these positions are confirmed by a recent fix from celestial observations or other information, the prediction should be highly accurate. But if no fix has been available for several days, considerable doubt may surround the landfall.

Often the approximate distance offshore, if not the position, can be determined by means of soundings. Along most of their coasts the continents have a **continental shelf** of relatively shoal water extending outward for a varying distance. A similar **insular shelf** extends outward from many island groups. At the outer edge, called the **continental talus** (or **insular talus**), a sharp increase in depth occurs. This is usually at about the 100-fathom curve. Therefore, the crossing of this curve is often quite abrupt, and gives information on the distance offshore. The position of this and other depth curves may be indicated on the chart.

The place of making landfall has a definite relationship to the safety of the vessel, particularly in an area where shoaling is not uniform along the beach. For some time before making a landfall in such an area, it may be advisable to maintain both a dead reckoning and estimated position plot. The best obtainable position should be determined. Methods which are acceptable a thousand miles from land may not provide sufficiently exact data when a landfall is expected.

Only judgment, based upon existing circumstances, can determine the existence of a dangerous situation. If the water has shoaled to a dangerous degree, for instance, and the position of the vessel is seriously in doubt, one may have no recourse but to stand off or anchor and await daylight, improved visibility, or better information.

When contact is made with land, the first step should be to identify the point of contact. The *anticipated* point of making contact should be of assistance, but one should be alert to the possibility of similarly appearing land at other points within a reasonable distance on each side. The position of the vessel relative to land might be established even before land is sighted. Soundings, radio bearings, and radar may be used for this purpose.

2308. Entering port.—Before entering port, the navigator should have reliable information regarding the draft of his vessel. He should also have a reliable position relative to the land. Preparations for entering are similar to those for getting underway. The tide and tidal current tables, light list, coast pilot or sailing directions, and

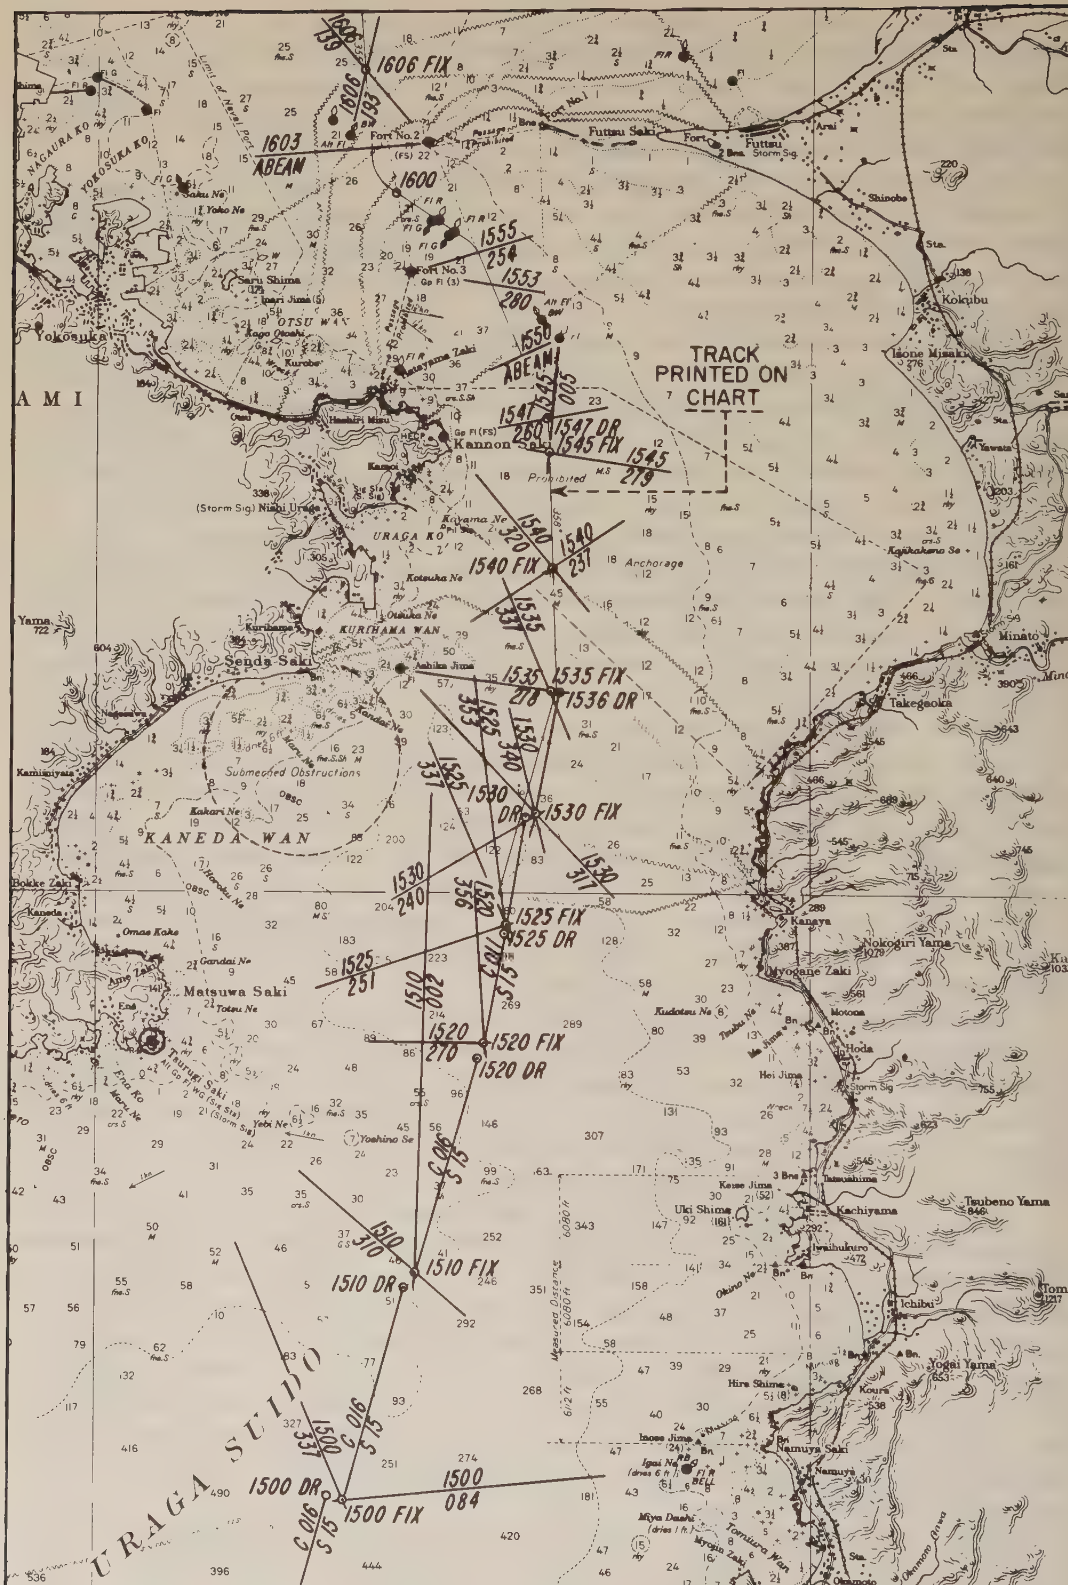

FIGURE 2308.—Typical plot in pilot waters.

charts should all be broken out and studied so that one is familiar with conditions to be encountered. The *time* of entering might be selected to take advantage of favorable currents, and to arrive at the assigned berth at slack water. One should have a mental picture of what to expect when approaching from seaward under the anticipated conditions of lighting and visibility. The characteristics of all aids to navigation by day or night, as appropriate, and fog signals should be known or immediately available. In entering a strange port the navigator should carefully select the most suitable aids to use, with substitutes if these prove inadequate, or if there is any doubt as to their identity. Useful ranges, natural or artificial, should be noted. Danger bearings and danger circles should be drawn in and labeled, if this has not already been done. A danger sounding should be selected and drawn on the chart, if needed. Any shoal areas, wrecks, areas of unusually swift current, etc., should be noted.

The courses to be steered and the distance on each should be determined and recorded, or drawn and labeled on the chart. The identification of each turning point should be indicated. Definite courses should be steered, and changes made only when established positions indicate a departure from the planned track, or when necessitated by traffic. Course changes should occur at preselected points having definite identification. The position should not be permitted to be in doubt at any time, even in ports which are familiar to the navigator and considered easy to enter. Most avoidable groundings are caused by erroneous assumptions which should have been verified. The position should be checked frequently, using the most reliable information available. This may seem to be an unnecessary refinement, but in an emergency a position might be needed at a time when it cannot be obtained. When changes of course are ordered, it is good practice to indicate the amount and direction of change, or the new course, to avoid the possibility of having one's attention diverted at the moment the order should be given to check the swing or steady on the new course. In general, course changes are best made when a given aid to navigation or other landmark is abeam, or when the ship is on a range.

If it becomes necessary to pass between visible dangers without suitable marks for obtaining fixes, a track midway between dangers can be followed by eye more accurately than one closer to either side. If a vessel is to pass near reefs or shoals, it is sometimes possible to observe these from a position aloft, particularly if the sun is astern.

The actual navigation while entering port is similar to that when leaving port. A typical plot in pilot waters is shown in figure 2308. The entering of pilot waters should be accompanied by a mental reorientation and an increased alertness. The use of a local pilot, unless this is a mandatory requirement, is a matter which should be decided in each case. Whether or not a pilot is used, local harbor regulations should be followed, for the presence of a pilot does not relieve the master of his responsibility. One should not forget to note the time of entering the area where local or inland rules of the road apply.

Speed in the vicinity of wharves, construction work, dredges, small boats, etc., should be carefully controlled to avoid damage to them.

If the vessel anchors, the anchorage should be selected carefully, considering local regulations as well as suitability and safety, including the holding qualities of the bottom. If there is any doubt as to the depth of water, a boat might be sent in ahead to take soundings. If space is limited, the approach to the anchorage should be planned and executed carefully. As soon as the anchor is let go, the position should be determined accurately, preferably by horizontal sextant angles. Bearings of a number of prominent landmarks and lights should be measured and recorded, as a guide in determining whether or not the vessel drags anchor.

2309. Fog.—During periods of reduced visibility, the navigator's work is more difficult. At sea he is prevented from making celestial observations. Even when the fog is so shallow that celestial bodies are visible, the horizon is not available as a reference. An artificial-horizon sextant may prove of some value at such a time, but unless the sea is almost a flat calm, the results are likely to be less reliable than the dead reckoning. Radio aids to navigation are affected little by fog. Unless the vessel is approaching land, there is generally no cause for concern regarding the navigation, the principal danger being one of collision with other vessels. Usually the navigator merely waits for the fog to lift.

When a coast is approached, however, a wait may be impractical. The safety of the vessel requires reliable positional information. Along a coast where the shoaling is gradual, the echo sounder or sounding machine can be of great assistance in indicating the distance off. But along a coast having abrupt shoaling, the first indication of shallow water may be obtained so close to the beach that action to avoid grounding is not possible. If radio aids such as loran, radio direction finder, and radar are available, they can provide useful information. If the vessel is near enough to a shore with steep cliffs, the echo of the vessel's whistle may provide indication of the distance off.

The decision of whether to enter a fogbound harbor should be made carefully. Once committed to the channel, the vessel may have no alternative but to continue on to the anchorage or wharf, for in some areas there is not room to turn back, and anchoring is unsafe. It is sometimes wiser to stand off or anchor for a few hours than to risk danger of grounding or collision.

If the decision is made to enter, one should be prepared for any reasonable eventuality. The proximity of danger and the presence of currents make necessary the maintenance of a good position at all times. Fog limits the number of objects that can be used for fixing position, and destroys the overall view of the area. The radio direction finder and radar, both shipborne and shore-based, have done much to reduce the hazard due to fog, but they have not eliminated it. The need for special precautions and increased vigilance is still present.

During periods of reduced visibility the practice of steering exact courses, with precise changes at definite points, is of great assistance in pilot waters. If the vessel is following a channel, each buoy should be located successively. If the fog is dense, this requires careful steering and attention to all details, such as indications of current, changes of wind, etc. If a single buoy is missed, consideration should be given to anchoring and waiting for improved visibility.

With the possible exception of radar, the most important navigational aid during fog in pilot waters is the echo sounder, sounding machine, or hand lead. Continuous soundings, compared with the chart, can provide valuable information on the position and safety of the vessel. The decision as to whether to plot a line of soundings on transparent material, or along the edge of a piece of paper, and compare this with the chart is a matter of judgment. In general, the procedure is valuable when approaching a harbor or proceeding in an open part of a large bay, but in a channel or other restricted waters the method is not needed and might prove distracting.

During fog one should keep a sharp lookout for any objects that might appear momentarily through thin places in the fog. It is well to have a lookout stationed aloft, and another in the bow, for the visibility may vary with height.

The lookouts and all persons on the bridge should listen intently for fog signals. As soon as such a signal is heard, an effort should be made to identify its source and determine its bearing. However, experience in the use of sound signals indicates that they are not wholly reliable. In particular, relative intensity of a sound is not a reliable indication of its distance, or whether the distance is increasing or decreasing. A signal

may be totally inaudible in certain areas close to its source. Neither is its apparent direction always a correct indication of its actual direction. A fog signal may not be in operation when fog is present a short distance from a station but is unobserved from it. Transmission of sound through water is subject to uncertainties due principally to differences in density in different parts of the sea, causing the sound to be deflected.

It is well to remember that at reduced speed the relative effect of current is correspondingly greater, since the effect of current is proportional to time, not to the speed of the vessel.

2310. Navigation of small craft.—In principle, the navigation of small craft is the same as that of a large ship, but because of the shallower draft, greater maneuverability, and possible limitations of equipment of small craft, there are important differences. Small craft spend most of their time within sight of land, where navigation is largely a matter of piloting. They generally skirt the beach close enough to be able to reach safety in case of storm or fog, and since most of them are used primarily for pleasure, there is a natural tendency for the navigation to be a less continuous process than in larger craft.

The equipment carried and the type of navigation employed depend primarily upon the use of the craft and the preference of the user. If a rowboat, canoe, or small sailboat is to be used only close to the shore in good weather, "seaman's eye" might be sufficient for all navigational purposes. But if there is any possibility of the craft being out in a fog, or proceeding to greater distances from shore, fog-signalling apparatus, a compass, and some means of taking soundings should be carried.

A wide variety of equipment is available for yachts, and from this, suitable items can be selected. A minimum list should include a compass, pelorus, charts, plotting equipment (many types are available), means for determining speed or distance, log book, tide and tidal current tables, light list, coast pilot or sailing directions, hand lead, binoculars, flashlight, and fog-signal apparatus. A barometer and thermometer are useful.

Several items of electronic equipment, some of which are relatively inexpensive, are available for use in small craft, to aid in navigation and increase safety. The principal item of radio equipment, from the standpoint of safety, is a marine radiotelephone, which in addition to providing normal communication to other boats and the shore, permits the boat carrying it to call for help in distress, and assists in the location of the distressed vessel. The radio direction finder is a simple device requiring little power, an important factor on small craft. A multiband direction finder may be used as a second receiver in the broadcast and radiotelephone bands. Portable broadcast receivers permit reception of weather information on even the smallest boats. For larger craft, where ample power is available, radar and loran may be good investments. In addition, every small craft should carry a corner reflector (art. 1209), so as more readily to reflect radar signals. In an emergency a metal bucket might be of some value as a reflector.

If the craft is to proceed out of sight of land for more than short intervals, celestial navigation equipment should be carried. This includes a sextant, an accurate timepiece, an almanac, sight reduction tables, and perhaps a star finder. If there is doubt as to advisability of including some item of equipment, the safer decision is to include it. It is better to have unused equipment than to risk danger of becoming lost because of lack of needed equipment.

The practice of navigation in small craft varies even more widely than the equipment carried. The variation extends from complete navigation similar to that of a large ocean steamer to no navigation other than by eye. The completeness of the navigation should fit the circumstances. There is an understandable tendency among small

craft navigators of limited experience to underestimate the need for thorough and complete navigation. In general, it is good practice for the navigator of a small craft to establish the routine of always following definite courses from buoy to buoy or from landmark to landmark, so that the sudden onset of low visibility will not find him unable to proceed to safety without delay. He should change course at established points, maintain knowledge of his position at all times, and have reliable information on the deviation of his compass. There is a place in small craft navigation for a complete, accurate, neat plot. Where this is impractical because of heavy weather or limited plotting space, a careful log and dead reckoning by table 3 should be substituted.

The accounts given in yachting magazines, and the large number of calls for assistance received by the Coast Guard, indicate an inadequacy of the navigation of many small craft. Part of this is due to a lack of appreciation of the need for careful navigation. Much of it is due to lack of knowledge on the part of the small craft owner. The decision to omit some part of navigation should stem from knowledge, not ignorance. To the adequately informed, navigation can be part of the pleasure of yachting.

CHAPTER XXIV

SUBMARINE NAVIGATION

2401. Introduction.—Submarines deserve special consideration, from a navigational viewpoint, because of their inherent or self-imposed limitations. Somewhat different techniques are used in each of four operating conditions, which will be considered separately. These are: (1) surfaced, (2) submerged by day and surfaced by night, (3) submerged at periscope depth, and (4) totally submerged.

2402. Surfaced.—The navigation of a submarine on the surface is essentially the same as that of other vessels, but there are some special considerations. The amount and type of equipment available is limited somewhat by space. Most of it is housed inside the hull, where it can be available for use when the vessel is submerged.

Careful dead reckoning by hand plot is important because of the lesser accuracy of mechanical equipment for this purpose. Speed or distance is measured as in other vessels. Direction measurement is dependent largely upon the gyro compass, because of the difficulty of adequately adjusting a magnetic compass heavily shielded by a steel hull. The areas of weak horizontal intensity of the earth's field, in which the magnetic compass is unreliable (art. 2513), are larger for submarines than for other vessels. Normally, leeway is negligible.

Piloting of submarines on the surface is carried on as in other vessels. However, the amount of exposed equipment is somewhat limited, as is the space for plotting and chart stowage. Because of the low height of eye, aids to navigation are not visible as far away as in other vessels of like size. At ten feet above the surface the horizon is only 3.6 miles away, while at 50 feet it is 8.1 miles distant. This may be an advantage when picking up a dark buoy, which may be more conspicuous against the background of a bright sky than against the darker water.

Electronic navigation is available to the submarines equipped to use it, but again space limitations are a consideration. Most submarines are equipped with radar, radio direction finders, and loran, as well as sonar and echo-sounding equipment. The low antenna height restricts the range at which signals can be received in some cases, particularly with radar.

With most of its hull under water, a submarine generally offers a steady platform for making celestial observations. However, if there is much of a sea, difficulty may be experienced in keeping the sextant mirrors dry, because the ship tends to go *through* the waves instead of riding over them. Because of the low height of eye, the state of the sea is an important consideration, and a correction for wave height (art. 1608) may be justified. If the sea is calm, excessive and somewhat unpredictable refraction may be encountered, particularly for heights of eye below about six feet.

2403. Submerged by day and surfaced by night.—This condition is not unusual during war patrols. By day the ship proceeds largely by dead reckoning, which becomes of even greater importance than on the surface, where ample means of checking its accuracy are usually available. Below the surface, where the ship is not buffeted by waves and wind, a steady course can be steered. The steadiness increases the reliability of the gyro compass. Speed is determined by log or shaft revolutions. If the latter is being used, it is well to remember that when the submarine is proceeding near the bottom, its actual speed may be somewhat less than indicated. Dead reckoning

should be kept up-to-date by a careful hand plot. The mechanical equipment for this purpose provides a useful check, but is less accurate. **Doppler** or **inertial navigation** (art. 809) may prove useful in submarines. The **ship's inertial navigation system (SINS)** is particularly promising.

Because of the very slow speeds normally used by submarines dependent upon batteries, current is an important consideration. Its drift may equal or even exceed the speed of the ship through the water. Pilot charts give helpful information on surface currents, but both the set and drift of the current below the surface may differ considerably. In relatively shallow water the drift may be greater for a short distance below the surface, but generally the drift decreases with depth. Near the bottom, the drift is noticeably reduced by friction. All available knowledge of subsurface currents should be used, but information on the subject is far from complete. A device called the **geomagnetic electrokinetograph,** or **GEK,** has been successfully used to determine ocean currents by a surface vessel towing two electrodes. If this device can be further perfected and adapted for use by submerged submarines, it will remove one of the principal uncertainties of underwater navigation.

It may not be advisable to take echo soundings because of the danger of revealing one's presence, but when they can be obtained, allowance should be made for the depth of the submarine below the surface.

Determination of sunset and the end of evening twilight has added significance to the crew of a submerged submarine in a war zone. In enemy waters it may not be safe to surface until full darkness has set in. By this time the visible horizon is gone, but if the sky is clear, there is no shortage of celestial bodies. If the moon is available, it may provide enough illumination to permit reasonably accurate altitude observations. However, false horizons frequently appear below a bright moon, and better results can usually be obtained by making back sights (art. 1633) of bodies near the moon's azimuth.

Some experiments have been made with night vision and star observations on a dark night. By thoroughly adapting their eyes to darkness and looking a little above or below the image of the body on the horizon, some navigators have reported acceptable results, using a relatively large number of observations. Most navigators using the method prefer a six-power telescope, as from a pair of binoculars, but others use no magnification and keep both eyes open.

When using this method, it is particularly desirable to observe stars all around the horizon, so that any constant error in estimating the position of the horizon will have minimum effect. When taking such observations, it is essential that nothing be done to disturb the dark-adaptation of the eyes, which must operate at peak performance. The observer and the assistant timing the observations should stand back to back. The timer's flashlight should be shielded so as to give a minimum of light needed for reading the watch. When the time has been noted and written down, the light should be turned off. The observer then hands the sextant to the assistant, who again faces away, turns on his light, and reads and records the sextant altitude. He then turns off the light, hands the sextant back to the observer, and the routine is repeated for the next observation. A dim red or blue light is preferable, and safer in a war zone. It is good practice to take and time several observations of each body, alternately increasing and decreasing the altitude setting of the sextant. If the results are plotted on cross-section paper, using altitude versus time, it should be possible to determine the best shots for solution.

In fairing a line through the plotted points, it may be helpful to know the correct *direction* of the line. One way of determining this direction is by means of H.O. Pub. No. 214. Since Δt is the unit change in altitude (to two decimal places), $15 \times \Delta t$ is the change for 15 minutes of arc (one minute of time). However, this result is for a sta-

tionary observer. To correct for his motion, multiply the distance run in one minute by the cosine of the relative azimuth of the body. If the body is forward of the beam, add the correction to $15 \times \Delta t$ if the body is rising, and subtract it if setting. For a body abaft the beam, reverse these signs. Having determined the change in altitude in one minute, draw a line at the slope indicated and move it parallel to itself until it best fits the plotted points. In fitting the line to the points, it is usually good practice to ignore the inconsistent shots. If Δt is changing rapidly, the change of altitude with time is not satisfactorily represented by a straight line, and should be plotted as a curve. This is most apparent for a body near the meridian, particularly one at a high altitude. Once the line is located, *any* point on it can be taken as the observation, whether or not it coincides with a plotted point, as long as the corresponding time is used. Thus, any convenient time or altitude might be selected.

Bubble or pendulum sextants (art. 1513) usually do not produce satisfactory results aboard ship because of the large acceleration errors produced by the motions of the vessel. However, it is desirable for a submarine to be provided with an artificial-horizon sextant, for there may be occasions when it affords the only available method of determining position, and the results may be of usable accuracy. With a reasonably smooth sea and a large number of observations, quite satisfactory results can be obtained. Since this instrument does not depend upon a visible horizon, the number of observations that can be obtained is limited only by the number of navigational bodies visible, and the time available to the observer. The assumed positions for the various sights should all be advanced or retired to a common time before the lines of positions are plotted, so that no confusion can result from the presence of the additional lines on the chart. For correction of artificial-horizon sextant altitudes, see article 1625. In using an artificial-horizon sextant, it may be desirable to make a number of observations of each body and plot them as explained above. Since acceleration error is due mostly to rolling, better observations can often be made over the bow or stern. If conditions warrant, the ship should be headed directly toward or away from each body as it is observed.

Whatever the method of observation, practice and some ingenuity are needed for best results.

2404. Submerged at periscope depth.—At periscope depth the view is seriously restricted, but not entirely lost. Reasonably accurate bearings of landmarks can be obtained through the periscope. Electronic navigation is available if an antenna can be surfaced, or, in some cases, kept submerged near the surface.

When the sun passes within a few degrees of the zenith, a number of azimuths can sometimes be measured by periscope before and after meridian transit. In using this information, it should be remembered that azimuth lines are great circles. Plot the geographical position at the time of each observation, and advance or retire it for the ship's run, so that all sights are for a common time. Apply the conversion angle correction from table 1 as for radio bearings, and plot the azimuth lines from the adjusted positions. Reasonably accurate results have been reported with this method when within about 400 miles of the geographical position of the sun. It can be used at greater distances if accurate azimuths can be obtained. The method requires a good level and cross-level of the periscope, and practice. For best results plot the azimuths against time on cross-section paper. Fair a curve through the plotted points, ignoring inconsistent observations. The points to use for plotting the azimuth lines on the chart or plotting sheet are taken at uniform intervals along the curve. If plotting is done on a gnomonic chart, conversion angle is not applied. However, because of the very small scale of these charts, plotting must be done carefully if accurate results are to be obtained. Lambert conformal charts can be used, but with some loss of

accuracy. The method can be used for similar observations of the moon, planets, and stars, if observations of these bodies can be made and the bodies identified. If a single body is used, the best times are just before and just after meridian transit, when the azimuth changes most rapidly and the ship is nearest the geographical position of the body. The principal limitation of the method is the accuracy with which azimuths can be observed. Unless the sea is almost a flat calm, the distance limitations are severe, and considerable skill is needed for good results under any conditions.

Some success has been obtained with altitude observations by means of the periscope, but this is difficult at best, and is limited to low altitudes. At low-power magnification, altitudes as high as 25° can be measured, but at high power the method is limited to about 7°. For good results the periscope should be accurately in the vertical, and steady. One method of obtaining the altitude is by counting the graduations of the vertical scale between the horizon and the body. Some navigators prefer the use of the periscope stadimeter, which may give satisfactory results in either of two ways. First, it may be offset so that the zero line of its vertical scale coincides with a selected line (as at 5° or 6°) of the periscope field. This causes a false horizon to appear at the selected periscope field line. As a body appears to cross this false horizon, it is at the selected altitude. A variation of this method is to offset the stadimeter zero line until the false horizon appears at the body, when the amount of the offset is the altitude. The second way of using the stadimeter is to read the distance corresponding to some arbitrarily chosen height. This height divided by the corresponding distance is the tangent of the altitude, which can be found in table 31. Better results might be obtained by noting the moment at which the lower or upper limb of the sun or moon is tangent to the horizon (or a planet or star crosses the horizon), and using the altitude as 0°00.′0, than by attempting to measure a low altitude through the periscope. Correction of low-altitude observations is explained in article 1632.

Solution of low-altitude observations can be made by virtually any method, including H.O. Pub. No 214. Low-altitude sight reduction is discussed in article 2010.

2405. Totally submerged.—The navigation of a totally submerged submarine is a problem which has not been fully solved. Some of the methods being developed or in use cannot be discussed because of security limitations. However, the following information should serve as a useful guide.

Dead reckoning, the basic form of navigation under virtually any conditions, is of increased importance to the totally submerged submarine. Submerged dead reckoning is discussed in article 2403.

Soundings can be used to help establish position in an area where a reliable chart of the bottom configuration is available, if allowance is made for the depth of the submarine below the surface. Sonar (art. 1108) can sometimes be useful in avoiding obstacles or even in locating position when there are identifiable, charted targets. Both sofar and rafos (art. 1313) can be used when available.

Electronic navigation has limited application unless an antenna is above water. However, very low frequency signals penetrate sea water to some extent, and if the submerged antenna can be placed close to the surface, usable signals can sometimes be obtained at great distances. These frequencies are little used for navigational information, but increased requirements for navigation below the surface will undoubtedly result in additional development in this part of the spectrum.

A useful method of submerged navigation might be based upon measurement of any quantity that varies from place to place in a known pattern, such as gravity or some element of the earth's magnetism, some form of radiation, or even water temperature or salinity. The use of such a method would require an instrument to provide

sufficiently accurate measurements, and an accurate chart showing the pattern at the time of observation. This would be similar to using bottom contours. Since a method of this type might often provide lines of position only, two or more methods may be needed to establish a fix.

Celestial navigation is not used by a totally submerged submarine.

The navigation of a submarine which remains below the surface for long periods, with nothing extending above water, presents a challenge that is partly met by making full use of every item of applicable information, and applying a generous amount of judgment and common sense.

CHAPTER XXV

POLAR NAVIGATION

Polar Regions

2501. Introduction.—No single definition of the limits of the polar regions satisfies the needs of all who are interested in these areas. Astronomically, the parallels of latitude at which the sun becomes circumpolar (the arctic and antarctic circles at about latitude 67°5) are considered the lower limits. Meteorologically, the limits are irregular lines which, in the arctic, coincides approximately with the tree line. For general purposes, the navigator may consider polar regions as extending from the geographical poles of the earth to latitude 70° (in the arctic coinciding approximately with the northern coast of Alaska), with transitional **sub-polar regions** extending for an additional 10° (in the northern hemisphere extending to the southern tip of Greenland).

This chapter deals primarily with marine navigation in high latitudes. Information relating to navigation ashore is given in chapter XXVII.

2502. Polar geography.—The north polar region, the **arctic,** consists of an elongated central water area a little smaller than the United States, almost completely surrounded by land (fig. 2502a). Some of this land is high and rugged with permanent **ice caps,** but part of it is low and marshy when thawed. Underlying **permafrost,** permanently frozen ground, prevents adequate drainage, resulting in large numbers of lakes and ponds and extensive areas of **muskeg,** soft spongy ground with characteristic growths of certain types of moss and tufts of grass or sedge. There are also large areas of **tundra,** low treeless plains with vegetation consisting of mosses, lichens, shrubs,

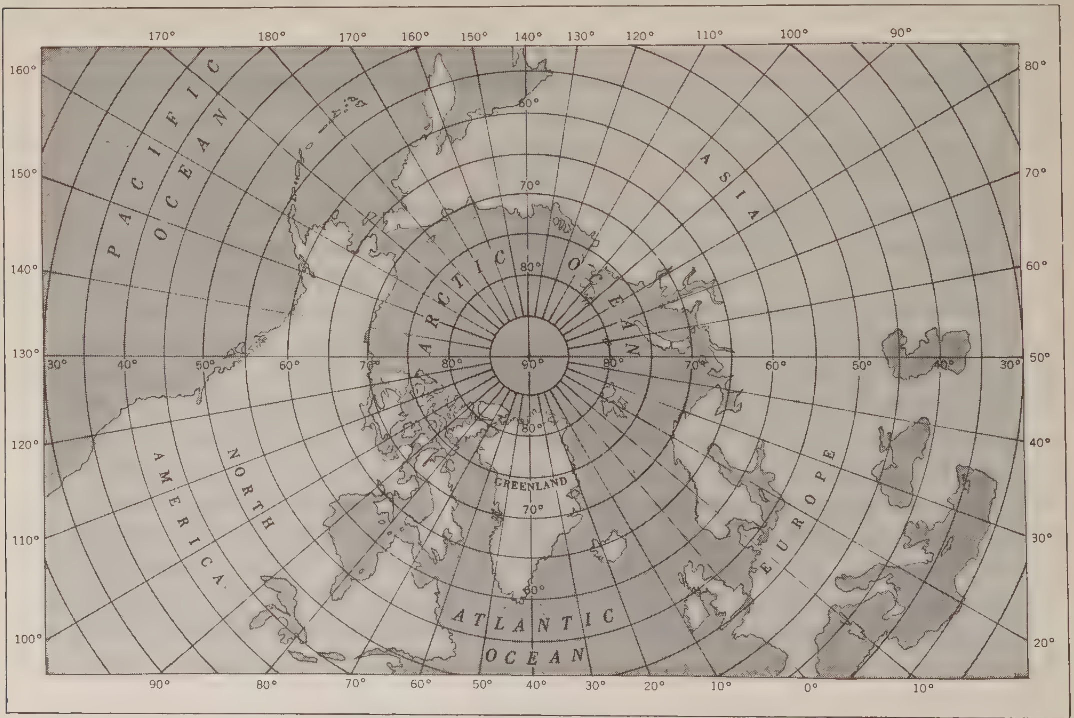

FIGURE 2502a.—The north polar region, or *arctic*.

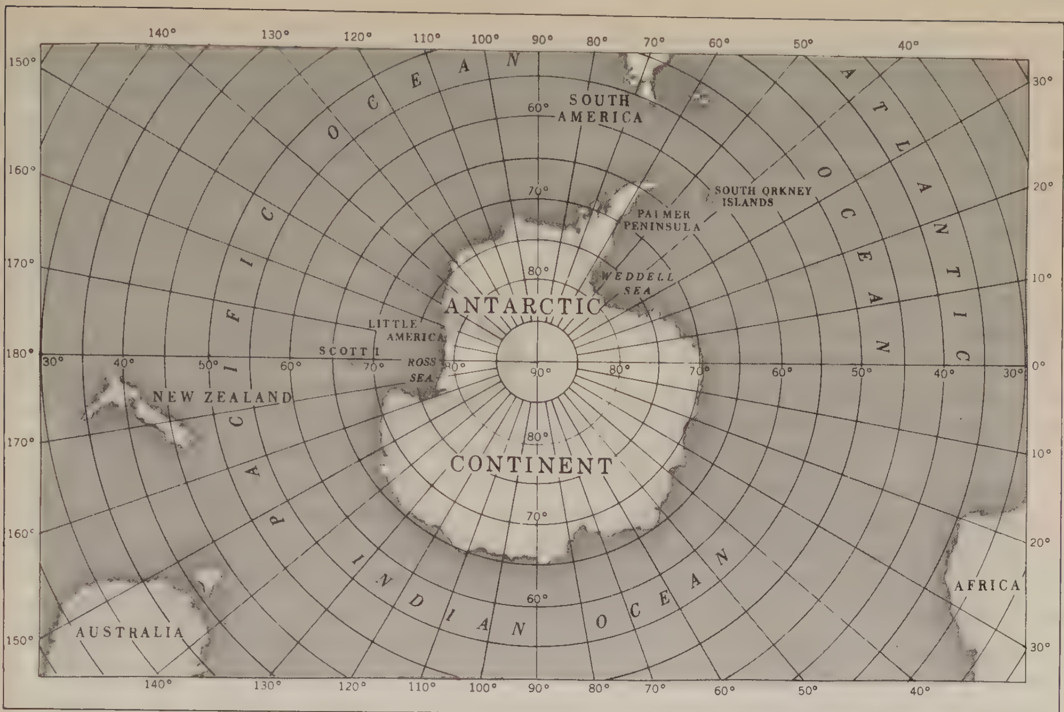

FIGURE 2502b.—The south polar region, or *antarctic.*

willows, etc., and usually having an underlying layer of permafrost. The northernmost point of land is Kap Morris Jesup, Greenland, about 380 nautical miles from the pole.

The central part of the **Arctic Ocean,** as the body of water is called, is a basin of about 12,000 feet average depth. However, the bottom is not level, having a number of seamounts and deeps. The greatest depth is probably a little more than 16,000 feet. At the north pole the depth is 14,150 feet. Surrounding the polar basin is an extensive continental shelf, broken only in the area between Greenland and Svalbard (Spitsbergen). The many islands of the Canadian archipelago are on this shelf. The Greenland Sea, east of Greenland; Baffin Bay, west of Greenland; and the Bering Sea, north of the Aleutians, each has its independent basin. In a sense, the Arctic Ocean is an arm of the Atlantic, as shown in figure 2502a.

The south polar region, the **antarctic,** is in marked contrast to the arctic in physiographical features. Here a high, mountainous land mass about twice the area of the United States is surrounded by water (fig. 2502b). An extensive polar plateau covered with snow and ice is about 10,000 feet high. There are several mountain ranges with peaks rising to heights of more than 13,000 feet. The average height of Antarctica is about 6,000 feet, which is higher than any other continent. The height at the south pole is about 9,500 feet. The barrier presented by land and tremendous **ice shelves** 500 to 1,000 feet thick prevent ships from reaching very high latitudes. Much of the coast of Antarctica is high and rugged, with few good harbors or anchorages.

2503. Navigation in polar regions.—Special techniques have been developed to adapt navigation to the unique conditions of polar regions. These conditions are largely the result of (1) high latitude, and (2) meteorological factors.

2504. High-latitude effects.—Much of the thinking of the marine navigator is in terms of the "rectangular" world of the Mercator projection, on which the meridians are equally spaced, vertical lines perpendicular to the horizontal parallels of latitude. Directions are measured relative to the meridians, and are maintained by means of a

magnetic or gyro compass. A straight line on the chart is a rhumb line, the line used for ordinary purposes of navigation. Celestial bodies rise above the eastern horizon, climb to a maximum altitude often high in the sky as they cross the celestial meridian, and set below the western horizon. By this motion the sun divides the day naturally into two roughly equal periods of daylight and darkness, separated by relatively short transitional periods of twilight. The hour of the day is associated with this daily motion of the sun.

In polar regions conditions are different. Meridians all converge at the poles, which are centers of series of concentric circles constituting the parallels of latitude. The rapid convergence of the meridians renders the usual convention of direction inadequate for some purposes. A rhumb line is a curve which differs noticeably from a great circle, even for short distances. Even visual bearings cannot adequately be represented as rhumb lines. At the pole all directions are south or north, depending upon the pole. Direction in the usual sense is replaced by longitude.

At the pole the zenith and celestial pole coincide. Hence, the celestial horizon and celestial equator also coincide, and declination and computed altitude are the same. Therefore, celestial bodies change computed altitude only by changing declination. Stars circle the sky without noticeable change in altitude. Planets rise and set once each sidereal period (12 years for Jupiter, 30 years for Saturn). At the north pole the sun rises about March 21, slowly spirals to a maximum altitude of about 23°27′ near June 21, as slowly spirals downward to the horizon about September 23, and then disappears for another six months. At the south pole a similar cycle takes place but during the opposite time of year. It requires about 32 hours for the sun to cross the horizon, during which time it circles the sky 1⅓ times. The twilight periods following sunset and preceding sunrise last for several *weeks*. The moon rises and sets about once each month. Half the sky is *always* visible and the other half is *never* seen.

The long polar night is not wholly dark. The full moon at this time rises relatively high in the sky. Light from the **aurora borealis** in the arctic and the **aurora australis** in the antarctic is often quite bright, occasionally exceeding that of the full moon. Even the planets and stars contribute an appreciable amount of light in this area where a snow cover provides an excellent reflecting surface.

All time zones, like all meridians, meet at the poles. *Local* time does not have its usual significance, since the hour of the day bears no relation to periods of light and darkness or to altitude of celestial bodies.

2505. Meteorological effects.—Polar regions are cold, but the temperature at sea is not as extreme as inland. The average winter temperature over the Arctic Ocean is (−) 30° F to (−) 40° F, with an extreme low value near (−) 60° F. Colder temperatures have been recorded in Yellowstone National Park. During the summer the temperature remains above freezing over the ocean. Inland, extreme values are sometimes reached. At least one point on the arctic circle has experienced a temperature of 100° F. Few points on the antarctic continent have recorded temperatures above freezing, and the interior is probably the coldest part of the world.

Fog and clouds are common in polar regions, yet there is less precipitation than in some desert regions, since the cold air has small capacity for holding moisture. Very cold air over open water sometimes produces steaming of the surface, occasionally to a height of several hundred feet. This is called **frost smoke** or **sea smoke** (fig. 2505). When there is no fog or frost smoke, the visibility is often excellent. Sounds can sometimes be heard at great distances.

Sharp discontinuities or inversions in the temperature lapse rate sometimes produce a variety of mirages and extreme values of refraction. The sun has been known to rise several *days* before it was expected in the spring. False horizons are not uncommon.

Strong winds are common in the sub-arctic and in both the antarctic and sub-antarctic. The belt of water surrounding Antarctica has been characterized as the stormiest in the world, being an area of high winds and high seas. Strong winds are not encountered over the Arctic Ocean.

In the polar and sub-polar regions the principal hazard to ships is ice, both that formed at sea and land ice which has flowed into the sea in the form of glaciers. Many low land areas are ice-free in summer. Ice is considered in more detail in chapter XXXVI.

When snow obliterates surface features, and the sky is covered with a uniform layer of cirrostratus or altostratus clouds, so that there are no shadows, the horizon

Figure 2505.—Frost smoke.

disappears and earth and sky blend together, forming an unbroken expanse of white, without features. Landmarks cannot be distinguished, and with complete lack of contrast, distance is virtually impossible to estimate. This is called **arctic** (or **antarctic**) **whiteout.** It is particularly prevalent in northern Alaska during late winter and early spring.

2506. Miscellaneous.—The cold surface water of the Arctic Ocean flows outward between Greenland and Svalbard and is replaced by warmer subsurface water from the Atlantic. The surface currents depend largely upon the winds, and are generally quite weak in the Arctic Ocean. However, there are a number of well-established currents flowing with considerable consistency throughout the year. The

general circulation in the arctic is clockwise on the American side and around islands, and counterclockwise on the Asian side. Tidal ranges in this area are generally small. In the restricted waters of the upper Canadian-Greenland area both tides and currents vary considerably from place to place. In the Baffin Bay-Davis Strait area the currents are strong and the tides are high, with a great difference between springs and neaps. In the antarctic, currents are strong, and the general circulation offshore is eastward or *clockwise* around the continent. Close to the shore, a weaker westerly or *counterclockwise* current may be encountered, but there are many local variations.

Since both magnetic poles are situated within the polar regions, the horizontal intensity of the earth's magnetic field is so low that the magnetic compass is of reduced value, and even useless in some areas. The magnetic storms centered in the auroral zones (art. 2526) disrupt radio communications and alter magnetic compass errors. The frozen ground in polar regions is a poor conductor of electricity, another factor adversely affecting radio wave propagation.

2507. Summary of conditions in polar regions.—The more prominent characteristic features associated with large portions of the polar regions may be summarized as follows:

1. High latitude.
2. Rapid convergence of meridians.
3. Nearly horizontal diurnal motion of celestial bodies.
4. Long periods of daylight, twilight, and semidarkness.
5. Low mean temperatures.
6. Short, cool summers and long, cold winters.
7. High wind-chill factor.
8. Low evaporation rate.
9. Scant precipitation.
10. Dry air (low absolute humidity).
11. Excellent sound-transmitting conditions.
12. Periods of excellent visibility.
13. Extensive fog and clouds.
14. Large number and variety of mirages.
15. Extreme refraction and false horizons.
16. Winter freezing of rivers, lakes, and part of the sea.
17. Areas of permanent land and sea ice.
18. Areas of permanently frozen ground.
19. Large areas of tundra (arctic).
20. Large areas of poor drainage, with many lakes and ponds (arctic).
21. Large areas of muskeg (a grassy marsh when thawed) (arctic).
22. Extensive auroral activity.
23. Large areas of low horizontal intensity of earth's magnetic field.
24. Intense magnetic storms.
25. Uncertain radio wave propagation.
26. Strong winds (antarctic).
27. Frequent blizzards (antarctic).
28. Large quantities of blowing snow.

Charts

2508. Projections.—In polar regions, as elsewhere, the chart is an important item of navigational equipment. The projections used for polar charts are considered in articles 321 and 322.

For ordinary navigation the Mercator projection has long been the overwhelming favorite of marine navigators, primarily because a rhumb line appears as a straight line on this projection. Even in high latitudes the mariner has exhibited an understandable partiality for Mercator charts, and these have been used virtually everywhere that ships have gone.

However, as the latitude increases, the superiority of the Mercator projection decreases, primarily because the value of the rhumb line becomes progressively less. At latitudes greater than 60° the decrease in utility begins to be noticeable, and beyond latitude 70° it becomes troublesome. In the clear polar atmosphere, visual bearings are observed at great distances, sometimes 50 miles or more. The use of a rhumb line to represent a bearing line introduces an error at any latitude, but at high latitudes this error becomes excessive.

Another objection to Mercator charts at high latitudes is the increasing rate of change of scale over a single chart. This results in distortion in the shape of land masses and errors in measuring distances.

At some latitude the disadvantages of the Mercator projection outweigh its advantages. The latitude at which this occurs depends upon the physical features of the area, the configuration and orientation of land and water areas, the nature of the operation, and, mostly, upon the previous experience and personal preference of the mariner. Because of differences of opinion in this matter, a transitional zone exists in which several projections may be encountered. The wise high-latitude navigator is prepared to use any of them, since coverage of his operating area may not be adequate on his favorite projection.

2509. Adequacy.—Charts of most polar areas are generally inferior to those of other regions in at least three respects:

1. *Lack of detail.* Polar regions have not been surveyed with the thoroughness needed to provide charts of the accustomed detail. Relatively few soundings are available and many of the coastal features are shown by their general outlines only. Large areas are perennially covered by ice, which presents a changing appearance as the amount, position, and the character of the ice change. Heavy covers of ice and snow prevent accurate determination of surface features of the earth beneath. Added to this is the similarity between adjacent land features where the hundreds of points and fiords in a rugged area or the extensive areas of treeless, flat coastal land in another look strikingly alike. The thousands of shallow lakes and ponds along a flat coastal plain lack distinctive features.

2. *Inaccuracy.* Polar charts are based upon incomplete surveys and reports of those who have been in the areas. These reports are less reliable than in other areas because icebergs are sometimes mistaken for islands, ice-covered islands are mistaken for grounded icebergs, shore lines are not easy to detect when snow covers both land and attached sea ice, inlets and sounds may be completely obscured by ice and snow, and meteorological conditions may introduce inaccuracy in determination of position. Consequently, many features are inaccurately shown in location, shape, and size, and there are numerous omissions. Isogonic lines, too, are based upon incomplete information, resulting in less than desired accuracy.

3. *Coverage.* Relatively few nautical charts of polar regions are available, and the limits of some of these are not convenient for some operations. As in other areas, charts have been made as the need has arisen. Hence, large-scale charts of some areas are completely lacking. Aeronautical charts are sometimes quite helpful, as they often show more detail of land areas than do the nautical charts. However, aeronautical charts do not show soundings.

2510. Polar grid.—Because of the rapid convergence of the meridians in polar regions, the true direction of an oblique line near the pole may vary considerably over a relatively few miles. The meridians are radial lines meeting at the poles, instead of being parallel, as they appear on the familiar Mercator chart.

Near the pole the convenience of parallel meridians is attained by means of a **polar grid.** On the chart a number of lines are printed parallel to a selected reference meridian, usually that of Greenwich. On transverse Mercator charts the fictitious meridians may serve this purpose. Any straight line on the chart makes the same angle with all grid lines. On the transverse Mercator projection it is therefore a **fictitious rhumb line.** On any polar projection it is a close approximation to a great circle. If north along the reference meridian is selected as the reference direction, all parallel grid lines can be considered extending in the same direction. The constant direction relative to the grid lines is called **grid direction.** North along the Greenwich meridian is usually taken as grid north in both the northern and southern hemispheres.

The value of grid directions is indicated in figure 2510. In this figure A and B are 400 miles apart. The true bearing of B from A is 023°, yet at B this bearing line, if continued, extends in true direction 163°, a change of 140° in 400 miles. The grid direction at any point along the bearing line is 103°.

When north along the Greenwich meridian is used as grid north, interconversion between grid and true directions is quite simple. Let G represent a grid direction and T the corresponding true direction. Then for the arctic,

$$\mathrm{G}=\mathrm{T}+\lambda\mathrm{W}.$$

That is, in the western hemisphere, in the arctic, grid direction is found by *adding* the longitude to the true direction. From this it follows that

$$\mathrm{T}=\mathrm{G}-\lambda\mathrm{W},$$

and in the eastern hemisphere

$$\mathrm{G}=\mathrm{T}-\lambda\mathrm{E},$$
$$\mathrm{T}=\mathrm{G}+\lambda\mathrm{E}.$$

In the southern hemisphere the signs (+ or −) of the longitude are reversed in all formulas.

If a magnetic compass is used to follow a grid direction, variation and convergency can be combined into a single correction called **grid variation** or **grivation.** It is customary to show lines of equal grivation on polar charts rather than lines of equal variation. Hydrographic Office chart number 1706 GN shows the **isogrivs** (lines of equal grivation) for the entire arctic.

With one modification the grid system of direction can be used in any latitude. Meridians 1° apart make an angle of 1° with each other where they meet at the pole. The **convergency** is one, and the 360° of longitude cover all 360° around the pole. At the equator the meridians are parallel and the convergency is zero. Between these two limits the convergency has some value between zero and one. On a sphere it is equal to the sine of the latitude. For practical navigation this relationship can be used on the spheroidal earth. On a simple conic or Lambert conformal chart a constant convergency is used over the entire chart, and is known as the **constant of the cone.** On a simple conic projection it is equal to the sine of the standard parallel. On a Lambert conformal projection it is equal (approximately) to the sine of the latitude midway between the two standard parallels. When convergency is printed on the chart, it is generally adjusted for ellipticity of the earth. If K is the constant of the cone,

$$K=\sin\tfrac{1}{2}\,(\mathrm{L}_1+\mathrm{L}_2),$$

where L_1 and L_2 are the latitudes of the two standard parallels. On such a chart, grid navigation is conducted as explained above, except that in each of the formulas the longitude is multiplied by K:

$$G = T + K\,\lambda W,$$
$$T = G - K\,\lambda W,$$
$$G = T - K\,\lambda E,$$
$$T = G + K\,\lambda E.$$

Thus, a straight line on such a chart changes its true direction, not by 1° for each degree of longitude, but by $K°$. As in higher latitudes, convergency and variation can be combined.

In using grid navigation one should keep clearly in mind the fact that the grid lines are parallel *on the chart.* Only on the transverse Mercator and polar gnomonic projections do the grid lines have geographical significance. On these projections, the grid lines are great circles which meet at "poles" on the equator, 90° from the meridian used as the fictitious equator. Since distortion varies on charts of different projections, and on charts of conic projections having different standard parallels, *the grid direction*

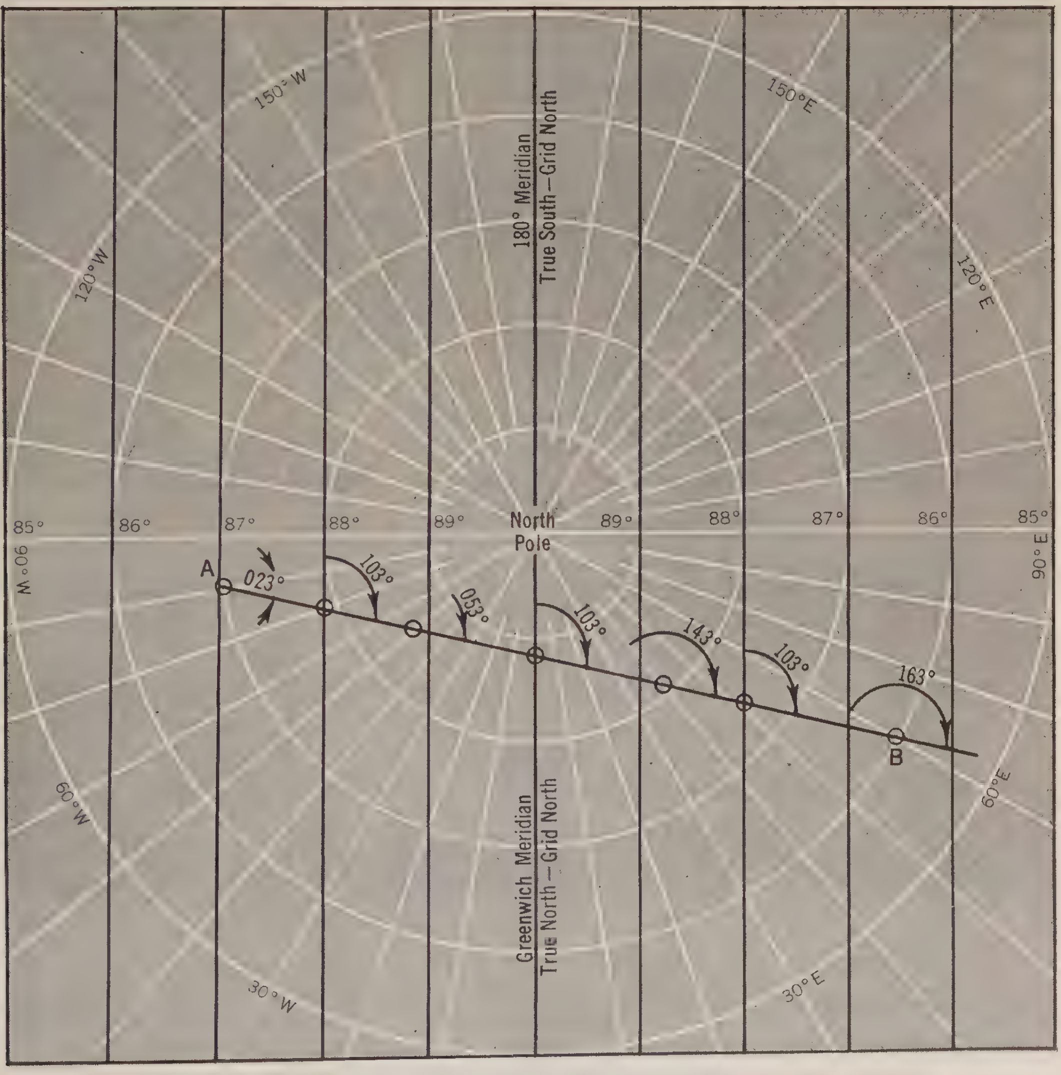

FIGURE 2510.—Polar grid navigation.

between any two given points is not the same on all charts. For operations which are to be coordinated by means of grid directions, *it is important that all charts showing the grid be on a single graticule.*

Except for nuclear powered submarines, ships seldom reach such high latitudes that grid navigation with full convergency of one is used. In the sub-polar regions in which most high-latitude surface ship navigation is conducted, a grid on a suitable projection should be available.

2511. Plotting on polar charts, as on other charts, involves the measurement of distance and direction. On a Mercator chart this is done as in lower latitudes. However, as latitude increases, expansion of the latitude scale increases at a more rapid rate. For accurate results, it is essential that distances be measured in relatively short steps and that an accurate mid latitude be used for each step, as shown in figure 2511a. As latitude increases, the departure of a rhumb line from a great circle becomes greater, and rhumb lines lose some of their value. If they are used to approximate a great circle,

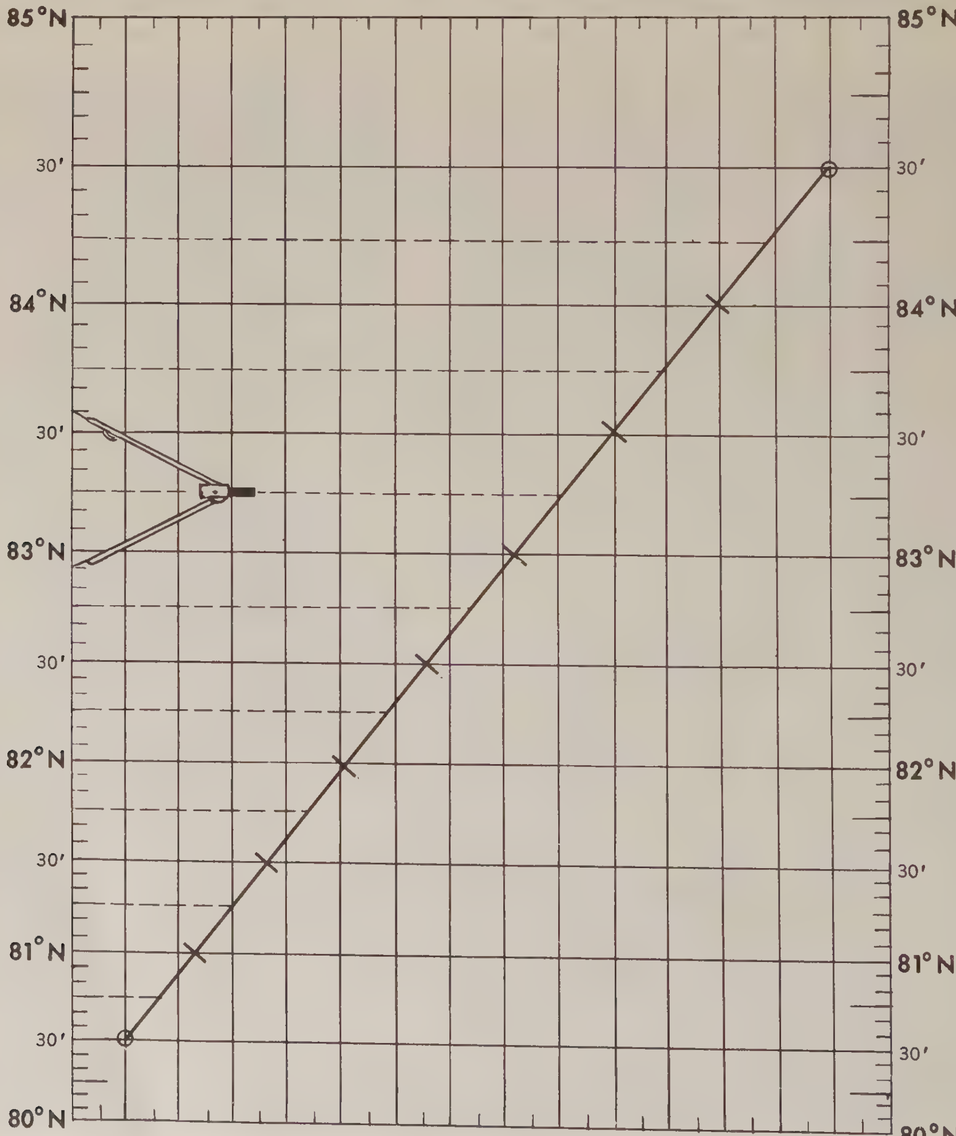

FIGURE 2511a.—Measuring distance on a high-latitude Mercator chart.

as in great-circle sailing, shorter legs are needed to retain a good approximation. Even visual bearing lines cannot accurately be represented by rhumb lines if the distance is great, unless a Mercator correction (tab. 1) is applied as in the case of radio bearings. Such reasons indicate using more suitable projections in high latitudes.

On a chart with converging meridians, as one on the Lambert conformal projection, distance is measured by means of the latitude scale, as on a Mercator chart, but this scale is so nearly constant that any part of it can be used without introducing a significant error. A mile scale is sometimes shown in or near the margin of such a chart, and can be used anywhere on that chart.

Since the meridians converge, a straight line makes a different angle with each meridian, as shown in figure 2510. For this reason, compass roses are not customarily shown on such a chart. If they do appear, *each one applies only to the meridian on which it is located.* The navigator accustomed to using a Mercator chart can easily forget this point, and hence will do well to ignore compass roses. If a drafting machine is used, it should be aligned with the correct meridian each time a measurement is made. Since this precaution can easily be overlooked, especially by a navigator accustomed to resetting his drafting machine only when the chart is moved, and since the resulting error may be too small to be apparent but too large to ignore, it is good practice to discard this instrument when the Mercator chart is replaced by one with converging meridians, unless positive steps are taken to prevent error.

The most nearly fool-proof and generally the most satisfactory method of measuring directions on a chart with converging meridians is to use a protractor, or some kind of plotter combining the features of a protractor and straightedge. One of the most popular is the type B–2 aircraft plotter (fig. 2511b) available to U. S. naval activities from the Aviation Supply Office at Philadelphia, or the AN plotter (or commercial counterpart) shown in figure 2511c.

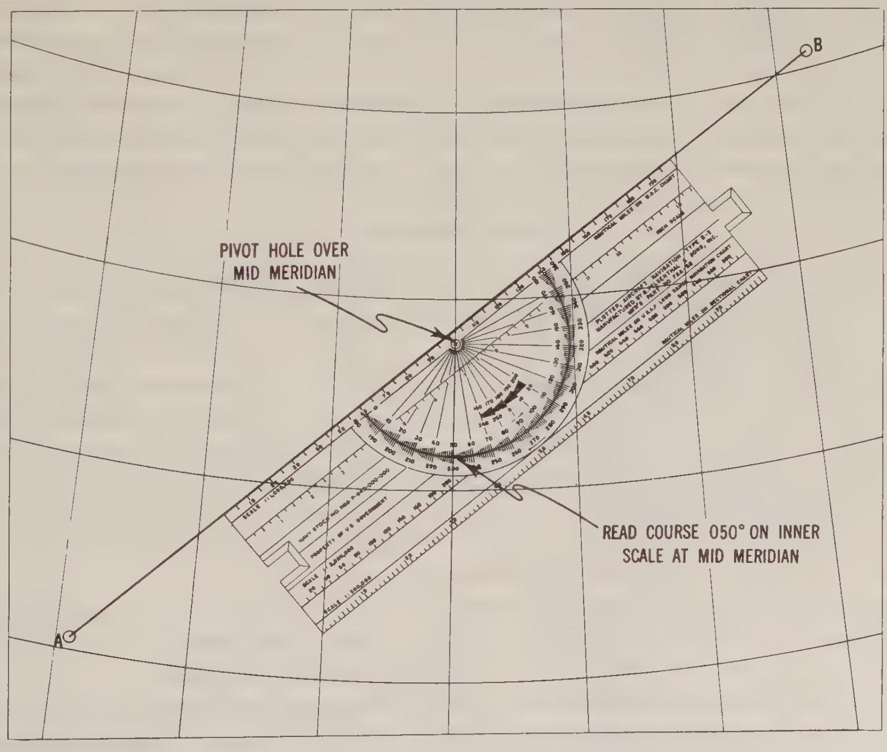

FIGURE 2511b.—Measuring a course on a Lambert conformal chart, by B–2 aircraft plotter. Note that measurement is made at the mid meridian.

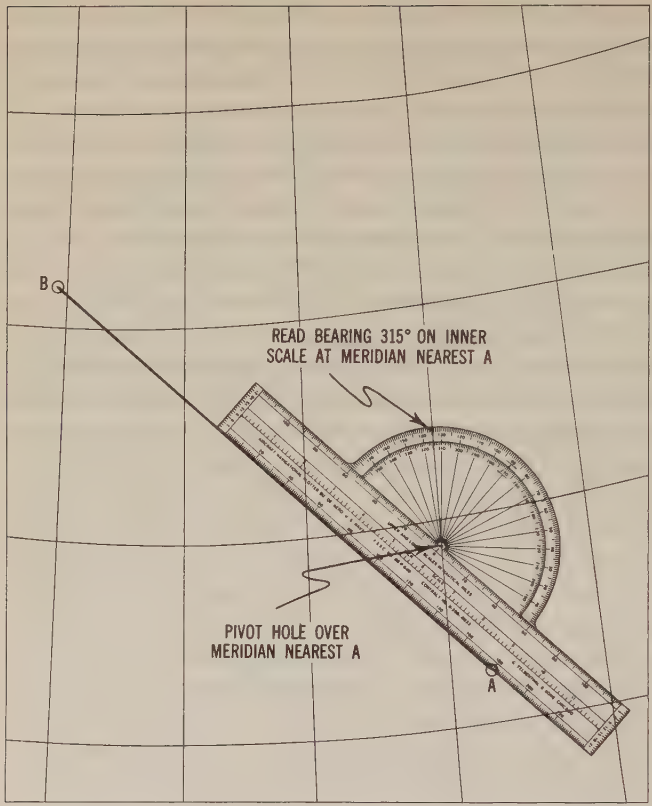

FIGURE 2511c.—Measuring a bearing on a Lambert conformal chart, by AN plotter. Note that measurement is made at the meridian nearest the ship.

If a course is to be measured, the mid meridian of each leg should be used, as shown in figure 2511b. If a bearing is to be measured, the meridian nearest the point at which the bearing was determined should be used, as shown in figure 2511c. Thus, in the usual case of determining the bearing of a landmark from a ship, the meridian nearest the ship should be used. In using either of the plotters shown in figures 2511b or 2511c, note that the center hole is placed over the meridian used, the straightedge part is placed along the line to be drawn or measured, and the angle is read on the protractor at the same meridian which passes under the center hole. It is sometimes more convenient to invert the plotter, so that the protractor part extends on the opposite side of the straightedge.

For plotting grid directions, angles are measured from grid north, using *any* grid meridian. Any convenient method can be used. If a protractor or plotter is being used for plotting grid directions, it is usually desirable to use the same instrument for plotting true directions. The distance is the same whether grid or true directions are used.

Dead Reckoning

2512. Polar dead reckoning.—In polar regions, as elsewhere, dead reckoning involves measurement of direction and distance traveled, and the use of this information for determination of position.

Direction is normally determined by a compass, but in polar regions both magnetic and gyro compasses are subject to certain limitations not encountered elsewhere. However, the navigator who thoroughly understands the use of these instruments in high latitudes can get much useful information from them. It is wise to carry, in addition, some form of *celestial compass*, discussed in article 2515. The polar navigator should not overlook the value of radar tracking or visual tracking for determining direction of motion. This is discussed in article 2516.

Speed or distance is normally measured by log or engine revolution counter, but these methods are not entirely suitable when the ship is operating in ice. The problem of determining speed or distance in ice is discussed in article 2516.

2513. The magnetic compass depends for its directive force upon the horizontal intensity of the magnetic field of the earth. As the magnetic poles are approached, this force becomes progressively weaker until at some point the magnetic compass

becomes useless as a direction-measuring device. In a marginal area it is good practice to keep the magnetic compass under almost constant scrutiny, as it is somewhat erratic in dependability and its errors may change rapidly. Frequent compass checks by celestial observation or any other method available are wise precautions. A log of compass comparisons and observations is useful in predicting future reliability.

The magnetic poles themselves are somewhat elusive, since they participate in the normal diurnal, annual, and secular changes in the earth's field, as well as the more erratic changes caused by magnetic storms. Measurements indicate that the north magnetic pole moves within an elongated area of perhaps 100 miles in a generally north-south direction and somewhat less in an east-west direction. Normally, it is at the southern end of its area of movement at local noon and at the northern extremity twelve hours later, but during a severe magnetic storm this motion is upset and becomes highly erratic. Because of the motions of the poles, they are sometimes regarded as *areas* rather than points. There is some evidence to support the belief that several secondary poles exist, although such alleged poles may be anomalies (local attractions), possibly of intermittent or temporary existence. Various severe anomalies have been located in polar areas and others may exist.

The continual motion of the poles may account, at least in part, for the large diurnal changes in variation encountered in high latitudes. Changes as large as 10° have been reported.

Measurements of the earth's magnetic field in polar regions are neither numerous nor frequent. The isogonic lines in these areas are close together, resulting in rapid change in short distances in some directions, and their locations are imperfectly known. As a result, charted variation in polar regions is not of the same order of accuracy as elsewhere.

The decrease in horizontal intensity encountered near the magnetic poles, as well as magnetic storms, affects the deviation. Any deviating magnetic influence remaining after adjustment, which is seldom perfect, exerts a greater influence as the directive force decreases. It is not uncommon for residual deviation determined in moderate latitudes to increase 10- or 20-fold in marginal areas. Interactions between correctors and compass magnets exert a deviating influence that may increase to a troublesome degree in high latitudes. The heeling magnet, correcting for both permanent and induced magnetism, is accurately located only for one magnetic latitude. Near the magnetic pole its position might be changed, but this may induce sufficient magnetism in the Flinders bar to more than offset the change in deviation due to the change in the position of the heeling magnet. The relatively strong vertical intensity may render the Flinders bar a stronger influence than the horizontal field of the earth. When this occurs, the compass reading remains nearly the same on any heading.

Another effect of the decrease in the directive force of the compass is a greater influence of frictional errors. This, combined with an increase in the period of the compass, results in greatly increased sluggishness in its return to the correct reading after being disturbed. For this reason the compass performs better in a smooth sea free from ice than in an ice-infested area where its equilibrium is frequently upset by impact of the vessel against ice.

Magnetic storms affect the magnetism of a ship as well as that of the earth. Changes in deviation of as much as 45° have been reported during severe magnetic storms, although it is possible that such large changes may be a combination of deviation and variation changes.

The area in which the magnetic compass is of reduced value cannot be stated in specific terms. In general, a remote-reading Flux Gate compass performs as well or better than a regular compass. A magnetic compass in an exposed position performs

better than one in a steel pilot house. The performance of the compass varies considerably with the type of compass, sensitiveness and period, thoroughness of adjustment, location on the vessel, and magnetic properties of the vessel. It also varies with local conditions.

In a very general sense the magnetic compass can be considered of reduced reliability when the horizontal intensity is less than 0.09 oersted, erratic when the field is less than 0.06 oersted, and useless when it is less than 0.03 oersted. The extent of these areas in the northern hemisphere is indicated in figure 2513. Similar areas extend

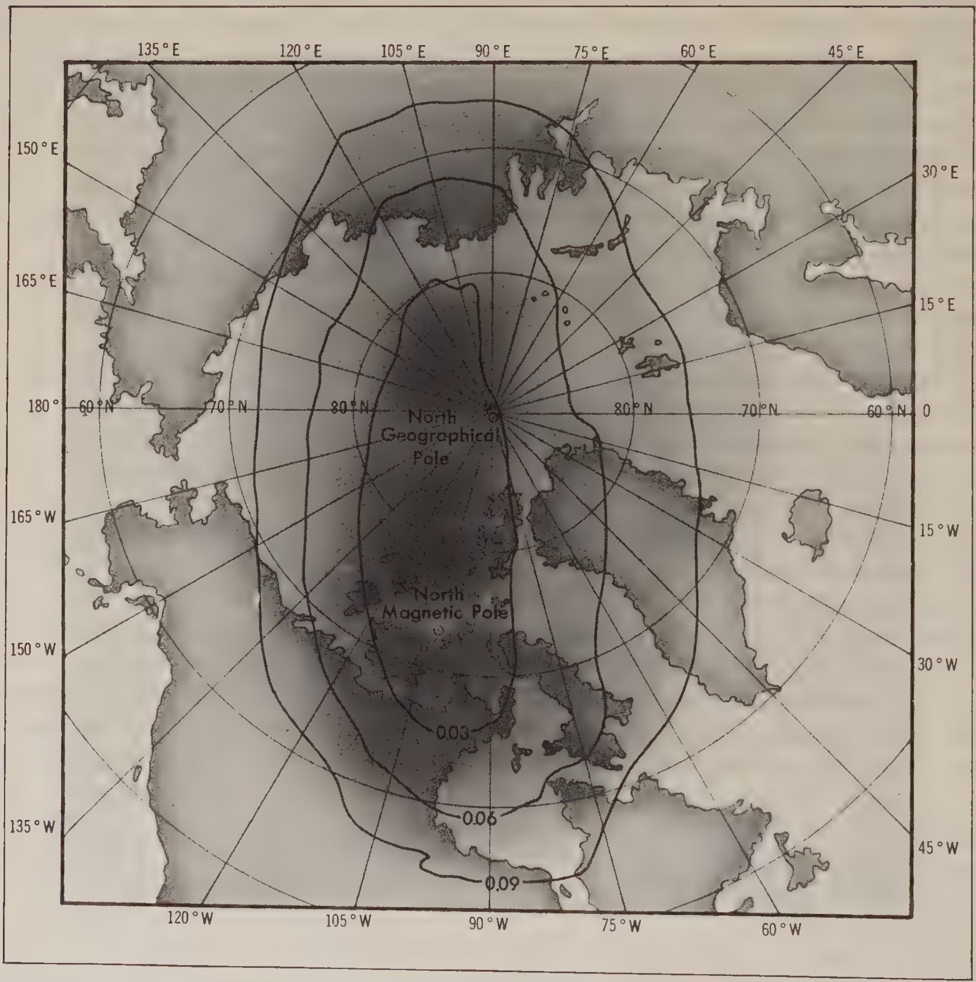

Figure 2513.—Arctic areas in which the magnetic compass is of reduced value. Inside the curves representing the 0.09, 0.06, and 0.03 oersted values of horizontal intensity the compass can be considered of reduced reliability, erratic, and useless, respectively.

around the south magnetic pole, which is located at latitude 68° S, longitude 144° E, not far from the eastern shore of the Ross Sea. Hydrographic Office charts 1701 N and 1701 S show lines of equal horizontal intensity in the north and south polar regions, respectively. However, the effectiveness of the magnetic compass is influenced also by local conditions. A compass on a vessel making a voyage through the islands of the Canadian archipelago has been reported to give fair indication of direction in certain small areas where the horizontal intensity is less than 0.02 oersted, yet to be useless at some places where the horizontal intensity is greater than 0.04 oersted.

Despite its various limitations, the magnetic compass is a valuable instrument in much of the polar regions, where the gyro compass is also of reduced reliability. With careful adjustment, frequent checks, and a record of previous behavior, the polar navigator can get much useful service from his instrument.

When a compass is subjected to extremely low temperatures, there is danger of the liquid freezing. Sufficient heat to prevent this can normally be obtained from the compass light, which should not be turned off during severe weather.

2514. The gyro compass depends for its operation upon the rotation of the earth about its axis. Its maximum directive force is at the equator, where the axis of the compass is parallel to the axis of the earth. As the latitude increases, the angle between these two axes increases. At the *geographical* poles the gyro compass has no directive force.

The gyro compass is generally reliable to latitude 70°. At higher latitudes the disturbing effect of imperfections in compass or adjustment is magnified. Latitude adjustment becomes critical. Speed error increases as the speed of the vessel approaches the rotational speed of the earth. Ballistic deflection error becomes large and the compass is slow to respond to correcting forces. Frequent changes of course and speed, often necessary when proceeding through ice, introduce errors which are slow to settle out. The impact of the vessel against ice deflects the gyro compass. which does not return quickly to the correct reading.

The error increases and becomes more erratic as the vessel proceeds to higher latitudes. Extreme errors as large as 27° have been reported at latitudes greater than 82°. The gyro compass probably becomes useless at about latitude 85°. At latitude 70° the gyro error should be determined frequently, perhaps every four hours, by means of celestial bodies when these are available. As the error increases and becomes more erratic, with higher latitude, it should be determined more frequently. In heavy ice at extreme latitudes an almost constant check is desirable. The gyro and magnetic compasses should be compared frequently and a log kept of the results of these comparisons and the gyro error determinations.

Most gyro compasses are not provided with a latitude correction setting above 70°. Beyond this, correction can be made by either of two methods: (1) set the latitude and speed correctors to zero and apply a correction from a table or diagram obtainable from the manufacturer of the compass, or constructed as explained in article 640; or (2) use an equivalent latitude and speed setting. Both of these methods have proved generally satisfactory, although the second is considered superior to the first because it at least partly corrects for errors introduced by a change in course. At least one gyro compass has been made with provision for setting the latitude corrector to 80°. As experience in high latitudes accumulates, improved gyro compass performance will undoubtedly become available. In certain later types of gyro compasses, facilities for their operation as directional gyros even to the poles is provided.

2515. Celestial compasses.—In some areas neither the magnetic nor gyro compass provides adequate directional reference. In all areas of reduced compass reliability frequent celestial checks are desirable. Several instruments are available for making the celestial observations needed for determining heading in this manner.

A pelorus, alidade, or azimuth circle can be used for measuring the relative or compass azimuth of a celestial body. Compass azimuth can then be compared with a computed true azimuth to determine compass error. However, this can become tedious and time-consuming when frequent heading checks are needed. Several instruments provide a quick mechanical solution.

A **sun compass** indicates direction by means of a shadow cast by a shadow pin exposed to sunlight. The course on a horizontal, graduated azimuth dial is set opposite a lubber's line aligned with the fore-and-aft axis of the vessel. By means of another dial adjusted by a latitude scale so as to be parallel to the plane of the equator, the shadow pin, perpendicular to the plane of this dial and hence parallel to the polar axis of the earth, is set to the local apparent time. When the vessel is on course, the shadow of the pin falls across the center of the local apparent time dial. In some models the local apparent time is maintained by clockwork; in others it is set frequently

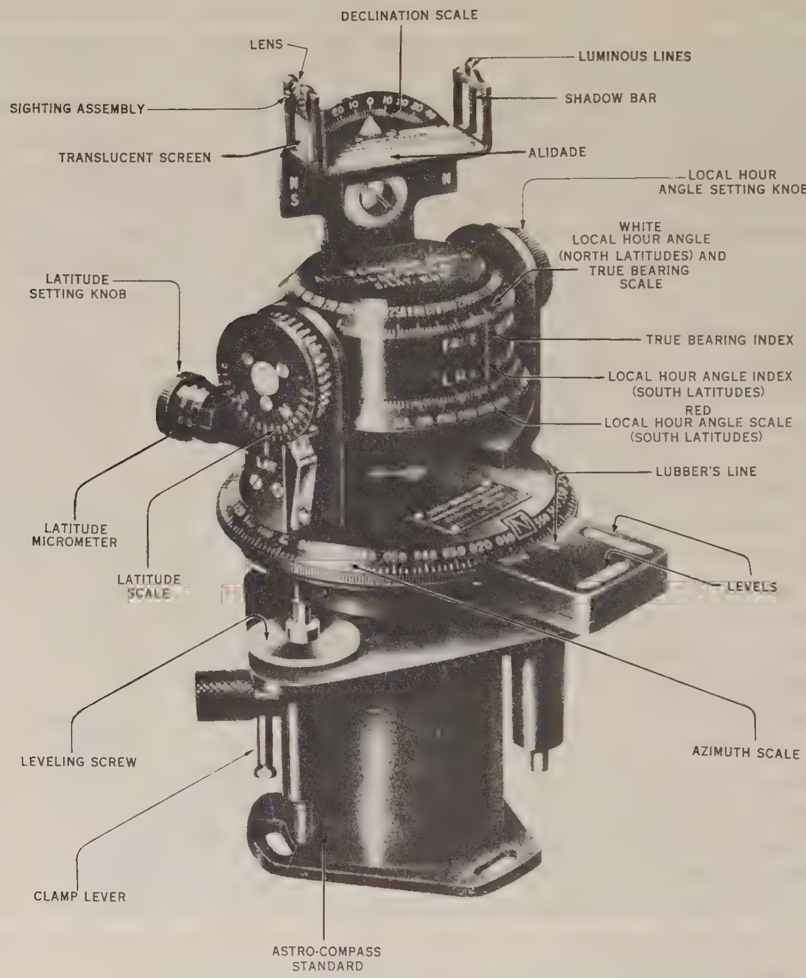

FIGURE 2515.—An astro compass.

by hand. The latitude and local apparent time (which varies with longitude) settings are adjusted from time to time to agree with the changing position of the vessel. The instrument is usable only when the sun is visible and when a knowledge of the position is available.

An **astro compass** is similar in principle to a sun compass, but is usable with any celestial body. When the device is set to the latitude of the observer and the local hour angle and declination of the body, and rotated until the sighting assembly points toward the body, the true heading is indicated at the lubber's line. This device is illustrated in figure 2515.

A **sky compass** indicates direction by means of the polarizing effect of the earth's atmosphere on sunlight. Unpolarized sunlight, upon entering the earth's atmosphere, is scattered and becomes *plane polarized*, its vibrations being in a plane perpendicular to the line from the sun to the observer. When the sun is on the horizon, this plane is vertical. By means of a suitable *analyzer* of Polaroid material and Cellophane, the sky compass detects this plane and the vertical plane which is perpendicular to it, or in the direction of the sun. A possible 90° or 180° ambiguity exists, but this is not of practical significance because the relative brightness of the sky indicates which of the four possible directions is toward the sun. The instrument is set to local apparent time, and a clock maintains this time. The analyzer is then rotated until dark and light portions are of equal brightness, and the heading is indicated at the lubber's line. Unlike the sun and astro compasses, the sky compass is maintained with its face in a level position, pointing at the zenith, which must be clear and unobstructed for an accurate reading. *The sun itself need not be visible*, and can even be several degrees *below* the horizon. Therefore, the compass can be used during twilight, when no other celestial bodies may be visible. For this reason it is sometimes called a **twilight compass.** It is most accurate when the zenith distance of the sun is 90°, and is seldom used when the sun is more than a few degrees from the horizon. Its usefulness arises principally from the fact that twilight periods in high latitudes are of several hours duration, during which time no celestial body is visible unless the moon or a bright planet is above the horizon.

Any celestial compass must be aligned with the fore-and-aft axis of the craft, and is limited in its usefulness to periods when the celestial body being observed (the zenith in the case of the sky compass) is visible. For accurate results certain parts must be kept level. Despite their limitations, these are useful instruments in high latitudes and a ship operating in these areas should be provided with one or more of them.

2516. Distance and direction in ice.—In ice-free waters, distance or speed is determined by some form of log or by engine revolution counter. In the presence of ice, however, most logs are inoperative or inaccurate due to clogging by the ice. Engine revolution counters are not accurate speed indicating devices when a ship is forcing its way through ice. With experience, one can estimate the speed in relation to ice, or a correction can be applied to speed by engine revolution counter. At best, however, these methods are seldom of the desired accuracy.

If ranges and bearings of a land feature can be determined either visually or by radar, course and speed of the vessel or distance traveled over the ground can be determined by tracking the landmark and plotting the results. The feature used need not be identified. Ice can be used if it is grounded or attached to the shore. Course and speed or distance through the water can be determined by tracking a floating iceberg or other prominent floating ice feature. However, an error may be introduced by this method if the effect of wind and current upon the floating feature is different than upon the ship.

Example 1.—The radar operator of a ship proceeding through ice measures the following bearings and ranges of a grounded iceberg:

Time	*Bearing*	*Range*
0835	028°	8,100 yds.
0840	037°	7,600 yds.
0845	047°	7,300 yds.
0850	057°	7,000 yds.
0855	066°	7,200 yds.

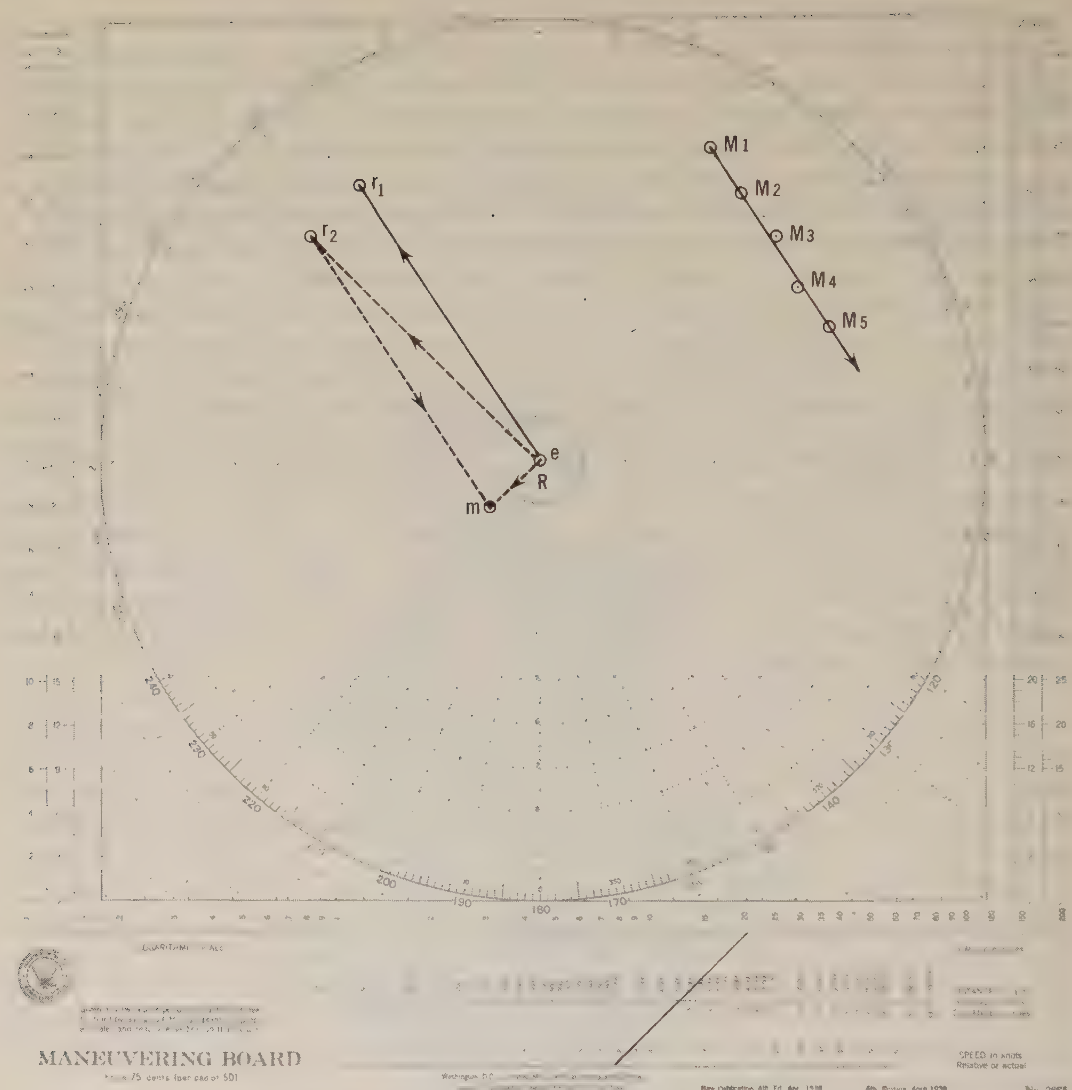

FIGURE 2516.—Determining course and speed by tracking an iceberg.

Required.—The course and speed of the ship.

Solution (fig. 2516).—The solution is conveniently made on a maneuvering board, H.O. 2665–10, but this form is not essential.

(1) From R, representing the ship, plot points M_1, M_2, M_3, M_4, and M_5 representing successive positions of the iceberg *relative to the ship*.

(2) Fair a straight line through the points thus determined.

(3) Measure the direction of line M_1M_5, 147°. This is the direction of the iceberg relative to the ship. The direction of the ship's motion relative to the iceberg is opposite, or 327°. Since the iceberg is stationary, this is the course of the ship.

(4) Measure the length of line M_1M_5, 5,000 yards or 2.5 miles. This is the distance of relative motion, and since the iceberg is stationary, the distance traveled by the ship, in 20 minutes. The distance traveled in 60 minutes, or the speed, is $3\times2.5=$ 7.5 knots. This solution is shown by nomogram at the bottom of the maneuvering board. Vector er_1 represents the course and speed of the ship.

Answers.—C 327°, S 7.5 kn.

Example 2.—Solve example 1 assuming the iceberg is estimated to be moving southwest at a speed of 1.5 knots.

Solution (fig. 2516).—(1) Plot R, M_1, M_2, M_3, M_4, and M_5 and fair a straight line as in example 1.

(2) From e, plot em, the course and speed vector of the iceberg, locating point m.

(3) Determine the direction and speed of the ship relative to the iceberg as in steps (3) and (4) of example 1. Lay this off from m, locating point r_2. The vector r_2m is the relative movement of the iceberg with respect to the ship.

(4) Draw er_2, the course and speed vector of the ship.

Answers.—C 315°, S 7.3 kn.

If speed only is required, the method can be simplified. Elapsed time of tracking and the relative distance covered can be determined by plot, as indicated above, or possibly from the radar scope directly. Speed may then be determined by nomogram or by the formula $S=\frac{60D}{T}$ in which S is the speed in knots, D the distance in miles, and T the time in minutes. If distance is given in yards, the formula is $S=\frac{3D}{100T}$, and if in feet, $S=\frac{D}{100T}$. If a standard distance or time is used, the formula can be further simplified because D or T becomes a constant. For instance, if a distance of five miles or 10,000 yards is used, $S=\frac{300}{T}$, or if a time interval of ten minutes is used, $S=6D$ if D is in miles $\left(\frac{3D}{1000}\text{ if D is in yards, or }\frac{D}{1000}\text{ if D is in feet}\right)$.

This is the basis of the **Dutchman's log,** which can be used without tracking. A ship traveling at one knot covers one mile or about 6076.1 feet in 60 minutes, or approximately 100 feet per minute. A length of 100 feet, or some fraction or multiple of this, can be measured off in a fore-and-aft direction along the ship, and the ends of the measured length marked. For maximum accuracy the longest possible line should be used. A man is then stationed at each mark to note the time of passing some object dead in the water, such as a prominent ice feature or an opening in pack ice. The elapsed time between marks is measured and the speed calculated, using $S=\frac{D}{100T}$ if D is measured in feet and T in minutes. In this application, T may be more conveniently measured in seconds, when $S=\frac{60D}{100T}=\frac{3D}{5T}$. For D=100 feet, $S=\frac{60}{T}$, or speed is found by dividing the number of seconds into 60. Thus, if T=15 seconds, the speed is $\frac{60}{15}=4$ knots. If D=200 feet, $S=\frac{60\times200}{100T}=\frac{120}{T}$; if D=50 feet, $S=\frac{30}{T}$, etc.

Speed over the ground can be determined by two fixes. However, fixes relative to land are not suitable for this purpose unless the land is accurately located on the chart, or the same land features are used for both fixes. High-latitude electronic and celestial fixes, too, are sometimes of less than usual accuracy (arts. 2526–2535).

2517. Tide, current, and wind.—Relatively little is known of tides and currents in the polar regions. The tables do not extend to these areas, but some information is given in the sailing directions. In general, tidal ranges are small, and the water in most anchorages is relatively deep.

Currents in many coastal areas are strong and somewhat variable. When a vessel is operating in ice, the current is often difficult to determine because of frequent changes

in course and speed of the vessel and inaccuracies in the measurement of direction and distance traveled.

In the vicinity of land, and in the whole antarctic area, winds are variable in direction, gusty, and often strong. Offshore, in the Arctic Ocean, the winds are not strong and are steadier, but ships rarely operate in this area. The wind in polar regions, as elsewhere, has two primary navigational effects upon vessels. First, its direct effect is to produce leeway. When a vessel is operating in ice, the leeway may be different from that in open water. It is well to determine this effect for one's own vessel. The second effect is to produce wind currents in the sea.

2518. Keeping the dead reckoning.—Because of the lack of facilities for fixing the position of a vessel in polar regions, accurate dead reckoning is even more important than elsewhere. The problem is complicated by the fact that the *elements* of dead reckoning, direction and distance, are usually known with less certainty than in lower latitudes. This only heightens the need for *keeping* the dead reckoning with all the accuracy obtainable. This may usually be accomplished by careful hand plotting on the available charts or plotting sheets.

Mechanical dead reckoning equipment is generally less accurate than a carefully-kept hand plot. Older models of such equipment cannot be set to a higher latitude than 70°. Newer equipment has provision for setting to latitude 80°. Dead reckoning equipment has been used beyond its maximum range by setting to a lower latitude and applying a correction, but this procedure is of questionable advisability because of the error introduced by a gyro compass also operating beyond its range. This equipment is intended for use with the Mercator projection. When a different projection is used, better results are generally obtainable by setting the equipment to latitude 0°, and letting its latitude indications represent change in latitude, and its difference of longitude indications represent miles in an east-west direction.

Piloting

2519. Piloting in high latitudes is basically no different from that elsewhere. However, in polar regions piloting is the primary method of marine navigation. As previously indicated, dead reckoning is difficult and generally less accurate than in lower latitudes. Celestial navigation has limited application. Electronic navigational aids are almost nonexistent.

Piloting is associated with proximity to land and shoal water. A ship in polar regions is seldom far from land, and the areas are not so accurately surveyed that the navigator can be sure that uncharted shoals are not nearby.

Piloting is characterized by an alertness not required when a vessel is far from danger of grounding. Nowhere is this alertness more necessary than in polar regions. Added to the usual reasons for constant vigilance are the uncertainties of charted information and the lack of detail, as discussed in article 2509.

2520. Aids to navigation are virtually nonexistent in polar regions. There are no lighthouses, few beacons, and very few buoys. Channels and shoals are not marked and may not even be indicated on the chart. A few radiobeacons are available, notably along the northern coast of Russia. Other radio transmitters are occasionally available for use as beacons.

2521. Natural landmarks are plentiful in some areas, but their usefulness is restricted by the difficulty in identifying them, or locating them on the chart. Along many of the coasts the various points and inlets bear a marked resemblance to each other. The appearance of a coast is often very different when many of its features are obliterated by a heavy covering of snow or ice than when it is ice-free.

2522. Bearings are useful, but have limitations. When bearings on more than two objects are taken, they may fail to intersect at a point because the objects may not be charted in their correct relation to each other. Even a point fix may be considerably in error geographically if all of the objects used are shown in correct relation to each other, but in the wrong position on the earth. However, in restricted waters it is usually more important to know the position of the vessel relative to nearby land and shoals than its latitude and longitude. The bearing and distance of even an unidentified or uncharted point are valuable.

When a position is established relative to nearby landmarks, it is good practice to use this to help establish the identity and location of some prominent feature a considerable distance ahead, so that this feature, in turn, can be used to establish future positions.

In high latitudes it is not unusual to make use of bearings on objects a considerable distance from the vessel. Because of the rapid convergence of the meridians in these areas, such bearings are not correctly represented by straight lines on a Mercator chart. If this projection is used, the bearings should be corrected in the same manner that radio bearings are corrected (using table 1), since both can be considered great circles. Neither visual nor radio bearings are corrected when plotted on a Lambert conformal chart.

2523. Soundings are so important in polar regions that echo sounders are customarily operated continuously while the vessel is under way. It is good practice to have at least two such instruments, preferably those of the recording type and having a wide flexibility in the range of the recorder. In few parts of the polar regions have enough soundings been obtained and made available to charting agencies to permit adequate portrayal of the bottom configuration. However, since depth of water is a primary consideration in avoiding an unwanted grounding, a constant watch should be maintained to avoid unobserved shoaling.

Polar regions have relatively few shoals, but in some areas, notably along the Labrador coast, a number of pinnacles and ledges rise abruptly from the bottom. These constitute a real danger to vessels, since they are generally not surrounded by any apparent shoaling. In such an area, or when entering an unknown harbor or any area of questionable safety, it is good practice to send one or more small craft ahead with portable sounding gear.

In very deep water, of the order of 1,000 fathoms or more, the echo returned from the bottom is sometimes masked by the sound of ice coming in contact with the hull, but this is generally not a problem when the bottom is close enough to be menacing.

The hand lead is of little value to a ship underway in ice, because the ice generally prevents its effective use unless the vessel is stopped.

If a ship becomes **beset** by ice, so that steerage way is lost and the vessel drifts with the ice, it may be in danger of grounding as the ice moves over a shoal. Hence, it is important that soundings be continued even when beset. If necessary, a hole should be made in the ice and a hand lead used. A vessel with limited means for freeing itself may prudently save such means for use only when there is danger of grounding.

Useful information on the depth of water in the vicinity of a ship can sometimes be obtained by watching the ice. A stream of ice moving faster than surrounding ice, or a stretch of open water in loose pack ice often marks the main channel through shoal water. A patch of stationary ice in the midst of moving ice often marks a shoal.

Knowledge of earth formations may also prove helpful. The slope of land is often an indication of the underwater gradient. Shoal water is often found off low islands, spits, etc., but seldom near a steep shore. Where glaciation has occurred, the moraine

deposits are likely to have formed a bar some distance offshore. Submerged rocks and pinnacles are more likely to be encountered off a rugged shore than near a low, sandy beach.

2524. Anchorages.—Because good anchorages are not plentiful in high latitudes, there is an understandable temptation to be less demanding in their selection. This is dangerous practice, for in polar regions some of the requirements are accentuated. The factors to be considered are:

1. *Holding quality of the bottom.* In polar regions a rocky bottom or one with only fair to poor holding qualities is not uncommon. Sometimes the bottom is steep or irregular. Since the nature of the bottom is seldom adequately shown on charts, a wise precaution is to sample the bottom, and sound in the vicinity before anchoring.

2. *Adequacy of room for swing.* Because high winds are frequent along polar shores, sometimes with little or no warning, long scopes of anchor chain are customarily used. Some harbors are otherwise suitable, but allow inadequate room for swing of the vessel at anchor, or even for its yaw in a high wind. If a vessel is to anchor in an unsurveyed area, the area should first be adequately covered by small boats with portable sounding gear to detect any obstructions.

3. *Protection from wind and sea.* In polar regions protection from wind is probably the most difficult requirement to meet. Generally, high land is accompanied by strong wind blowing directly down the side of the mountains. Polar winds are extremely variable, both in direction and speed. Shifts of 180° accompanied by an increase in speed of more than 50 knots in a few minutes have been reported. It is important that ground tackle be in good condition and that maximum-weight anchors be used. All available weather reports should be obtained and a continuous watch kept on the local weather. Whenever a heavy blow might reasonably be anticipated, the main engines should be kept in an operating condition and on a standby status. Heavy seas are seldom a problem.

4. *Availability of suitable exit in event of extreme weather.* In ice areas it is important that a continuous watch be kept to prevent blocking of the entrance by ice, or actual damage to the vessel by floating ice. However, in an unsurveyed area it may be dangerous to shift anchorage without first sounding the area. It is a wise precaution to do this in advance. Unless the vessel is immediately endangered by ice, it is generally safer to remain at anchor with optimum ground tackle and use of engines to assist in preventing dragging, than to proceed to sea in a high wind, especially in the presence of icebergs and growlers, and particularly during darkness.

5. *Availability of objects for position determination.* The familiar polar problem of establishing a position by inaccurately charted or inadequately surveyed landmarks is accentuated when an accurate position is desired to establish the position of an anchor. Sometimes a trial and error method is needed, and it may be necessary to add landmarks located by radar or visual observation. Because of chart inadequacy, the suitability of an anchorage, from the standpoint of availability of suitable landmarks, cannot always be adequately predicted before arrival.

An unsurveyed harbor should be entered with caution at slow speed, with both the pilot house and engine room force alerted to possible radical changes in speed or course with little or no warning. The anchor should be kept ready for letting go on short notice and should be adequately attended. An engine combination providing full backing power should be maintained.

2525. Sailing directions for high latitudes contain a wealth of valuable information acquired by those who have previously visited the areas. However, since high latitudes have not been visited with the frequency of other areas, and since they are inadequately surveyed, the sailing directions for polar areas are neither as complete

nor as accurate as for other areas, and information on unvisited areas is completely lacking. Until traffic in high latitudes increases and the sailing directions for these areas incorporate the additional information obtained, unusual caution should accompany their use. Each vessel that enters polar regions can help correct this condition by recording accurate information and sending it to the U. S. Navy Hydrographic Office or its counterpart in other countries.

Electronic Navigation

2526. Propagation.—In general, radio wave propagation in high latitudes follows the same principles that apply elsewhere, as described in chapter X. However, certain anomalous conditions occur, and although these are but imperfectly understood, and experience to date has not always seemed consistent, there is much that has been established. An understanding of these conditions is important if maximum effective use is to be made of electronics in high latitudes.

FIGURE 2526.—The auroral zone of the northern hemisphere.

Because of the influence of the ionosphere (art. 1008) upon radio wave propagation, the most disruptive effects are associated with **ionospheric disturbances,** one aspect of the familiar **magnetic storms.** These have been found to be related to sunspot activity, and this association provides a basis for their prediction. Warnings based upon such predictions are broadcast by radio station WWV, National Bureau of Standards, Washington, D. C., and by major U. S. Navy radio stations. Such warnings, usually broadcast several hours before the start of a disturbance, are confined to the expected occurrence. Predictions of intensity or duration have not been possible.

Severe ionospheric disturbances affect radio wave propagation throughout the world, but the most erratic and persistent effects occur in the **auroral zones.** The auroras (**aurora borealis** or "northern lights" in the northern hemisphere, and the **aurora australis** or "southern lights" in the southern hemisphere) are believed to be caused by emissions from the sun. When the emitted particles enter the earth's magnetic field, they tend to follow the earth's lines of force downward toward the geomagnetic poles (art. 706). When they encounter the ionosphere, they become luminous, constituting the aurora familiar to the night observer in high latitudes. The maximum auroral activity occurs in two belts, each about 600 miles wide and centered at about 1,200 miles from one of the geomagnetic poles, as shown in figure 2526. In the auroral zones, the aurora is a common occurrence, being visible on nearly any dark, clear night. Frequency of occurrence decreases with increased distance from the zones. During magnetic storms the auroral zones have a tendency to shift outward from the geomagnetic poles.

When an ionospheric disturbance occurs, fading and ionospheric absorption increase. The maximum usable frequency (art. 1008) decreases, and the minimum useful

high frequency increases. In extreme cases, the entire band of useful frequencies disappears, resulting in a radio **blackout** which may continue for any period from a few minutes to several days. In the auroral zones, higher frequencies used for communication have been known to be blacked out for as long as two weeks. The return to normal usually occurs first on lower frequencies.

During the early stages of an ionospheric disturbance, the *path* of propagation may deviate erratically from normal, resulting in erroneous direction finder bearings and consol readings.

Because of the shift of the auroral zones during a magnetic storm, radio propagation *within* the usual positions of the belts may improve. Transmission is usually of greater range *along* radial lines from the geomagnetic poles than *across* these lines.

Very low frequencies (10–30 kc) originating outside the auroral zone are not affected appreciably by ionospheric disturbances, and propagation between 30 and 200 kc may even improve. This is believed to be due to a great increase in the density of the lowest (D) layer of the ionosphere, which acts as a wave guide for lower frequencies, while absorbing higher frequency transmissions.

In polar regions, long-range, high frequency propagation is sometimes erratic even when conditions seem normal, and the usual procedure for selection of optimum working frequencies for communication is not always valid. The shielding effect of mountains seems to be greater than in lower latitudes.

2527. Radar.—In polar regions, where fog and long periods of continuous daylight or darkness reduce the effectiveness of both celestial navigation and visual piloting, and where other electronic aids are generally not available, radar is particularly valuable. Its value is further enhanced by the fact that polar seas are generally smooth, resulting in relatively little oscillation of the shipborne antenna. When ice is not present, relatively little sea return is encountered from the calm sea.

However, certain limitations attend the use of radar in polar regions. Similarity of detail along the polar shore is even more apparent by radar than by visual observation. Lack of accurate detail on charts adds to the difficulty of identification. Identification is even more of a problem when the shore line is beyond the radar horizon and accurate contours are not shown on the chart. When an extensive ice pack extends out from shore, accurate location of the shore line is extremely difficult.

Good training and extensive experience are needed to interpret accurately the returns in polar regions where ice may cover both land and sea. A number of icebergs close to a shore may be too close together to be resolved, giving an altered appearance to a shore line, or they may be mistaken for off-lying islands. The shadow of an iceberg or pressure ridge and the lack of return from an open lead in the ice may easily be confused. Smooth ice may look like open water. In making rendezvous, one might inadvertently close on an iceberg instead of a ship.

As with visual bearings, radar bearings need correction for convergency unless the objects observed are quite close to the ship.

2528. Loran is usable in polar regions, but the coverage is greatly restricted. As shown in the coverage diagram, figure 1302a, Loran-A groundwave coverage extends into the edge of the arctic in several places. The skywave coverage extends some distance beyond. Extensive areas in the arctic and all of the antarctic are without coverage.

2529. Other electronic aids are virtually nonexistent in polar regions.

The *radio direction finder* is useful when the few transmitting stations are within range. One of the principal uses of RDF in polar regions is to assist in locating other vessels, for rendezvous or other purposes. This is particularly true in an area of many icebergs, where radar may not distinguish between ships and icebergs.

Consol is available in the Norwegian Sea between Norway and Greenland.

The *echo sounder* is highly useful, as indicated in article 2523, and is operated continuously in high latitudes.

Sonar is useful primarily for detecting ice, particularly growlers. Since about ½ to ⅞ of the ice is under water, its presence can sometimes be detected by sonar when it is overlooked by radar or visual observation.

Celestial Navigation

2530. Celestial navigation in high latitudes.—Of the various types of navigation, celestial is perhaps least changed in polar regions. However, certain special considerations are applicable.

Because of the limitations of other forms of navigation, as discussed earlier in this chapter, celestial navigation provides the principal means of determining geographical position. However, as indicated in article 2522, position relative to nearby dangers is usually of more interest to the polar navigator than geographical position. Since ships in high latitudes are seldom far from land, and since celestial navigation is attended by several limitations, discussed in article 2531, its use in marine navigation is generally confined to the following applications:

1. Navigation while proceeding to and from polar regions.
2. Checking the accuracy of dead reckoning.
3. Checking the accuracy of charted positions of landmarks, shoals, etc.
4. Providing a directional reference, either by means of a celestial compass (art. 2515) or by providing a means of checking the magnetic or gyro compass.

Although its applications are limited, celestial navigation is important in high latitudes. Application 3 above, and application 4, even more so, can be of great value to the polar navigator.

2531. Celestial observations.—The best celestial fixes are usually obtained by star observations during twilight. As the latitude increases, these periods become longer, providing additional time for observation. But with this increase comes longer periods when the sun is just below the horizon and the stars have not yet appeared. During this period, which in the extreme condition at the pole lasts for several *days*, no celestial observations may be available. The moon is sometimes above the horizon during this period and bright planets, notably Venus and Jupiter, may be visible. With practice, the brighter stars can be observed when the sun is 2° to 3° below the horizon.

Beyond the polar circles the sun remains above the horizon without setting during part of the summer. The length of this period increases with latitude. At Thule, Greenland, about 10° inside the arctic circle, the sun remains above the horizon for four months. During this period of continuous daylight the sun circles the sky, changing azimuth about 15° each hour. A careful observation, or the average of several observations, each two hours provides a series of running fixes. An even better check on position is provided by making hourly observations and establishing the most probable position at each observation. Sometimes the moon is above the horizon, but within several days of the new or full phase it provides lines of position nearly parallel to the sun lines and hence of limited value in establishing fixes.

During the long polar night the sun is not available and the horizon is often indistinct. However, the long twilight, a bright aurora, and other sources of polar light (art. 2504) shorten this period. By adapting their eyes to darkness, some navigators can make reasonably accurate observations throughout the polar night. The full moon in winter remains above the horizon more than half the time and attains higher altitudes than at other seasons.

In addition to the long periods of darkness in high latitudes, other conditions are sometimes present to complicate the problem of locating the horizon. During daylight the horizon is frequently obscured by low fog, frost smoke, or blowing snow, yet the sun may be clearly visible. Hummocked sea ice is sometimes a problem, particularly at low heights of eye. Nearby land or an extensive ice foot can also be troublesome. Extreme conditions of abnormal refraction are not uncommon in high latitudes, sometimes producing false horizons and always affecting the refraction and dip corrections.

Because of these conditions, it is advisable to be provided with an artificial-horizon sextant (art. 1513). This instrument is generally not used aboard ship because of the excessive acceleration error encountered as the ship rolls and pitches. However, in polar regions there is generally little such motion and in the ice there may be virtually none. Some practice is needed to obtain good results with an artificial-horizon sextant, but these results are sometimes superior to those obtainable with a marine sextant, and when some of the conditions mentioned above prevail, the artificial-horizon sextant may provide the only means of making an observation. Better results with this instrument can generally be obtained if the instrument is hung from some support, as it generally is when used in aircraft.

An artificial horizon (art. 1512) can sometimes be used effectively, even an improvised one, as by placing heavy lubricating oil in a bucket.

It is sometimes possible to make better observations by artificial-horizon sextant or artificial horizon from a nearby cake of ice than from the ship.

Clouds and high fog are frequent in high latitudes, but it is not uncommon, particularly in the antarctic, for the fog to lift for brief periods, permitting an alert navigator to obtain observations.

As the latitude increases, an error of time has less effect upon altitude. At the equator an error of four seconds in time may result in an error in the location of the position line of as much as one mile. At latitude 60° a position error of this magnitude cannot occur unless the timing error is eight seconds. At 70° nearly 12 seconds are needed, and at 80° about 23 seconds are needed for such a position error.

Polaris is of diminished value in high northern latitudes because of its high altitude. At high latitudes the second correction to observed altitude (a_1) becomes greater. The almanac makes no provision for applying this beyond latitude 68°. Bodies at high altitudes are not desirable for azimuth determination, but if Polaris is used, the use of the actual azimuth given at the bottom of the Polaris tables of the *Nautical Almanac* is of increased importance because of its larger variation from 000° in high latitudes. No azimuth is provided beyond latitude 65°.

In applying a sextant altitude correction for dip of the horizon, one should use height of eye *above the ice at the horizon*, instead of height above water. The difference between ice and water levels at the horizon can often be estimated by observing ice near the vessel.

2532. Low-altitude observations.—Because of large and variable refraction at low altitudes, navigators customarily avoid observations below some minimum, usually 5° to 15°, if higher bodies can be observed. In polar regions low-altitude observations are often the only ones available. The sun, moon, and planets remain low in the sky for relatively long periods, their diurnal motion being nearly horizontal. The only lower limit is that imposed by the horizon itself. In fact, good observations can sometimes be made without a sextant by noting the time at which either the upper or lower limb is tangent to the horizon. To such an observation sextant altitude corrections are applied as for a marine sextant without an index correction.

Correction of low-altitude observations made by marine sextant is discussed in article 1632. If a bubble or other artificial-horizon sextant is used, corrections are made

as for higher altitudes, being careful to use the refraction value corrected for temperature, or to make a separate correction for air temperature. In addition, a correction for atmospheric pressure (tab. 24) is applied if of sufficient size to be of importance.

Solution of low-altitude observations is discussed in article 2010.

2533. Abnormal refraction and dip.—Tables of refraction correction are based upon a standard atmosphere. Variations in this atmosphere result in changes in the refraction, and since the atmosphere is seldom exactly standard, the mean refraction is seldom the same as shown in the tables. Variations from standard conditions are usually not great enough to be troublesome.

In polar regions, however, it is normal for the atmosphere to differ considerably from the standard, particularly near the surface. This affects both refraction and dip, as indicated in article 1606. Outside polar regions, variations in refraction seldom exceed 2′ or 3′, although extreme values of more than 30′ have been encountered In polar regions refraction variations of several minutes are not uncommon and an extreme value of about 5° has been reported. This would produce an error of 300 miles in a line of position. The sun has been known to rise as much as ten *days* before it was expected.

Most celestial observations in polar regions produce satisfactory results, but the high-latitude navigator should be on the alert for abnormal conditions, since they occur more often than elsewhere, and have greater extreme values. A wise precaution is to apply corrections for air temperature (tab. 23) and atmospheric pressure (tab. 24), particularly for altitudes of less than 5°.

Abnormal dip affects the accuracy of celestial observations equally at any altitude, if the visible horizon is used. Such errors may be avoided in any *one* of four ways:

1. The artificial-horizon sextant may be used, as indicated in article 2531.

2. When stars are available, three stars may be observed at azimuth intervals of approximately 120°, (or four at 90° intervals, five at 72°, etc.). Any error in dip *or refraction* will alter the size of the enclosed figure, but will not change the location of its center unless the dip or refraction error varies in different directions. The stars should preferably be at the same altitude.

3. The altitude of a single body may be observed twice, facing in opposite directions. The sum of the two readings differs from 180° by twice the sum of the index and dip corrections (also personal and instrument corrections, if present). This method assumes that dip is the same in both directions, an assumption that is usually approximately correct. Also, the method requires that the arc of the sextant be sufficiently long and the altitude of the body sufficiently great to permit observation of the back sight in the opposite direction. In making such observations, it is necessary that allowance be made for the change of altitude between readings. This may be done by taking a direct sight, a back sight, and then another direct sight at equal intervals of time, and using the average of the two direct sights.

4. A correction for the difference between air and sea temperatures (art. 1607) may be applied to the sextant altitude. This will often provide reasonably good results. However, there is considerable disagreement in the manner in which temperature is to be measured, and in the factor to use for any given difference. Therefore, the validity of this correction is not fully established.

There is still much to be learned regarding refraction and even with all known precautions, results may occasionally be unsatisfactory.

2534. Sight reduction in polar regions is virtually the same as elsewhere. Computation can be made by nearly any method. In H.O. Pub. No. 214, tabulations are not extended below an altitude of 5°, but this method can be used for lower altitudes, which are not uncommon in polar regions, by selecting an assumed position some distance away,

in the general direction of the body. Thus, if the altitude is 2°, an assumed position 3° (180 miles) nearer the body (4° is a better choice to allow for possible error in the dead reckoning and for adjustment for a convenient assumed position) should result in a computed altitude of 5° or more. This method will result in an unusually long altitude difference, but the error introduced will be negligible *if* the assumed position is in the direction of the body, and the chart used is one on which a straight line is a close approximation to a great circle. A Lambert conformal chart is satisfactory for this purpose. An example of such a solution is given in article 2010.

Some navigators prefer to use another method of sight reduction. Both H.O. Pub. No. 208 and H.O. Pub. No. 211 are suitable for this purpose, but perhaps the most satisfactory method is H.O. Pub. No. 249, which provides solutions down to the visible horizon for any height of eye to be anticipated aboard ship and for any reasonable altitude difference. However, except for certain specified stars, the method is limited to celestial bodies having declinations not exceeding 30°. This provides for the sun, moon, planets, and a number of good navigational stars. Having been designed for air navigation, H.O. Pub. No. 249 provides computed altitudes to the nearest whole minute, and azimuth to the nearest whole degree. For low altitudes this precision is realistic.

From latitude 70° to the pole, hour angles in H.O. Pub. No. 249 are tabulated at intervals of 2°. Near the pole this interval could be greatly increased because of the small diameter of the parallels of latitude. Based upon this and the fact that azimuth approaches LHA ±180° near the north pole (360°−LHA near the south pole), various special methods have been suggested for high latitudes, providing very short tables. However, there is considerable advantage in using familiar methods and avoiding special ones of limited application and often of little advantage.

One special method of considerable interest is conveniently applicable only within about 5° of the pole, a higher latitude than is usually attainable by ships. This is the method of using the pole as the assumed position. At this point the zenith and pole coincide and hence the celestial equator and celestial horizon also coincide, and the systems of coordinates based upon these two great circles of the celestial sphere become identical. The declination is computed altitude, and GHA replaces azimuth. A "toward" altitude difference is plotted along the upper branch of the meridian over which the body is located, and an "away" difference is plotted in the opposite direction, along the lower branch. Such a line or its AP is advanced or retired in the usual manner. This method is a special application of the meridian altitude sometimes used in lower latitudes. Beyond the limits of this method the meridian altitude can be used in the usual manner (art. 2103) without complications and with time of transit being less critical. However, table 29, for reduction to the meridian, extends only to latitude 60°. Tables providing a correction to permit use of the pole-assumed-position method with the polar stereographic projection at considerable distance from the pole have been prepared, but are rarely used, and never by mariners. These are known as the **Ellsworth Tables.**

2535. Plotting lines of position from celestial observations.—Lines of position from celestial observations in polar regions are plotted as elsewhere, using an assumed position, altitude difference, and azimuth. If a Mercator chart is used, the error introduced by using rhumb lines for the azimuth line (a great circle) and line of position (a small circle) is accentuated. This can be overcome by using a good dead reckoning or estimated position as the assumed position or by using a chart on a more favorable projection.

If a chart with nonparallel meridians, such as the Lambert conformal, is used, the true azimuth should be plotted by protractor or plotter and measured at the meridian

of the assumed position. On a chart having a grid overprint the true azimuth can be converted to grid azimuth, using the longitude of the assumed position, and the direction measured from any grid line. This method involves an additional step, with no real advantage.

Lines of position from high-altitude observations, to be plotted as circles with the geographical position as the center (art. 2011), should not be plotted on a Mercator chart because of the rapid change of scale, resulting in distortion of the circle as plotted on the chart.

Lines of position are advanced or retired as in any latitude. However, the movement of the line is no more accurate than the estimate of the direction and distance traveled, and in polar regions this estimate may be of less than usual accuracy. In addition to his problem of estimating direction of travel, the polar navigator may encounter difficulty in accurately plotting the direction determined. If an accurate gyro compass is used, the ship follows a rhumb line, which is accurately shown only on a Mercator chart. If a magnetic compass is used, the rapid change in variation may be a disturbing factor. If the ship is in ice, the course line may be far from straight.

Because of the various possible sources of error involved, it is good practice to avoid advancing or retiring lines for a period longer than about two hours. When the sun is the only body available, best results can sometimes be obtained by making an observation every hour, retiring the most recent line one hour and advancing for one hour the line obtained two hours previously. The present position is then obtained by dead reckoning from the running fix of an hour before. Another technique is to advance the one or two previous lines to the present time for a running fix. A third method is to drop a perpendicular from the dead reckoning or estimated position to the line of position to obtain a new estimated position, from which a new dead reckoning plot is carried forward to the time of the next observation. A variation of this method is to evaluate the relative accuracy of the new line of position and the dead reckoning or estimated position run up from the previous position and take some point *between* them, halfway if no information is available on which to evaluate the relative accuracies. None of these techniques is suitable for determining set and drift of the current.

2536. Rising, setting, and twilight data are tabulated in the almanacs to latitude 72° N and 60° S. Within these limits the times of these phenomena are determined as explained in chapter XVIII.

Beyond the northern limits of these tables the values can be obtained from a series of graphs given near the back of the *Air Almanac*. These graphs are shown in appendix W. For high latitudes, graphs are used instead of tables because graphs give a clearer picture of conditions, which may change radically with relatively little change in position or date. Under these conditions interpolation to practical precision is simpler by graph than by table. In those parts of the graph which are difficult to read, the times of the phenomena's occurrence are themselves uncertain, being altered considerably by a relatively small change in refraction or height of eye.

On all of these graphs any given latitude is represented by a horizontal line, and any given date by a vertical line. At the intersection of these two lines the duration is read from the curves, interpolating by eye between curves.

The "Semiduration of Sunlight" graph gives the number of hours between sunrise and meridian transit or between meridian transit and sunset. The dot scale near the top of the graph indicates the LMT of meridian transit, the time represented by the minute dot nearest the vertical date line being used. If the intersection occurs in the area marked "sun above horizon," the sun does not set; and if in the area marked "sun below horizon," the sun does not rise.

Example 1.—Find the zone time of sunrise and sunset at lat. 71°30′.0 N, long. 10°00′.0 W near Jan Mayen Island, on August 25, 1958.

Solution.—

	August 25	
LMT	1202	LAN, from top of graph
dλ	(−) 20	
ZT	1142	LAN
semidur.	840	from graph
ZT	0302	sunrise (− semidur.)
ZT	2022	sunset (+ semidur.)

A vertical line through August 25 passes nearest the dot representing LAN 1202 on the scale near the top of the graph. This is LMT; at longitude 10°00′.0 W the ZT is 20^m earlier, or at 1142. The intersection of the vertical date line with the horizontal latitude line occurs between the 8^h and 9^h curves, at approximately $8^h\ 40^m$. Hence, sunrise occurs at this interval before LAN and sunset at this interval after LAN.

The "Duration of Twilight" graph gives the number of hours between the beginning of morning *civil* twilight (center of sun 6° below the horizon) and sunrise, or between sunset and the end of evening civil twilight. If the sun does not rise, but twilight does occur, the time taken from the graph is half the total length of the single twilight period, or the number of hours from beginning of morning twilight to LAN, or from LAN to end of evening twilight. If the intersection occurs in the area marked "continuous twilight or sunlight," the center of the sun does not get more than 6° below the horizon; and if in the area marked "no twilight nor sunlight," the sun remains more than 6° below the horizon throughout the entire day.

Example 2.—Find the zone time of beginning of morning twilight and ending of evening twilight at the place and date of example 1.

Solution.—

	Twilight	
ZT	0302	sunrise, from example 1
dur.	153	from graph
ZT	0109	morning twilight

	Twilight	
ZT	2022	sunset, from example 1
dur.	153	from graph
ZT	2215	evening twilight

The intersection of the vertical date line and the horizontal latitude line occurs approximately one-sixth of the distance from the 2^h line toward the $1^h\ 20^m$ line; or at about $1^h\ 53^m$. Morning twilight begins at this interval before sunrise, and evening twilight ends at this interval after sunset.

The "Semiduration of Moonlight" graph gives the number of hours between moonrise and meridian transit or between meridian transit and moonset. The dot scale near the top of the graph indicates the LMT of meridian transit, each dot representing one hour. The phase symbols indicate the date on which the principal moon phases occur, the open circle indicating full moon and the dark circle indicating new moon. If the intersection of the vertical date line and the horizontal latitude line falls in the "moon above horizon" or "moon below horizon" area, the moon remains above or below the horizon, respectively, for the entire 24 hours of the day.

If approximations of the times of moonrise and moonset are sufficient, the values of semiduration taken from the graph can be used without adjustment. For more accurate results, the times on the required date and the adjacent date (the following date in west longitude and the preceding date in east longitude) should be determined, and an interpolation made for longitude, as in any latitude, since the intervals given are for the Greenwich meridian.

Example 3.—Find the zone time of moonrise and moonset at lat. 74°00′.0 N, long. 108°00′.0 W on May 16, 1958, and the phase of the moon on this date.

Solution.—

	May 16		May 17	
LMT	0952	LMT	1036	meridian transit, from graph
dλ	(+) 12	dλ	(+) 12	
ZT	1004	ZT	1048	meridian transit
semidur.	8^h48^m	semidur.	9^h55^m	from graph
ZT	0116	ZT	0053	(moonrise − semidur.)
ZT	1852	ZT	2043	(moonset + semidur.)

	Moonrise			Moonset	
ZT	0116	May 16	ZT	1852	May 16
ZT	0053	May 17	ZT	2043	May 17
diff.	(−) 23		diff.	(+) 111	
23×108.0/360	(−) 7		111×108.0/360	(+) 33	
ZT	0109		ZT	1925	

The phase is crescent, about three days before new moon. The LMT of meridian transits are found by noting the intersections of the vertical date lines with the dot scale near the top of the graph, interpolating by eye. At longitude 108°00′.0 W the ZT is 12^m later. The semiduration is found by noting the position, with respect to the semiduration curves, of the intersection of the vertical date line with the horizontal latitude line. This interval is subtracted from the time of meridian transit to obtain moonrise, and added to obtain moonset. These solutions are made for both May 16 and 17, and the difference determined in minutes. The adjustment to be applied to the ZT on May 16 at Greenwich is determined by multiplying this difference by the ratio λ/360. The phase is determined by noting the position of the vertical date line with respect to the phase symbols. If the answer indicates that the phenomenon occurs on a date differing from that desired, a new solution should be made, adjusting the starting date accordingly. The phenomenon may occur twice on the same day, or it may not occur at all. In high latitudes the effect on the time of moonrise and moonset of a relatively small change in declination is considerably greater than in lower latitudes, resulting in greater differences from day to day.

Sunlight, twilight, and moonlight graphs are not available for south latitudes. Beyond latitude 65° S, the northern hemisphere graphs can be used for determining the semiduration or duration, by using the vertical date line for a day when the declination has the same numerical value but opposite sign. The time of meridian transit and the phase of the moon are determined as explained above, using the correct date. Between latitudes 60° S and 65° S solution is made by interpolation between the tables and the graphs.

Several other methods of solution of these phenomena are available. The *Tide Tables* tabulate sunrise and sunset from latitude 76° N to 60° S. A supplement to the American Ephemeris of 1946, entitled *Tables of Sunrise, Sunset, and Twilight,* provides tabulations from latitude 75° N to 75° S and graphs for semiduration of sunlight and duration of twilight, with separate graphs for civil, nautical, and astronomical twilights. Semiduration or duration can be determined graphically by means of a diagram on the plane of the celestial meridian (art. 1432), or by computation. When computation is used, solution is made for the meridian angle at which the required negative altitude occurs. The meridian angle expressed in time units is the semiduration in the case of sunrise, sunset, moonrise, and moonset; and the semiduration

of the combined sunlight and twilight, or the time from meridian transit at which morning twilight begins or evening twilight ends. For sunrise and sunset the altitude used is (−) 50′. Allowance for height of eye can be made by algebraically subtracting (numerically adding) the dip correction from this altitude. The altitude used for twilight is (−) 6°, (−) 12°, or (−) 18° for civil, nautical, or astronomical twilight, respectively. The altitude used for moonrise and moonset is −34′−SD+HP, where SD is semidiameter and HP is horizontal parallax, from the daily pages of the *Nautical Almanac.* The time sight formula can be used for making the computation:

$$\text{hav } t = \sec L \csc p \cos s \sin (s-h),$$

where t=meridian angle, $s=\frac{1}{2}(h+L+p)$, h=altitude, L=latitude, and p=90°−d for L and d (declination) same name and 90°+d for L and d contrary name. Another formula which can be used is

$$\cos t = \sec L \sec d (\sin h - \sin L \sin d),$$

with the same notation as above.

General

2537. Ice.—Several references have been made to ice. The almost constant presence of large quantities of ice is one of the distinctive features of polar regions, and is one of the primary considerations in any operations in these areas. The subject of ice in the sea is covered in chapter XXXVI.

2538. Knowledge of polar regions.—Operations in polar regions are attended by hazards and problems not encountered elsewhere. Lack of knowledge, sometimes accompanied by fear of the unknown, has prevented navigation in these areas from being conducted with the same confidence with which it is pursued in more familiar areas. As experience in high latitudes has increased, much of the mystery surrounding these areas has been dispelled, and operations there have become more predictable.

Before entering polar regions, the navigator will do well to acquaint himself with the experience of those who have preceded him into the areas and under the conditions he anticipates. This information can be found in a growing literature composed of the accounts of explorers, reports of previous operations in high latitudes, articles in professional journals, and several books on operations in polar regions. Some of it is given in various volumes of sailing directions, particularly those for Antarctica (H.O. Pub. No. 27). Additional information is available at the U.S. Navy Hydrographic Office.

The search for knowledge should not be confined to navigation. The wise polar navigator will seek information on living conditions, survival, geography, ice, climate and weather, and operational experience of others who have been to the same area. As elsewhere, knowledge and experience are valuable.

2539. Planning, important in any operation, is vital to the success of polar navigation. The first step to adequate planning is the acquisition of full knowledge, as discussed in article 2538. No item, however trivial, should escape attention. The ship should be provided with all the needed charts, publications, and special navigational material. All available data and information from previous operations in the area should be studied. Key personnel should be adequately instructed in polar navigation prior to departure or while en route to the polar regions. Forecasts on anticipated ice and weather conditions should be obtained before departure and after getting under way. All equipment should be put in top operating condition. All material should be carefully inspected for completeness and condition. The navigator should make certain that all items of equipment are familiar to those who will use them. This is par-

ticularly true of items not generally used at sea, such as charts on an unfamiliar projection, or a bubble sextant. Do not *assume* anything that can be *known*. On the adequacy and thoroughness of the advanced planning and preparation, perhaps more than anything else, will depend the success of polar navigation.

Problems

2510a. Convert the following true directions to grid directions using (1) a convergency of one, (2) a convergency of 0.866. (Give answers to nearest whole degree.)

True	*Latitude*	*Longitude*
157°	N	27° W
353°	N	114° E
118°	S	63° E
042°	S	147° W

Answers.—(1) 184°, 239°, 181°, 255°; (2) 180°, 254°, 173°, 275°.

2510b. Convert the following grid directions to true directions using (1) a convergency of 0.629, (2) a convergency of one.

Grid	*Latitude*	*Longitude*
003°	N	174° W
148°	S	9° W
317°	N	64° E
256°	S	155° E

Answers.—(1) 254°, 154°, 357°, 159°; (2) 189°, 157°, 021°, 101°.

2516a. The radar operator of a ship proceeding through ice measures the following bearings and ranges of an iceberg:

Time	*Bearing*	*Range*
1430	110°	4,000 yds.
1435	121°	3,300 yds.
1440	139°	2,600 yds.
1445	163°	2,300 yds.
1450	188°	2,500 yds.
1455	206°	3,100 yds.

Required.—(1) The course and speed of the ship if the iceberg is stationary.

(2) The course and speed of the ship if the iceberg is moving north at two knots.

Answers.—(1) C 075°, S 6.5 kn.; (2) C 059°, S 7.3 kn.

2516b. A navigator measures off a distance of 300 feet in a fore-and-aft direction along the deck and stations a man at each end of this line. A stop watch is started when a prominent ice feature is opposite the forward man. When the after man reports that the same feature is opposite him, the watch is stopped, and the elapsed time is found to be 34 seconds.

Required.—Speed.

Answer.—S 5.3 kn.

2536a. Find the zone time of sunrise and sunset at lat. 79°20′.0 N, long. 33°00′.0 E, on August 31, 1958.

Answers.—Sunrise, ZT 0119; sunset, ZT 2219.

2536b. Find the zone time of beginning of morning civil twilight, sunrise, sunset, and ending of evening civil twilight at lat. 67°30′.0 N, long. 167°00′.0 W, on May 4, 1958.

Answers.—Morning twilight, ZT 0105; sunrise, ZT 0305; sunset, ZT 2105; evening twilight, ZT 2305.

2536c. Find the zone time of moonrise and moonset at lat. 82°30′.0 N, long. 56°15′.0 W, on June 23, 1958, and the phase of the moon on this date.

Answers.—Moonrise, ZT 0904; moonset, ZT 0315; phase, crescent, about one day before first quarter.

CHAPTER XXVI

LIFEBOAT NAVIGATION

Before Emergency Arises

2601. Introduction.—The methods and techniques used in lifeboat navigation are those available at the time. With full equipment, lifeboat navigation differs little from that aboard ship. More often, however, it is a matter of improvising equipment from available materials, and developing procedures from a knowledge of basic principles. Ingenuity is often essential. The officer who navigates by blindly "following the steps" may be of little more value in a lifeboat devoid of familiar navigational equipment than the man who has never set foot on the bridge of a ship. The wise officer becomes thoroughly familiar with the theory of navigation: the celestial triangle, the circle of equal altitude, and the other basic principles involved. He should be able to identify the most useful stars, and know how to solve his sights by any widely used method, because his favorite method may not be available. He should be able to construct a plotting sheet with a protractor, and use distress signaling equipment. Familiarity with the coordinates (latitude and longitude) of land points in the area of operations, ability to interpret wind and weather signs, knowledge of the ocean currents, and skill in handling a small boat are parts of the practical navigator's basic education which assume their greatest importance in an emergency. For the navigator prepared with such knowledge, and a determination to succeed, the situation is never hopeless. *Some* method of navigation is always available.

2602. Emergency navigation kit.—In time of national emergency, the prudent navigator will provide each lifeboat with a kit containing the equipment which it is practical to carry for emergency navigational purposes (art. 2603). Even in peacetime it is good practice to have one such kit permanently located in the chart house or the wheel house so that it can be quickly transferred to a lifeboat when needed.

The least preparation made should be a check-off list of items to be assembled if time permits, so that nothing will be overlooked. Such a list can be helpful even if one or more emergency kits have been provided. The list should be kept in a prominent place on the bridge or near the lifeboats, perhaps framed under glass. All officers should be familiar with its location and should be acquainted with the location and identity of each item listed.

Junior officers or reliable crew members should be assigned the duty of bringing to their stations, during abandon ship drill, emergency navigational equipment not permanently stowed in the boats. A senior officer should then check each item against the equipment check-off list to ascertain that nothing has been overlooked.

2603. Equipment.—If practicable, full navigational equipment should be provided. As many as possible of the items in the following list should be included. All of these except a timepiece, and possibly a sextant and radio, can be kept in the emergency navigation kit recommended in article 2602.

1. **Notebook** suitable for use as a deck log and for performing computations. Several items of information should be written in this notebook in advance, so as to be available when and if needed. Such items include the latitude and longitude of various places in the area of operation; any desired information on currents and weather;

declination and SHA of several widely scattered stars, with any needed information on identifying them; desired notes and tables from this chapter and elsewhere; any desired general information, such as a list of poisonous fish and those items which may prove useful for survival. This section of the notebook should be brief and the items limited to those most essential in time of emergency.

2. **Charts and other plotting materials.** A pilot chart is most suitable for lifeboat use, both for plotting and as a source of information on variation of the compass, shipping lanes, currents, winds, and weather. Charts for both the summer and winter seasons should be included. During World War II pilot charts were printed on waterproof material suitable for use in a lifeboat. **Plotting sheets** (art. 323) are useful but not essential if charts are available. The plotting sheets should cover the latitudes in which the ship operates. **Universal plotting sheets** (art. 324) may be preferred, particularly if the latitude coverage is large. Several **maneuvering boards,** H.O. 2665–10, (art. 1212) and several sheets of **cross-section paper** (preferably with ten squares per inch) should be included, as these have many uses.

3. **Plotting equipment.** Pencils, erasers, straightedge, protractor, dividers and compasses (not essential, but useful), and a knife or pencil sharpener should be included. Preferably, the straightedge and protractor should be combined in a single device constituting some kind of **plotter** (art. 605). A ruler graduated in inches and fractions may be useful.

4. **Timepiece.** A good watch is needed if longitude is to be determined astronomically. This watch should be waterproof or kept in a waterproof container which permits reading and winding of the watch without exposing it to the elements. The watch should be wound regularly and a record kept of its error and rate of change. Even if one or more such watches are available, the possibility of taking along the chronometers should not be overlooked.

5. **Sextant.** A marine sextant should be taken along if possible. However, since this may be impractical, a lifeboat sextant, or materials for constructing one, should be provided. Several commercially manufactured lifeboat sextants have been made available, particularly during wartime. A lifeboat sextant can be made of wood or other rigid material, two small mirrors, and a pivot. The graduations of the arc should be double those of a compass rose (an angle of 5° should be labeled 10°, etc.). It is not necessary to provide a vernier, or means of adjusting the sextant, since accuracy of 0.°1 is satisfactory for lifeboat use.

6. **Almanac.** A *Nautical Almanac* for the current year is desirable. In an emergency an almanac for another year can be used for stars and the sun without serious error by lifeboat standards, if suitable adjustment is made (art. 2617). Some form of long-term almanac, as that given in appendix X, might well be copied or pasted in the notebook suggested as item 1, above.

7. **Tables.** Some form of table will be needed for reducing celestial observations. The most suitable is one that does not require much space. If a table of trigonometric functions (either logarithmic or natural) is provided, formulas should be included with them. It is not wise to trust the memory for such vital information. A set of tables similar to H.O. Pub. No. 214 can be made at 5° intervals of t, d, and L. Only one page is needed for each latitude entry (5°) if declination is limited to about 30° (sufficient for bodies of the solar system and many stars), entries are given to the nearest 0.°1 for altitudes and 1° for azimuth, and the delta (Δ) values are omitted. **Traverse tables** and others given in this chapter are useful.

8. **Compass.** Each lifeboat is required to carry a magnetic compass. A deviation table for each compass should be made while in port, with magnetic material in its normal place. It would be well to check the accuracy of each table periodically.

9. **Flashlight.** A flashlight is required to be carried in each lifeboat. The batteries should be replaced from time to time, as necessary. Extra batteries and bulbs might well be carried.

10. **Portable radio.** If a portable radio is available, be sure it is included. Whether this is one of the transmitting-receiving sets approved by the Federal Communications Commission for lifeboat use, or merely a small receiver of limited range owned by a crew member, do not overlook it, as it may be used as a radio direction finder.

2604. Position of ship.—A knowledge of the position of the vessel at the time it is abandoned is of great importance. The officer on watch on the bridge should never permit himself to become careless in the matter of keeping a mental note of the approximate position of the vessel. During wartime, or whenever the possibility of abandoning ship might reasonably be anticipated, the radio operator should be provided with a list of advance dead reckoning positions.

Abandoning Ship

2605. Before lowering boats.—The period between the decision to abandon ship and the actual leaving of the vessel is a highly important one. It is also a period of mental strain and possible confusion. The degree to which the crew can be prepared for the ordeal ahead depends upon the amount of time available and the thoroughness of the preparation that has been made. If there has been advance warning of the possibility of the decision, certain preparations can be made before the decision is reached. If time permits, after the decision to abandon ship has been made, the radio operator should send a final distress message, giving the ship's position and any other pertinent information. It will be important later to know whether an acknowledgment of receipt of the message was received. Any available time can be wisely used to check the navigational equipment in each boat and assemble missing items. There may be time to make a last minute check of position of the ship, position of any nearby land, set and drift of current, present and forecast weather, watch error, and date. These items should be written down. Perhaps the chart can be taken along. Equipment should be properly secured before lowering the boats. In a rough sea it may be desirable to lower the sextant, chronometer, and radio into the boat after it is afloat.

2606. Establishing command.—The identity of the person in command of each boat, and the over-all commander, should be firmly established. Almost invariably this will be the senior officer present. In a lifeboat, perhaps more than in any other circumstances, strong leadership is required if the confidence of the crew is to be maintained. The officer whom the crew respects as a *man*, admires as a *seaman*, and recognizes as a *gentleman* will have little or no trouble with discipline and cooperation of all on board.

Morale is a prime consideration, and it grows in importance with the passage of time. The person in command should be recognized as the final authority in all matters, but it is important that he give to each person an opportunity to be heard, and that he keep all hands fully informed of the bad as well as of the good. Decisions will be more acceptable if the crew has been informed of each consideration as it arises, and so has been somewhat prepared. Complete fairness and impartiality are essential.

2607. Estimate of the situation.—Perhaps the first item which should engage the attention of the person in command, after the lifeboat has cleared the stricken vessel, is the questioning of each person aboard to collect all the useful information available. It is well to determine what is known regarding the position of the ship, ocean currents, weather, astronomy, navigation, seamanship, sailing, etc. Find out who owns watches and what each owner knows about the error and rate of his watch. Establish a routine for winding and comparing them. No useful skill or knowledge should be overlooked;

all should be fully considered in making the important decision of whether to remain in the vicinity of the disaster in the hope of rescue, or to attempt to reach land or a more heavily traveled shipping lane.

This decision of whether to stay or leave may be the most important one of the entire experience. Until comparatively recent times there was no problem. Because there was virtually no hope of assistance, the lifeboat crew had to rely upon itself. Since the development of modern communication and rescue facilities, however, it is often wiser to remain than to complicate the rescue problem by increasing the area to be searched.

The decision should not be made until careful consideration has been given to all factors, nor should it be delayed longer than necessary. Considerations vary with the circumstances, but certainly the following should be included:

Was a distress message sent before the ship was abandoned? Did it include the position of the ship? How accurate was the position? Is there any reasonable doubt that the message was received? If no message was sent, how soon will the ship be missed? What rescue facilities are available? How far away are they and how long will it be before help arrives? How conspicuous is the lifeboat? What facilities are available for attracting attention, either visually or by radar? How proficient is the crew in using such equipment? Is a radio transmitter available? What is the probable running time to the nearest land in several directions, considering the prevailing winds and currents, the motive power available, and the ability of the crew to use it? How long will the fresh water and rations last, and will they be sufficient to sustain the crew in the physical exertion required?

If the decision is to stay, how will the crew occupy its time, remembering the increased morale problem with an idle crew? How will position be maintained, or regained if the boat drifts? Would it be practical to wait two or three days, perhaps, in the hope of rescue, and then to set out for land if help does not come?

If the decision is to leave, where should the boat head? How soon can a well-traveled shipping lane be reached? In time of war, where is the enemy and where are friends? How large and conspicuous is the land in each direction, considering the low height of eye in a lifeboat? It may be better to head for conspicuous land 500 miles away than for a small, low island 200 miles away, particularly if the latter is in a direction of unfavorable winds or currents, or takes the boat farther away from shipping lanes.

Avoid, if possible, a hasty decision that will later be recognized as unwise. Discuss the matter thoroughly with the crew, and when the decision is made, inform them of the reason for it. Do this in a manner that will invite their confidence and support. Inform them of the best estimate of the situation.

2608. Selecting the route.—It is not always desirable to head directly for the objective. A longer route with favorable winds and currents may be quicker. A longer route by way of shipping lanes may enhance the possibility of rescue.

With clear skies, latitude can be found with relatively crude equipment. But unless accurate Greenwich time is available, longitude cannot be found astronomically, even with the best equipment; nor is a nonastronomical method likely to be available. In the absence of reliable longitude information, it is better to head for a point at the latitude of the destination but so far east or west of it that no reasonable doubt will exist as to the direction of land when that latitude is reached. The distance of the point from the destination depends upon the degree of uncertainty of the longitude, remembering that this uncertainty is likely to increase with time. This method of "parallel sailing" was used for centuries before a method of determining or "discovering" longitude at sea was developed.

If the objective has a considerable extent in a north-south direction, the need for a final east-west leg is less critical, and in attempting to reach a continent or very large island, one need not consider it at all. In the absence of better information, an east or west course should be selected from the outset, since most large land masses of the earth are oriented in a general north-south direction.

2609. Keeping boats together.—If more than one boat is launched, every effort should be made to keep them together. While the person in charge of each boat is responsible for decisions regarding his boat, considerable advantage is to be gained by keeping the boats together and recognizing one person, logically the senior officer present, as the over-all commander. Since navigational equipment and skill probably will differ widely from boat to boat, the benefits of any accurate navigation can be shared by all if the boats are close together. Other knowledge can be exchanged, equipment shared, and rations distributed equitably. It may be wise to shift some personnel among the boats, perhaps on a periodic basis, either to effect a better balance of skill and knowledge, or for morale purposes.

2610. Lookout.—Always there is the possibility of sighting another vessel. Hence, a lookout should be posted at all times. This becomes of even greater importance when approaching land, or if the location of all land along the route is not known. If it is possible to rig a metal object high in the boat, this should be done to enhance the possibility of detection by radar.

Dead Reckoning

2611. Importance of dead reckoning.—Of the various kinds of navigation, dead reckoning alone is always available in some form. It should never be neglected, but in a lifeboat it is of more than average importance. A close check should be kept on the direction and distance made good, and all disturbing elements such as wind and current should be carefully evaluated. Long voyages have been successfully completed by this method alone, and landfalls have been made with surprising accuracy. This is not meant to minimize the importance of other methods of determining position, but with the methods generally available in a lifeboat, one may well find that, during the first few days, his dead reckoning positions are more accurate than those determined by other methods. If the means of determining direction and distance—the elements of dead reckoning—are accurate, it might be well to make an adjustment to the dead reckoning only after consistent indication of the magnitude and direction of its error. The dropping of the dead reckoning at each uncertain "fix" is at best a questionable procedure. The conflicting information likely to be available calls for careful analysis and good judgment on the part of the navigator.

2612. Deck log.—From the beginning a careful log should be kept. The date and time of abandoning ship should be the first entry, followed by navigational information available, and the various important decisions and the reasons for them. Since the conservation of paper may be important, record only the essentials of the important items, but do not overlook the recording in considerable detail of the selection of a commanding officer, changes in command, deaths, missing persons, and navigational information.

The best determination of the position of abandoning ship should be recorded, followed by a full account of courses, distances, positions, winds, currents, and leeway. No important navigational information should be left to memory if it can be recorded.

2613. Direction.—As one of the elements of dead reckoning, direction is an important item. As indicated in article 2603, a deviation table for each lifeboat compass should be determined in port, and checked periodically. At the first convenient oppor-

tunity after abandoning ship the accuracy should be checked on the course to be followed.

If an almanac, accurate Greenwich time, and the necessary tables are available, the azimuth of any celestial body can be computed and this value compared with the azimuth as measured by the compass. If it is difficult to observe the compass azimuth, select a body dead ahead and note the compass heading. The difference between computed and observed azimuths is compass error. This is of more immediate value than deviation, but if the latter is desired, it can be determined by applying to the compass error the variation, from the pilot chart.

Several unique astronomical situations occur, permitting determination of azimuth without computation:

Polaris is always within 2° of true north for observers between the equator and latitude 60° N. When this star is directly above or below the celestial pole, its azimuth is exactly north at any latitude. This occurs approximately when the *trailing* star of either *Cassiopeia* (ϵ *Cassiopeiae*) or the big dipper (Alkaid) is directly above or directly below Polaris (fig. 2621). When a line through the trailing stars and Polaris is horizontal, the maximum correction should be applied. Below latitude 50° this can be considered 1°; and between 50° and 65°, 2°. If *Cassiopeia* is to the *right* of Polaris, the azimuth is 001° (or 002°), and if to the left, 359° (or 358°). The *south* celestial pole is located approximately at the intersection of a line through the longer axis of the southern cross with a line from the northernmost star of *Triangulum Australe* perpendicular to the line joining the other two stars of the triangle. No conspicuous star marks this spot (figs. 2205–2208).

Meridian transit. Any celestial body bears due north or south at meridian transit, either upper or lower. This is the moment of maximum (or minimum) altitude of the body. However, since the altitude at this time is nearly constant during a considerable change of azimuth, the instant of meridian transit may be difficult to determine. If time and an almanac are available, and the longitude is known, the time of transit can be computed.

Body on prime vertical. If any method is available for determining when a body is on the prime vertical (due east or west), the compass azimuth at this time can be observed. Table 25 provides this information. Any body on the celestial equator (declination 0°) is on the prime vertical at the time of rising or setting. For the sun this occurs at the time of the equinoxes (art. 1419). The star Mintaka (δ *Orionis*), the *leading* star of *Orion's* belt, has a declination of approximately 0°.3 S and can be considered on the celestial equator. For an observer near the equator, such a body is always nearly east or west. Because of refraction and dip, the azimuth should be noted when the center of the sun or a star is a little more than one sun diameter (half a degree) *above* the horizon. The moon should be observed when its *upper* limb is *on* the horizon.

Body at rising or setting. Except for the moon, the azimuth angle (art. 1428) of a body is almost the same at rising as at setting, except that the former is toward the *east* and the latter toward the *west.* If the azimuth is measured *both* at rising and setting, true south (or north) is midway between the two observed values, and the difference between this value and 180° (or 000°) is the compass error. Thus, if the compass azimuth of a body is 073° at rising, and 277° at setting, true south (180°) is at $\frac{073°+277°}{2}=175°$ by compass, and the compass error is 5° E. This method may be in error if the boat is moving rapidly in a north or south direction. If the declination and latitude are known, the true azimuth of any body at rising or setting can be deter-

mined by means of a diagram on the plane of the celestial meridian (art. 1432) or by computation (art. 2125). For this purpose the body (except the moon) should be considered as rising or setting when its center is a little more than one sun diameter (half a degree) above the horizon, because of refraction and dip.

The direction of the sun in relation to the hands of a watch is sometimes advocated, but the limitations of this method are too great to permit general application.

A simple nonastronomical method can be used for determining the *deviation*. An object that will float but not drift rapidly before the wind is thrown overboard. The boat is then steered as steadily as possible in the *opposite* direction to that desired. At a distance of perhaps half a mile, or more if the floating object is still clearly in view, the boat is turned around in the smallest practicable radius, and headed back toward the floating object. The *magnetic* course is midway between the course toward the object and the *reciprocal* of the course away from the object. Thus, if the boat is on compass course 151° while heading away from the object, and 337° while returning, the magnetic course is midway between 337° and $151°+180°=331°$, or $\frac{337°+331°}{2}=334°$. Since 334° magnetic is the same as 337° by compass, the deviation on this heading is 3° W.

If a compass is not available, any celestial body can be used to steer by, if its diurnal apparent motion is considered. A reasonably straight course can be steered by noting the direction of the wind, the movement of the clouds, the direction of the waves, or by watching the wake of the boat. A line can be secured to the side of the boat at a point amidships or forward. The line should tend parallel to the center line of the boat if on a straight course. The angle between the center line and the wake is an indication of the amount of leeway. The accuracy of the towed-object or wake method is affected adversely by a cross sea.

A body having a declination the same as the latitude of the destination is over the destination once each day, at the time when its hour angle is the same as the longitude, measured westward through 360°. At this time it should be dead ahead if the boat is following the great circle leading directly through the destination.

2614. Motive power.—A lifeboat is equipped with one or more of the following means of locomotion: oars, hand-operated propeller, motor, sail. Of these, only sail offers a practical means of travel over an extended period of time. Men living in an open boat, perhaps on reduced rations, should not attempt to expend their strength on hand locomotion, except for short periods. Likewise, the comparatively small fuel supply in a motorboat should be hoarded jealously. It may be desperately needed later, as for landing through a surf, preventing the boat from drifting onto a rocky coast, or making the land when a strong current is carrying the boat past an island.

A sail should be rigged, for in it lies the best hope of reaching distant land. If the standard lifeboat sail is not available, a substitute can usually be devised, using the boat cover, or even clothing, and oars.

2615. Distance can be determined directly between accurate fixes, but generally it is found by means of speed and elapsed time. A loaded lifeboat will not travel fast, under normal conditions. With fair wind and weather it may make good a speed of about two knots through the water. Hence the importance of wind and current. The navigator used to observing the sea from a high bridge usually overestimates his speed in a lifeboat, where he is only a few feet from the water. With practice, his ability should improve.

Speed may be determined by using a form of **chip log.** Attach a long line to a heavy, floating object. Put one knot in the line twelve or fifteen fathoms from the

object, and another just ten fathoms (or any convenient distance) from the first. Stream the device over the side and let the line run out freely, noting the elapsed time between passage of the two knots through the hand. A variation of this is the **Dutchman's log.** A floating object is thrown overboard at the bow, and the elapsed time required for a known length along the centerline to pass it is noted. If a line is attached to the object, it may be used many times. With either variation, it is well to tie the bitter end of the line to the boat, to minimize danger of losing the whole device overboard.

With either the chip or Dutchman's log, the speed is determined by the formula:

$$S=\frac{60 \text{ seconds per minute} \times 60 \text{ minutes per hour} \times \text{feet between marks}}{6{,}000 \text{ feet per mile} \times \text{ seconds of elapsed time}}.$$

This is equal to:

$$S=\frac{3{,}600 \times \text{feet between marks}}{6{,}000 \times \text{seconds of elapsed time}}=\frac{0.6 \times \text{feet between marks}}{\text{seconds of elapsed time}}.$$

Since the feet between marks is constant, a convenient number can be selected. Thus, if the length is 16⅔ feet, the formula becomes

$$S=\frac{10}{\text{seconds of elapsed time}}.$$

If the elapsed time is ten seconds, the boat is traveling at one knot; if five seconds, at two knots; if eight seconds, at 1¼ knots, etc.

If a watch is not available, a simple pendulum may be devised to time the interval. A piece of string with a weight attached, of a length of 9.8 inches (to the center of gravity of the weight), will, when suspended, make a complete swing (back *and* forth) once every second. For a pendulum 39.1 inches long the period is two seconds. With practice, time can be estimated with fair accuracy.

It is not always possible to head directly along the course to the destination, because of adverse winds. It is better to make good progress in the general direction desired than none at all, and much better on morale. However, at times conditions may be so adverse that it will be best to drop sail until the wind shifts or abates. At such a time a sea anchor should be streamed to minimize loss of precious mileage, and, in severe conditions, to keep the boat headed into the sea.

2616. Position by dead reckoning.—Plotting can be done directly on a pilot chart or plotting sheet. If this proves too difficult, or if an independent check is desired, some form of mathematical reckoning may be useful. Table 2616, a simplified traverse table, can be used for this purpose. This is a critical-type table, various factors being given for limiting values of certain angles. To find the difference or change of latitude, in minutes, enter the table with course angle, reckoned from north or south toward the east or west. Multiply the distance run, in miles, by the factor. To find the departure, in miles, enter the table with the *complement* of the course angle. Multiply the distance run, in miles, by the factor. To convert departure to difference of longitude, in minutes, enter the table with mid latitude. Divide the departure by the factor.

TABLE 2616.—Simplified traverse table.

Example.—A lifeboat travels 26 miles on course 205°, from L 41°44′ N, λ 56°21′ W.

Required.—Latitude and longitude of the point of arrival.

Solution.—The course angle is $205°-180°=S\,25°\,W$, and the complement is $90°-25°=65°$. The factors corresponding to these angles are 0.9 and 0.4, respectively. The difference of latitude is $26\times0.9=23'$ (to the nearest minute) and the departure is $26\times0.4=10$ mi. Since the course is in the southwestern quadrant, in the northern hemisphere, the latitude of the point of arrival is $41°44'\,N-23'=41°21'\,N$. The factor corresponding to the mid latitude $41°32'\,N$ is 0.7. The difference of longitude is $10\div0.7=14'$. The longitude of the point of arrival is $56°21'\,W+14'=56°35'\,W$.

Answer.—L 41°21′ N, λ 56°35′ W.

Celestial Navigation

2617. Celestial coordinates.—Almanac information, particularly declination and Greenwich hour angle of bodies, is important to celestial navigation. If the current *Nautical Almanac* is available, there is no problem. If the only copy available is for a previous year, it can be used for the sun, Aries, and stars without serious error, by lifeboat standards. However, for greater accuracy, proceed as follows: For declination of the sun, enter the almanac with a time that is *earlier* than the correct time by 5^h49^m times the number of years between the date of the almanac and the correct date, adding 24^h for each February 29 that occurs between the dates. If the date is February 29, use March 1 and reduce by one the number of 24^h periods added. For GHA of the sun or Aries determine the value for the correct time, adjusting the minutes and tenths of arc to agree with that at the time for which the declination is determined. Since the adjustment never exceeds half a degree, care should be used when the value is near a whole degree, to prevent the value from being in error by 1°. Appendix X is a long-term almanac giving values of GHA ♈, and GHA and declination of the sun. Instructions for its use are included in the appendix. A reproduction of this almanac might profitably be included in the navigational kit mentioned in article 2602.

If no almanac is available, a rough approximation of the declination of the sun can be obtained as follows: Count the days from the given date to the *nearer* solstice (June 21 or December 22). Divide this by the number of days from that solstice to the equinox (March 21 or September 23), using the equinox that will result in the given date being between it and the solstice. Multiply the result by 90°. Enter table 2616 with the angle so found, and extract the factor. Multiply this by 23°.45 to find the declination.

Example 1.—The date is August 24.

Required.—The approximate declination of the sun.

Solution.—The number of days from the given date to the nearer solstice (June 21) is 64. There are 94 days between June 21 and September 23. Dividing and multiplying by 90°,

$$\frac{64}{94}\times90°=61.^\circ3.$$

The factor from table 2616 is 0.5. The declination is $23.^\circ45\times0.5=11.^\circ7$. It is known to be north because of the date.

Answer.—Dec. 11°.7 N.

The accuracy of this solution can be improved by considering the factor of table 2616 as the value for the mid angle beween the two limiting ones (except that 1.00 is correct for 0° and 0.00 is correct for 90°), and interpolating to one additional decimal. In this instance the interpolation would be between 0.50 at 59°.5 and 0.40 at 66°. The interpolated value is 0.47, giving a declination of 11°.0 N. Still greater accuracy can be obtained by using a table of natural cosines instead of table 2616. By natural cosine the value is 11°.3 N.

If the latitude is known, the declination of any body can be determined by observing a meridian altitude. In a lifeboat it is usually best to make a number of observations shortly before and after transit, plot the values on cross-section paper, letting the ordinate (vertical scale) represent altitude, and the abscissa (horizontal scale) the time. The altitude is found by fairing a curve or drawing an arc of a circle through the points, and taking the highest value. A meridian altitude problem is then solved in reverse.

Example 2.—The latitude of a lifeboat is 40°16′S. The sun is observed on the meridian, bearing north. The *observed* altitude is 36°29′.

Required.—Declination of the sun.

Solution.—The zenith distance is $90° - 36°29' = 53°31'$. The sun is 53°31′ north of the observer, or 13°15′ north of the equator. Hence, the declination is 13°15′N.

Answer.—Dec. 13°15′N.

The GHA♈ can be determined approximately by considering it equal to GMT (in angular units) on September 23. To find GHA♈ on any other date, add 1° for each day following September 23. The value is approximately 90° on December 22, 180° on March 21, and 270° on June 21. The values so found can be in error by as much as several *degrees*, and so should not be used if better information is available. An approximate check is provided by the great circle through Polaris, Caph (the leading star of *Cassiopeia*), and the eastern side of the square of *Pegasus*. When this great circle coincides with the meridian, LHA♈ is approximately 0°. The hour angle of a body is equal to its SHA plus the hour angle of Aries.

If an error of as much as 4°, or a little more, is acceptable, the GHA of the sun can be considered equal to GMT ± 180° (12^h). For more accurate results, one can make a table of the equation of time from the *Nautical Almanac* perhaps at five- or ten-day intervals, and include this in the emergency navigation kit mentioned in article 2602. The equation of time is applied according to its sign to GMT ± 180° to find GHA.

2618. Altitude measurement.—If a sextant is available, either one from the pilot house or an emergency-type instrument, altitudes are measured in the usual manner. The sextant should be shielded as much as possible from wind and spray. If the sea is rough, the observer should brace himself against the mast and make his observation when on the crest of a wave, when the horizon is least likely to be obscured by nearby waves. It is usually good practice to make a number of observations and average both the altitudes and times, or plot on cross-section paper the altitudes versus time, using any convenient time and the corresponding altitude for solving the observation.

The improvisations which may be made in the absence of a sextant are so varied that in virtually any circumstances the application of a little ingenuity and some effort will produce a device for measuring altitude. The results obtained with any improvised method will be approximate at best, but if a number of observations are averaged, the accuracy should be improved. Almost always a measurement, however approximate, is better than an estimate. Two general classes of improvisation are available:

1. *By circle.* Any circular scale, such as a maneuvering board (H.O. 2665–10), compass rose, protractor, or plotter can be used to measure altitude or zenith distance directly. This is the principle of the ancient astrolabe (art. 124). A maneuvering board or compass rose is usually handled best by mounting it on a flat board. A protractor or plotter may be so mounted or used directly. There are a number of variations of the technique of using such a device. Some of them are:

A peg or nail is placed at the center of the circle and perpendicular to it. A weight is hung from the 90° graduation, and a string for holding the device is attached at the 270° graduation. When it is held with the weight acting as a plumb bob, the 0°–180°

line is horizontal (fig. 2618a). In this position the board is turned in azimuth until it is in line with the sun. The intersection of the shadow of the center peg with the arc of the circle indicates the altitude of the center of the sun.

The weight and loop can be omitted and pegs placed at the 0° and 180° points of the circle. While one observer sights along the line of pegs to the horizon, an assistant notes the altitude.

The weight can be attached to the center pin, and the three pins (0°, center, 180°) aligned with the celestial body. The reading is made at the point where the string holding the weight crosses the scale. The reading thus obtained is the zenith distance unless the graduations are labeled to indicate altitude. This method, illustrated in figure 2618b, is used for bodies other than the sun.

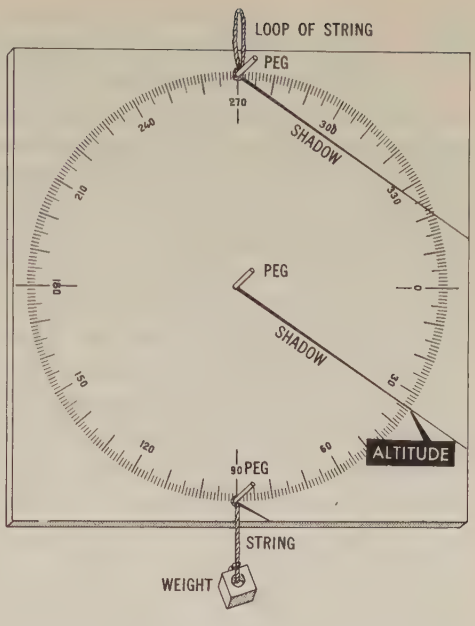

Figure 2618a.—Improvised astrolabe; shadow method. Pegs and board shown tilted for clarity.

Whatever the technique, it is good practice to reverse the device for half the readings of a series, to minimize errors of construction. Generally, the circle method produces more accurate results than the right triangle method, described below.

2. *By right triangle.* The principle of the ancient cross-staff can be used to establish one or more right triangles, which can be solved by measurement of the angle representing the altitude, either directly or by reconstructing the triangle. Another way of determining the altitude is to measure two of the sides of the triangle and divide one by the other to determine one of the trigonometric functions. This procedure, of course, requires a source of information on the values of trigonometric functions corresponding to various angles. If the cosine is found, table 2616 can be used. The tabulated factors can be considered correct to one additional decimal for the value midway between the limiting values (except that 1.00 is the correct value for 0° and 0.00 is the correct value for 90°) without serious error by lifeboat standards. Interpolation can then be made between such values. By either protractor or

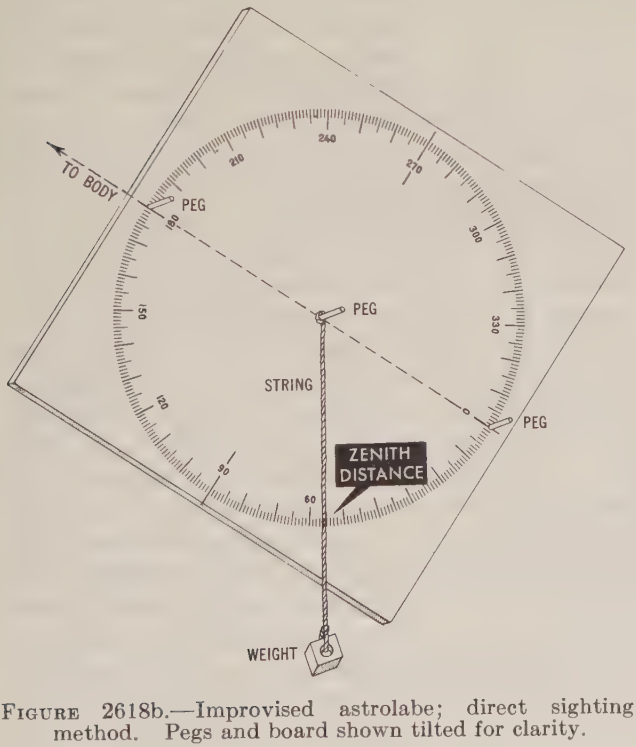

Figure 2618b.—Improvised astrolabe; direct sighting method. Pegs and board shown tilted for clarity.

table, most devices can be graduated in advance so that angles can be read directly. There are many variations of the right triangle method. Some of these are:

Two straight pieces of wood can be attached to each other in such a way that the shorter one can be moved along the longer, the two always being perpendicular to each other. The shorter piece is attached at its center. One end of the longer arm is held to the eye. The shorter arm is moved until its top edge is in line with the celestial body, and its bottom edge is in line with the horizon. Thus, two right triangles are used (the third sides being the slant distances between the ends of the arms) each representing half the altitude (fig. 2618c). For low altitudes, only one of the triangles is used, the long arm being held in line with the horizon. The length of half the short arm, divided by the length of that part of the long arm between the eye and the intersection with the short arm, is the tangent of half the altitude (the whole altitude if only one right triangle is used). The cosine can be found by dividing that part of the long arm between the eye and the intersection with the short arm by the slant distance from the eye to one end of the short arm. Graduations consist of a series of marks along the long arm indicating settings for various angles. The device should be inverted for alternate readings of a series.

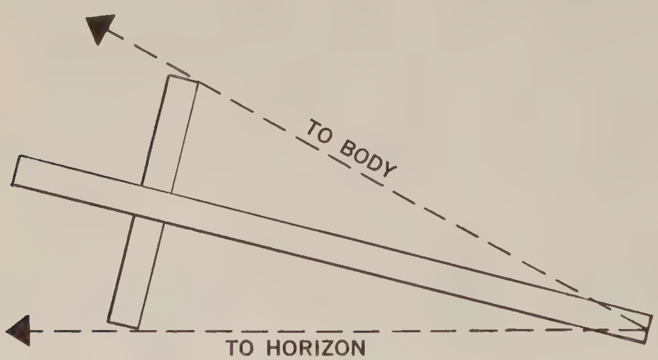

FIGURE 2618c.—Improvised cross-staff.

A rule or any stick can be held at arm's length. The top of the rule is placed in line with the celestial body being observed, and the top of the thumb is placed in line with the horizon. The rule is held vertical. The length of rule above the thumb, divided by the distance from the eye to the top of the thumb is the tangent of the angle observed. The cosine can be found by dividing the distance from the eye to the top of the thumb by the distance from the eye to the top of the rule. If the rule is tilted toward the eye until the minimum of rule is used, the distance from the eye to the middle of the rule is substituted for the distance from the eye to the top of the thumb, *half* the length of the rule above the thumb is used, and the angle found is multiplied by two. Graduations consist of marks on the rule or stick indicating various altitudes. For the average observer each inch of rule will subtend an angle of about 2°3, assuming an eye-to-ruler distance of 25 inches. This relationship is good to a maximum altitude of about 20°. The accuracy of this relationship for a specific observer can be checked by comparing the measurement against known angles in the sky. Angular distances between stars can be computed by sight reduction methods, including H.O. Pub. No. 214, by using the declination of one star as the latitude of the assumed position, and the difference between the hour angles (or SHA's) of the two bodies as the meridian angle. The angular distance is the complement of the computed altitude. The angular distances between some well-known star pairs are: end stars of *Orion's* belt, 2°7; pointers of the big dipper, 5°4; Rigel to *Orion's* belt, 9°0; eastern side of the great square of *Pegasus*, 14°0; Dubhe (the pointer nearer Polaris) and Mizar (the second star in the big dipper, counting from the end of the handle), 19°3.

The angle between the lines of sight from each eye is, at arm's length, about 6°. By holding a pencil or finger horizontal, and placing the head on its side, one can estimate an angle of about 6° by closing first one eye and then the other, and noting how much the pencil or finger appears to move in the sky.

The length of the shadow of a peg or nail mounted perpendicular to a horizontal board can be used as one side of an altitude triangle. The other sides are the height of the peg and the slant distance from the top of the peg to the end of the shadow. The height of the peg, divided by the length of the shadow, is the tangent of the altitude of the center of the sun. The length of the shadow divided by the slant distance is the cosine. Graduations consist of a series of concentric circles indicating various altitudes, the peg being at the common center. The device is kept horizontal by floating it in a bucket of water. Half the readings of a series are taken with the board turned 180° in azimuth.

Two pegs or nails can be mounted perpendicular to a board, with a weight hung from the one farther from the eye. The board is held perpendicular and the two pegs aligned with the body being observed. The finger is then placed over the string holding the weight, to keep it in position as the board is turned on its side. A perpendicular is dropped from the peg nearer the eye, to the string. The altitude is the acute angle nearer the eye. For alternate readings of a series, the board should be inverted. Graduations consist of a series of marks indicating the position of the string at various altitudes.

As the altitude decreases, the triangle becomes smaller. At the celestial horizon it becomes a straight line. No instrument is needed to measure the altitude when either the upper or lower limb is tangent to the horizon, as the "sextant" altitude is then 0°.

2619. Sextant altitude corrections.—If altitudes are measured by a marine sextant, the usual sextant altitude corrections apply (ch. XVI). If the center of the sun or moon is observed, either by sighting at the center or by shadow, the lower-limb corrections should be applied, as usual, and an additional correction of (−)16′ applied. If the upper limb is observed, use (−) 32′. If a weight is used as a plumb bob, or if the *length* of a shadow is measured, omit the dip (height of eye) correction.

If the almanac is not available for making corrections, each source of error can be corrected separately, as follows:

Index correction. If a sextant is used, the index correction should be determined and applied to all observations, or the sextant adjusted to eliminate index error.

TABLE 2619.—Refraction.

Refraction is given to the nearest minute of arc in table 2619. The value for a horizon observation is 34′. If the nearest 0°1 is sufficiently accurate, as with an improvised method of observing altitude, a correction of 0°1 should be applied for altitudes between 5° and 18°, and no correction applied for greater altitudes. Refraction applies to all observations, and is always a minus (−) correction.

Dip, in minutes of arc, is approximately equal to the square root of the height of eye, in feet. The correction applies to all observations in which the horizon is used as the horizontal reference. It is always a minus (−) correction. If 0°1 accuracy is used, no dip correction is needed for lifeboat heights of eye.

Semidiameter. The semidiameter of either the sun or moon does not differ greatly from 16′. The correction does not apply to other bodies or to observations of the center of the sun and moon, by whatever method, including shadow. The correction is plus (+) if the lower limb is observed, and minus (−) if the upper limb is observed.

Parallax. For lifeboat accuracy, parallax is applied to observations of the moon only. An approximate value, in minutes of arc, can be found by multiplying 57′ by the factor from table 2616, entering that table with altitude. For more accurate results the factors can be considered correct to one additional decimal for the altitude

midway between the limiting values (except that 1.00 is correct for 0° and 0.00 is correct for 90°), and the values for other altitudes can be found by interpolation. This correction is always plus (+).

For observations of celestial bodies on the horizon, the total correction for zero height of eye is:

Sun. Lower limb: (−) 18′, upper limb: (−) 50′.
Moon. Lower limb: (+) 39′, upper limb: (+) 7′.
Planet or star. (−) 34′.

Dip should be added algebraically to these values.

Since the "sextant" altitude is zero, the "observed" altitude is equal to the total correction.

2620. Sight reduction.—If any tables designed for sight reduction, such as H.O. Pub. No. 214, are available, they should be safeguarded to prevent loss or damage. If trigonometric tables and the necessary formulas are available, they will serve the purpose. Speed in solution is seldom a factor in a lifeboat. A slow method might actually be an asset, from a morale standpoint, as it will provide occupation for a limited time for at least one crew member. If tables but no formulas are available, carefully determine the mathematical knowledge possessed by the crew. Someone may be able to provide the missing information. If the formulas are available, but no tables, approximate natural values of the various trigonometric functions can be obtained graphically by the method explained in article O39. Graphical solution of the navigational triangle can be made by the orthographic method explained in article 1432. A maneuvering board (H.O. 2665–10) might prove helpful in the graphical solution for either trigonometric functions or altitude and azimuth. Very careful work will be needed for useful results by either method.

Unless full navigational equipment is available, better results might be obtained by making separate determinations of latitude and longitude.

2621. Latitude determination.—Several methods are available for determining latitude, and in none of them is accurate time needed.

Meridian altitude. Latitude can be determined by means of a meridian altitude of any body, if its declination is known. The method is explained in article 2103. If accurate time, knowledge of the longitude, and an almanac are available, the observation can be made at the correct moment, as determined in advance. However, if any of these is lacking, or if an *accurate* altitude-measuring instrument is unavailable, better procedure is to make a number of altitude observations before and after meridian transit. A plot is then made of altitude versus time, if cross-section paper is available, and the highest (or lowest, for lower transit) altitude is scaled from a curve faired through the plotted points. At lifeboat speeds this procedure is not likely to introduce a significant error. The time used for plotting the observations need not be accurate, as *elapsed* time between observations is all that is needed, and this is not of critical accuracy. Thus, even a watch that has run down and then been rewound can be used without resetting. Any altitudes that are not consistent with others of the series should be discarded.

Polaris. Latitude by Polaris is explained in article 2105. In a lifeboat, only the first correction is of practical significance. If suitable tables are not available, this correction can be estimated. The trailing star of *Cassiopeia* (ϵ *Cassiopeiae*) and Polaris have almost exactly the same SHA. The trailing star of the big dipper (Alkaid) is nearly opposite Polaris and ϵ *Cassiopeiae*. These three stars, ϵ *Cassiopeiae*, Polaris, and Alkaid, form a line through the pole (approximately). When this line is horizontal, there is no correction. When it is vertical, the maximum correction of 56′ applies.

It should be added to the observed altitude if Alkaid is at the top, and subtracted if ϵ *Cassiopeiae* is at the top. For any other position, estimate the angle this line makes with the vertical (fig. 2621), and multiply the maximum correction (56′) by the factor from table 2616, adding if Alkaid is higher than ϵ *Cassiopeiae*, and subtracting if it is lower. For more accurate results, the factor from table 2616 can be considered accurate to one additional decimal for the mid value between those tabulated (except that 1.00 is correct for 0° and 0.00 for 90°). Other values can be found by interpolation.

Length of day. The length of the day varies with latitude. Hence, latitude can be determined if the elapsed time between sunrise and sunset can be observed. Correct the observed length of day by *adding* 1^m for each 15′ of longitude traveled toward the east and *subtracting* 1^m for each 15′ of longitude traveled toward the west. The latitude determined by length of day is the value for the time of meridian transit. Since meridian transit occurs approximately midway between sunrise and sunset, half the interval may be observed and doubled. If a sunrise and sunset table is not available, the length of daylight can be determined graphically by means of a diagram on the plane of the celestial meridian (art. 1432). A maneuvering board (H.O. 2665–10) is useful for this purpose. This method cannot be used near the time of the equinoxes, and is of little value near the equator. The moon can be used if moonrise and moonset tables are available, but with the moon the half-interval method is of insufficient accuracy, and allowance should be made for the longitude correction.

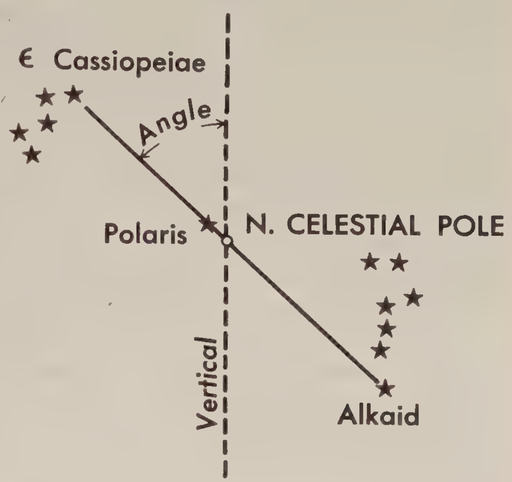

FIGURE 2621.—Relative positions of ϵ *Cassiopeiae*, Polaris, and Alkaid with respect to the north celestial pole.

Body in zenith. The declination of a body in the zenith is equal to the latitude of the observer. If no means are available for measuring the altitude, the position of the zenith may possibly be estimated in a calm sea by lying in the lifeboat and looking skyward. The accuracy of the results depends upon the ability to estimate the position of the zenith. Use of a plumb bob may help.

Variation of the compass can occasionally be used for determining latitude, as explained in article 2622.

2622. Longitude determination.—Unlike latitude, longitude requires accurate Greenwich time for its determination by astronomical means. All such methods consist of noting the Greenwich time at which a phenomenon occurs locally. In addition, a table indicating the time of occurrence of the same phenomenon at Greenwich, or equivalent information, is needed.

Time of transit. When a body is on the local celestial meridian, its GHA is the same as the longitude of the observer if in west longitude, or $360° - \lambda$ in east longitude. Thus, if the GMT of local transit is determined and a table of Greenwich hour angles (or time of transit of the Greenwich meridian) is available, longitude can be computed. If only the equation of time is available, the method can be used with the sun. This is the reverse of the problem of finding the time of transit of a body (art. 2104). The time of transit is not always apparent. If a curve is made of altitude versus time, as suggested in article 2621, the time corresponding to the highest altitude is used in the determination of longitude. Under some conditions it may be preferable to observe

an altitude before meridian transit and then again after meridian transit, when the body has returned to the same altitude as at the first observation. Meridian transit occurs midway between these two times. A body in the zenith is on the celestial meridian. If accurate azimuth measurement is available, note the time when the azimuth is 000° or 180°.

Sunrise and sunset. The difference between the observed GMT of sunrise or sunset and the LMT tabulated in the almanac is the longitude in time units, which can then be converted to angular measure. If the *Nautical Almanac* is used, this information is tabulated for each third day only. Greater accuracy can be obtained if interpolation is used for determining intermediate values. Moonrise or moonset can be used if the tabulated LMT is corrected for longitude (art. 1812). Planets and stars can be used if the means are available for determining the time of rising or setting. This can be determined by computation (art. 2536) or, approximately, by means of a diagram on the plane of the celestial meridian (art. 1432).

Either of these methods can be used in reverse to set a watch that has run down, or to check the accuracy of a watch, if the longitude is known. In the case of a meridian transit the time need not be determined at the instant of transit. The watch is started and the altitude is then measured several times before and after transit, or at equal altitudes. The times of these observations are noted and from them the time of meridian transit is determined. The difference between this time and the correct time of transit can then be used as a correction to reset the watch. If a watch runs down and cannot be reset from other timepieces, the correct time should be determined at the first opportunity, if the longitude accuracy is likely to deteriorate.

Variation of the compass. If the deviation of the compass is known accurately and an accurate azimuth can be observed, it is possible to determine the variation. If this is compared with the variation shown on the pilot chart, an approximate line of position can be determined. Since in many areas these lines run in a generally north-south direction, this may be an indication of the longitude. However, if the line has a large east-west component, it should be considered as any other such line of position, rather than as a longitude line. In some areas it is more nearly a latitude line. The accuracy of the method depends upon the accuracy with which the variation can be determined, and the spacing between adjacent isogonic lines.

Time sight. If altitude of a celestial body is available, including zero "sextant" altitude at rising or setting (art. 2619), longitude can be found by time sight (art. 2106).

Approaching Land

2623. Signs of land.—There are a number of signs which may indicate that the lifeboat is approaching land.

The sky will sometimes indicate a break in the open sea. A small fixed cloud, when surrounding ones are in motion or absent, will usually be over or close to land. At high latitudes, a light-colored reflection in the sky might be over an ice area; a light green reflection in the tropical sky might indicate a shallow lagoon. Such indications may be even more apparent on the under side of a uniform cloud layer.

Birds most often fly away from land at dawn and toward it at dusk. A large number of birds may indicate the nearness of land.

Swell, properly interpreted, may be used as a guide to land. Consecutive swells travel parallel until they reach an island and then "bend" around it. Eddies are formed where the distorted swell meets beyond the island. This eddy line may be used as a bearing to land, sometimes at a considerable distance.

The color of the sea may act as a guide in finding land as the open sea generally appears dark blue or dark green, and a lighter shade indicates shallow water, which may be near land.

The sound of the surf is often heard while still a considerable distance from land. Other sounds may also be heard at great distances.

Odors, as from burning wood, sometime carry a long way out to sea.

Sounds and odors may be particularly helpful in periods of reduced visibility.

2624. Distance off.—At sea in a lifeboat the navigator is handicapped by his limited range of visibility. Distance to the horizon, in nautical miles, is given approximately by the formula $1.15\sqrt{h}$, h being the height of eye in feet. Thus, distance in miles is approximately 1⅐ times the square root of the height in feet. At an eye height of nine feet, the horizon is about 3½ miles away. A loaded Victory ship, whose greatest mast height is about 81 feet above the water line, could be seen $1.15\sqrt{81}$ or 10.35 miles by an observer at zero height of eye. At a height of eye of nine feet the top of the mast should break the horizon when the ship is about 13.8 miles off.

If the height of an object above the horizon, or the distance between points on it, is known, a simple proportion can be solved to determine the distance off by use of the cross-staff (art. 2618) or a similar device. To do this, align the two ends of the crosspiece with top and bottom, or two ends, of the object. The ratio of the length of the crosspiece to the length from this piece to the eye is the same as the ratio of the

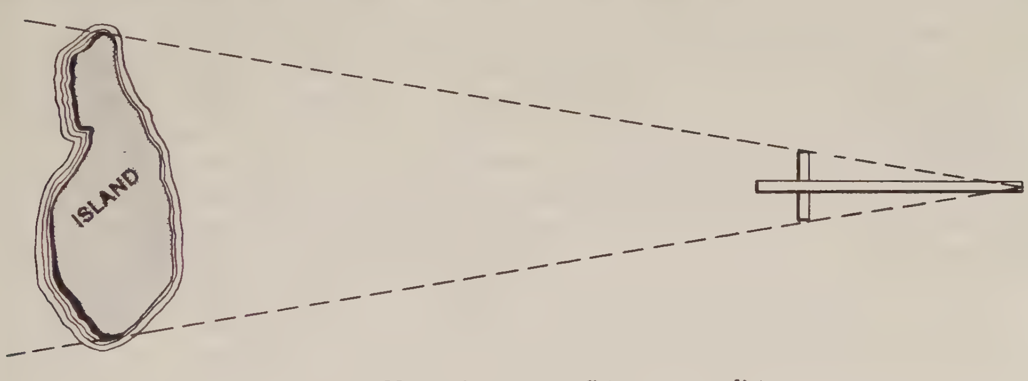

FIGURE 2624.—Using the cross-staff to measure distance.

height (or length) of the object to its distance from the observer (fig. 2624). Thus, if the crosspiece is 18 inches and the intercepted length of the long piece is 31 inches, the distance to an island 1½ miles wide in the line of sight is found from the proportion

$$\frac{18}{31}=\frac{1.5}{D}, \text{ or } \frac{D}{1.5}=\frac{31}{18}$$

$$D=\frac{1.5\times 31}{18}=2.6 \text{ miles.}$$

In this proportion the two parts of either fraction must be expressed in the same units if results are to be obtained without a conversion factor. Thus, both 18 and 31 are expressed in inches, and both 1.5 and 2.6 are in miles. For small or distant objects the crosspiece may be too long. In this case replace it with a shorter one, use half or less of it, or substitute some other device such as a rule held at arm's length. In the case of a height, only the visible part of the object is used if the horizon is between the observer and the object.

A variation of this method can produce approximate results rather quickly. Hold a pencil, stick, or finger vertical at arm's length. Close one eye and align the vertical member with one end of an object such as an island. Open the closed eye and close the other one. Estimate the distance the vertical member appears to move against the background. The distance of the background object is ten times the amount of apparent movement, in the same units. The actual ratio varies somewhat among individuals and can be determined by comparing the length of the outstretched arm with the distance between eyes—or by practice on objects of known size at known distances. For vertical objects hold the extended member horizontal and bend the head until it, also, is horizontal.

2625. Beaching the boat.—The beaching of a lifeboat may be one of the most dangerous parts of the entire experience. The approach to an island should be made on the lee side, if possible, and every effort should be made to attract the attention of any inhabitants so that advice on the best place to land, and perhaps assistance, might be obtained. If no help is available, sail parallel to the coast to study the terrain and determine the safest place to beach the boat. A lagoon or other sheltered area may be available. It may be necessary to delay the landing overnight to make a complete study of the terrain and to beach the boat by daylight. Surf appears less rough from the sea than from land. High spray indicates a rough surf.

If a steering oar is available, the rudder should be unshipped before the boat is brought in, as the steering oar will provide better control in the surf zone. The sea anchor should be used to lessen the possibility of broaching and capsizing. Storm oil should be used, if available, to reduce the roughness of the surf. It is possible that the course can be altered somewhat while heading in to the beach, to take advantage of a better opening, but care should be taken to avoid broaching. Additional information on handling a boat in a surf can be found in nearly any book on seamanship.

2626. Ashore.—Once the boat has been safely beached, the problem remains to lead the survivors to civilization. Perhaps the land will be heavily populated and the boat met by local people, or the way to safety may be indicated by a road or trail. But the boat may be beached at a deserted place where there are no signs of life.

Chapter XXVII, "Land Navigation," deals with this problem in detail, but remember that the choice of an initial course is almost as important in this case as it is at sea. Generally, it is good practice to follow the coast, but if the shore is obviously unsuitable for boat activity, a port is not likely to be nearby. The jungle should be avoided for travel, but it may be a plentiful source of food if nonpoisonous plants can be recognized. Often a stream can be followed to an inhabited place, for some source of water is essential to the maintenance of life. In an arid region, distant vegetation may be an indication of habitation.

Many of the methods used to determine position at sea may also be used ashore, and usually with greater accuracy due to the absence of motion. A distinctive method of determining the meridian while ashore is by a variation of the equal altitude method. Place a stick or rod upright on a level area, using a plumb bob to establish the perpendicularity of the stick. About an hour before noon mark the point where the tip of the stick's shadow falls, and draw a circle through this point, with the base of the stick as its center. Mark the point where the tip again falls exactly on the perimeter of the circle. Midway between the two points lies the meridian of the observer.

Problems

2613a. The compass azimuth of the sun is 126° at rising and 252° at setting.
Required.—Compass error.
Answer.—CE 9° W.

2613b. A life preserver is thrown overboard from a lifeboat and the boat headed away on course 355°. At a distance of half a mile the boat turns and heads back for the life preserver. The return course is 169°. The variation is 5° W.

Required.—(1) True course back to the life preserver.

(2) Deviation on this heading.

Answers.—(1) TC 167°, (2) D 3° E.

2615. The two knots in the log line of an improvised chip log of a lifeboat are 16⅔ feet apart. The elapsed time between passage of the knots through the hands of the observer is four seconds.

Required.—Speed of the lifeboat.

Answer.—S 2.5 kn.

2616. A lifeboat travels 18 miles on course 110°, from lat. 35°15′ S, long. 82°31′ W.

Required.—Latitude and longitude of the point of arrival.

Answer.—L 35°20′ S, λ 82°11′ W.

2617a. The date is November 15.

Required.—The approximate declination of the sun, without reference to an almanac.

Answer.—Dec. 18°.8 S.

2617b. The latitude of a lifeboat is 22°47′ N. A star is observed on the meridian, bearing north. The observed altitude is 66°50′.

Required.—Declination of the star.

Answer.—Dec. 45°57′ N.

2617c. The GMT is 1000, October 15.

Required.—Approximate GHA ♈, without reference to an almanac.

Answer.—GHA ♈ 172°.

2624. Approaching land, the navigator wishes to determine his distance from a lighthouse situated on the coast. He holds a rule at arm's length and finds that ⅝ inch of the rule appears the same height as the top of the lighthouse above water. He estimates the distance from his eye to the rule as 24 inches, and the height of the top of the lighthouse as 150 feet above water.

Required.—Distance to the lighthouse.

Answer.—D 0.9 mi.

CHAPTER XXVII

LAND NAVIGATION

2701. Introduction.—Land navigation is the process of directing movement across land or ice, from one point to another. When travel is along a well-marked system of highways, trails, railways, etc., a good map and distance-measuring device are all that are needed. But when travel is across unmarked areas, navigation may be more difficult. When the track leads across an open expanse of desert, tundra, or ice, the methods of navigation most nearly approach those used at sea or in the air.

The equipment used and the procedure followed should be suited to the circumstances. A high degree of common sense and adaptability is needed. It would be a waste of effort to measure accurately every change of course if one were following a stream whose general direction is known, but across an area without features, each change of course might be of great importance. Sometimes a considerable amount of ingenuity is needed to adapt available equipment or to improvise a suitable piece of equipment to meet a particular need. On land, as at sea or in the air, the navigator should use all available means to further his end. Even odors can be utilized to advantage in some instances. In any case, a preliminary estimate of the situation and advance planning are important, as is constant vigilance en route.

Basically, navigation on land combines the same elements as navigation at sea. Dead reckoning, piloting, electronic navigation, and celestial navigation all have their use. In general, the equipment should be simple, reliable, rugged, and capable of withstanding exposure to the weather. The mounting of equipment and the facilities for plotting may leave much to be desired. Plotting in a vehicle crossing rough terrain may be impossible while underway.

No trip across unfamiliar or desolate terrain should be attempted without provision for adequate navigation, whether travel is by wheeled vehicle, tank, dog sledge, or afoot. An adequately trained individual should have primary responsibility for navigation, and should be provided with the necessary navigational aids to suit the circumstances. Assistants or alternates should be provided when appropriate, as when a casualty is a reasonable possibility. During the trip the navigator should be given opportunity to perform his assignment. Sometimes this may involve stops that would not otherwise be scheduled.

2702. Charts.—The most useful charts for land navigation are topographic—those showing elevations and various features of the topography. With a large-scale map showing great detail, both the selecting and following of a route are relatively simple, if there is a sufficient number of identifiable landmarks. Over flat, open country the map is little more than a plotting sheet. The projection is not important, as long as it is conformal (art. 302) so that angles and small shapes are correctly represented. Since long, straight courses are rare, the form of representation of a great circle is seldom important.

2703. Dead reckoning on land, as on the sea or in the air, consists of determining position by means of the direction and distance traveled since leaving a known position. A careful log should be kept. If the track is across an unsurveyed area, and if there is a possibility of future passages over the same area, descriptions of the various landmarks encountered should be included in the log.

Plotting may or may not be desirable. Along a well-marked route, the track can be plotted in advance, and positions along the track can be marked as determined, either by dead reckoning or otherwise. Since it is usually difficult to plot accurately

while riding or walking, the usual procedure is to keep a log and stop at intervals to bring the plot up-to-date. Each item of the log should be recorded as it occurs, leaving nothing to memory.

Over rugged terrain it is seldom practical to proceed directly toward the objective, and the track selected is one which avoids the most difficult obstacles. Under these conditions, the directions and distances used are averages. With practice, one can become adept at estimating the course and distance made good along a track having many changes of direction. When traversing an unfamiliar or poorly mapped area, one may find it necessary to select the route as he proceeds, nearly always attempting to work closer to the destination, but frequently departing from the direct path to take advantage of features of the terrain.

Several types of mechanical dead reckoning equipment have been devised. One type, known as a **vehicle direction and position indicator,** is designed for vehicle installation and operates from the vehicle electrical system. With inputs from a gyro compass and the odometer drive, it automatically computes and continuously displays the vehicle position in map coordinates. It also computes and displays the distance and direction to a preselected destination. It is designed for the addition of a map plotter which can plot the course followed.

In any form of dead reckoning, it is well to keep in mind that if a heavy cross wind is blowing, a certain amount of leeway can occur.

2704. Direction.—Over flat, open country, a steady course is relatively easy to follow. In rugged or wooded country, many variations are needed. Under these circumstances the direction made good is more important than individual directions of motion. The determination of direction made good can often be accomplished by measuring the bearing of a distant feature such as a mountain peak, prominent tree or rock, a bend in a river or valley, etc., toward which one is steering. If the route follows a river, mountain ridge, etc., the general trend of the feature can usually be determined. The features which make necessary frequent changes of course can themselves sometimes be used for establishing average directions. Celestial bodies, too, can be used as a steering guide if their changing azimuth is considered. The sun and moon are invaluable aids. Polaris and bodies nearly east or west are particularly useful because of their relatively slow change of azimuth. Even a steady wind, sastrugi (windrows on snow), or clouds can be used, if one is careful to interpret them properly.

The type of compass used varies with the circumstances. Magnetic, gyro, and sun compasses are all used by land navigators.

FIGURE 2704a.—Pocket compass.

A **magnetic compass** used in land navigation is subject to the same errors as one used at sea or in the air. Seldom is a vehicle an ideal location for a compass. The deviating forces are large, and in some cases erratic. If a compass designed for the vehicle is not available, a boat compass might be used, but an aircraft-type compass may be more suitable. If the vehicle is a dog sledge, the compass might best be lashed to a convenient part. In a tank, truck, or jeep a permanent installation may be made. Frequent changes of compass from one vehicle to another should be avoided, but where this is necessary, some type of bracket or box should be provided to permit rapid installation and alignment.

Careful magnetic adjustment (compensation) is essential if accurate results are to be obtained. Usually, only permanent magnets are used, and in some compasses, notably those of the aircraft type, these are permanently mounted in the compass case, being controlled by a screw driver. If a compass is to be moved from vehicle to vehicle, the adjustment might be made in the vehicle itself. This is best done by attaching magnets to the box in which the compass is placed. With any type o adjustment, corrections may be needed if the magnetic latitude changes considerably

FIGURE 2704b.—Wrist compass.

Some experimentation may be necessary to establish the best location for the compass. In general, a position should be found as remote as convenient from the motor and electric wiring. A vertically graduated aircraft-type compass might be mounted near the top of the windshield with satisfactory results. The dashboard is probably the worst location in most instances.

Magnetic adjustment should be made with the motor running and with all magnetic equipment in its regular place. The effect on the compass of various electrical equipment, such as lights, windshield wiper, etc., should be noted. If needed, a deviation table should be made up, separate tables being made for as many conditions as necessary. In the determination of deviation, the vehicle can be pointed toward identifiable distant objects, or a hand-held compass used at a sufficient distance from the vehicle to permit accurate determination of direction and to preclude magnetic influence of the vehicle. A compass rose located on the surface of an aerodrome can be used satisfactorily, if available.

A **portable compass** has many uses, and if the party is proceeding on foot, it is the only type suitable. It may be a hand-held compass weighing several pounds, or, more often, a small pocket or wrist compass weighing but a few ounces. A pocket compass is shown in figure 2704a, and a wrist compass in figure 2704b. In figure 2704a note the

lubber's line and the sighting vanes for measuring bearings. No provision is made for adjusting a portable magnetic compass. When such an instrument is used, readings should be made a sufficient distance from a vehicle or other magnetic material and power lines to avoid any deviating influence. Magnetic material such as knives, keys, etc., should be removed from the observer's person during observation, unless it is determined that they have no effect on the compass in the position used. Magnetic material in the earth can cause deviation. The presence of such material is usually indicated by erratic operation of the compass when moved a short distance.

A vehicle **gyro compass** has been developed and is used where the need warrants. It is particularly useful in regions where the magnetic compass is not suitable, as near the magnetic poles and in areas of extensive deposits of magnetic material. It is also used in vehicles where satisfactory magnetic compass installations are difficult or impossible, as in some tanks.

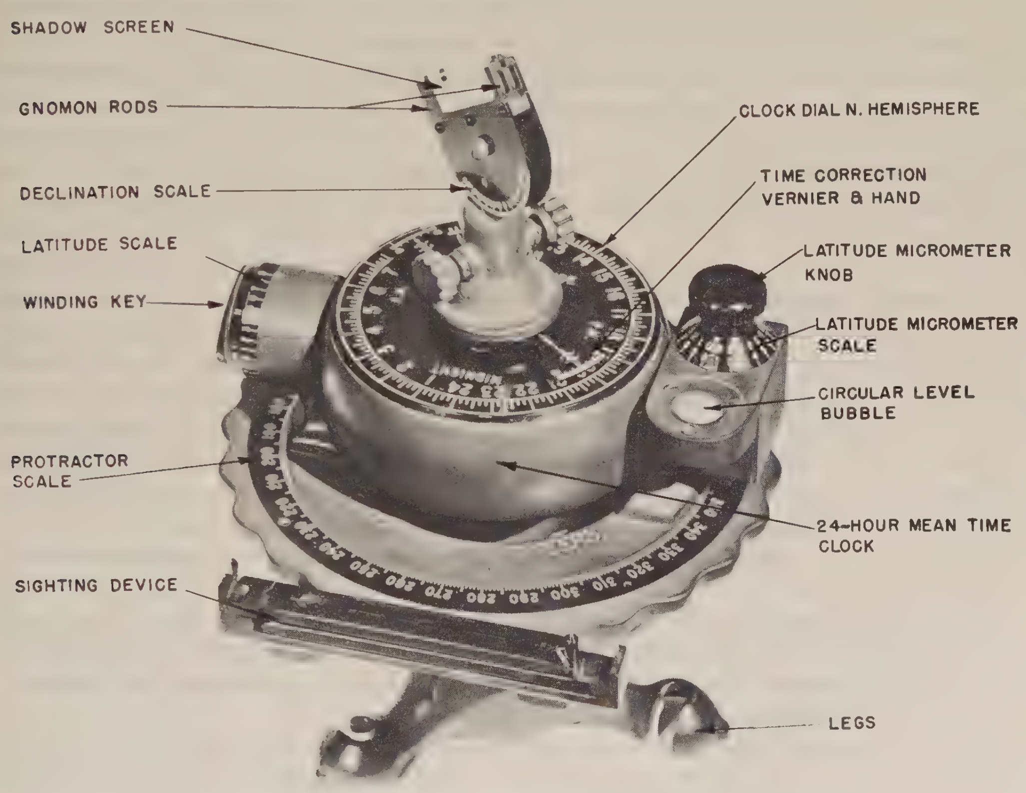

FIGURE 2704c.—Sun compass.

A **sun compass,** figure 2704c, is a mechanical device for determining true directions by means of celestial bodies, principally the sun. It is free from magnetic disturbances and gyro errors, and needs no source of power. However, an almanac or other source of celestial coordinates, accurate time, and a knowledge of the approximate position of the observer are needed, and use of the instrument is limited to periods when a celestial body is visible. This last limitation affects the choice of a mounting position for the instrument.

Like the astro compass used in aircraft (art. 2515), the sun compass is not a compass in the usual sense of *seeking* a reference direction. Both instruments consist of sighting

devices which are oriented with respect to the axis and equator of the earth, and the horizontal. When the device is so oriented and the sighting assembly or shadow is properly aligned with the celestial body, true directions are indicated on a circular scale. Generally, the device is not used as a continuous indication of direction, but as a means of checking direction at intervals. Each time an observation is made the setting of the instrument is changed to agree with the coordinates of the celestial body and observer at the time and place of observation. If the device is used for steering, it usually need not be reset oftener than every ten to 15 minutes.

Several emergency methods of establishing the approximate direction of north are available. These are discussed in chapter XXVI. The method of *double altitudes* is particularly applicable on land, where a plumb bob can be improvised and the length of the shadow measured. At the time the first altitude is observed, perhaps an hour before noon, an arc of a circle can be marked on the ground, with the center at the foot of the plumb line, and of radius equal to the length of the shadow. The position of the shadow tip on the circle is marked. The second altitude occurs when the end of the shadow is again on the arc of the circle. From the plumb line, north (or south if the sun is north of the observer) is midway between the two equal-length shadows, if the ground is level.

2705. Distance.—In land navigation, distance is usually determined directly, rather than by means of speed and time. Speed may be used if constant enough, but this is rarely the case.

For a vehicle with wheels, the obvious method is by **odometer,** the distance-measuring device associated with a speedometer. For accurate results such a device should be carefully calibrated. Size of tires, amount of tread left on tires, pressure, loading, speed of the vehicle, and nature of the surface over which the vehicle travels all affect the reading. However, except in extreme conditions, an average calibration should produce good results. If the odometer is attached to the drive shaft, a certain amount of slippage occurs, but allowance for this can be made in the calibration. Road slippage, as when traveling on a slippery surface or one of loose material, results in too great a reading. If the terrain is hilly, or if frequent minor changes in track are needed to avoid obstacles, the distance indicated by odometer is greater than that shown on the chart.

When one is traveling by sledge over snow or ice, a bicycle wheel can be attached and a metering device connected to it. Most accurate results can be obtained if the tire is used in a deflated condition, as it will then resist the tendency to increase in diameter by accumulation of snow.

When traveling on foot, one can use a **pedometer,** a small, watch-size instrument, usually attached to the belt, that records the number of steps taken. If this instrument is calibrated in distance, it should be adjusted to the length of step of the wearer. If such a device is not available, the number of steps or paces can be counted. If this is done, it is well to have some method of preventing loss of the count. This might be done by means of a counting device that registers each time a plunger is depressed. This may be done at each pace (two steps), or at each multiple such as ten or 100 paces. If no counting device is available, or if one of limited range is used, a small stone or other object transferred from one pocket to another at intervals, as each 1,000 paces, may prevent loss of count. With any method of counting steps or paces it is well to consider the nature of the terrain, and other factors affecting the length of the pace. Over soft ground, in high grass or weeds, and along inclined surfaces the length of the pace differs from that on firm, level ground, generally becoming shorter. It may also shorten as

the walker tires, and its effective length is reduced as he makes short detours to avoid obstacles. A strong wind may either shorten or lengthen the pace. Variations in the length of the pace can be handled by calibration over an area representative of the conditions encountered, or by dropping (or adding) one pace out of a certain number, as determined by measurement or estimate.

2706. Piloting.—In land navigation piloting is generally quite simple, consisting merely of the recognition of landmarks, and notation of the time and distance at which they are passed. It is somewhat similar to the passage of buoys as one proceeds along a channel. In open country with distant mountains, bearings of identifiable features can be plotted and ranges can be observed when two features are in line.

2707. Electronic navigation is seldom available on land, but should be used if one has access to it. The most common electronic aid used is some form of radio direction finder (directional characteristics of the loop antenna of a portable radio may be utilized), usually used in connection with a transmitter at the destination. In this case the direction finder is used as a homing device. If signals from other radio transmitters at known locations can be received, position can be determined by plotting two or more bearings. On land, radio reception is weak or nonexistent in certain "blind spots," and the accuracy of readings taken may be affected if the receiver is near man-made or natural obstacles. Power or telephone lines, fences, railroad tracks, buildings, or cliffs are particularly to be avoided if accurate bearings are required. Atmospheric and magnetic conditions also affect radio transmission.

2708. Celestial navigation.—In areas with an abundance of landmarks, or where an adequate method of homing is available, celestial navigation is not generally used, except, possibly, in relation to a sun compass (art. 2704). However, in open country without identifiable or stable features, as on the desert or in some parts of polar regions, celestial navigation may provide the only means, other than dead reckoning, of determining position.

A marine sextant is not suitable with the type of horizon generally encountered on land. However, if an artificial horizon (art. 1512) is available or can be improvised, the instrument can provide satisfactory results. An aircraft-type sextant with a built-in artificial horizon, such as a bubble (art. 1513), may be suitable. If greater precision is desired, a surveying instrument such as a theodolite (art. 4004) or astrolabe (art. 4002) can be used. For any of these instruments, accurate results can be expected only by stopping and making the observations from a stable position. Accurate timing of the observation is essential unless the observation is of a meridian altitude or Polaris, or unless the observer is near one of the geographic poles.

Sight reduction can be accomplished by any suitable method, several of which are described in chapters XX and XXI.

When one is operating in an area where celestial navigation is needed, it is good practice to obtain fixes twice daily, or oftener, if available. Celestial navigation may also be useful when the continuity of dead reckoning has been broken and identifiable landmarks are not available, as during a battle in time of war.

CHAPTER XXVIII

AIR NAVIGATION

2801. Introduction.—Air navigation is the navigation of all types of aircraft, including propeller-driven airplanes, jet airplanes, helicopters, dirigibles, blimps, balloons, and airborne guided missiles. The term **aircraft** includes any craft designed for transportation through the air, except (1) safety contrivances such as a parachute and (2) spacecraft designed for operation outside the earth's atmosphere.

The elements of air navigation are the same as those of marine and land navigation, but with some differences in methods, practices, and emphasis. These differences result primarily from unique conditions encountered in air navigation, as follows:

1. *Need for continued motion.* A ship or land vehicle can stop, if necessary, and resolve any uncertainty of position, awaiting more favorable conditions if necessary. Except to a limited extent, most aircraft must keep going.

2. *Limited endurance.* Most aircraft can remain aloft for a relatively short time, the period usually being a matter of hours.

3. *Greater speed.* The speed of propeller-driven aircraft is about 20 times that of ships. Jet aircraft are even faster. The speed of lighter-than-air craft and helicopters is about five to ten times that of ships. Quicker navigation methods are needed, even if some accuracy is sacrificed.

4. *Three-dimensional navigation.* In air navigation the third dimension is of considerably greater importance than in marine (even underwater) and land navigation.

5. *Effect of weather.* Except under extreme conditions, the weather element of greatest concern to the marine and land navigator is the visibility. In air navigation the visibility has a vital effect upon the ability to land and take-off, as well as the availability of landmarks. In addition, wind has a more direct effect upon the position of aircraft than upon that of ships or land vehicles. Changes of atmospheric pressure and temperature affect the height measurement of aircraft using barometric altimeters.

The importance of weather is reflected in the designations of different flight conditions, as follows:

Contact flight, when the surface of the earth is visible.

Visual flight, when the aircraft is more than a prescribed minimum distance above, below, or laterally from clouds.

Instrument flight, when the conditions of contact and visual navigation are not met.

A **closed aerodrome** is one at which the visibility (horizontal or vertical) is below certain prescribed minimums, rendering ordinary take-offs and landings unsafe.

Because of the conditions mentioned above, air navigation is closely regulated. In the United States, regulations are prescribed by the Civil Aeronautics Board (CAB) and the Federal Aviation Agency (FAA). Operating rules for military aircraft may differ from those governing commercial and private aircraft.

2802. Charts and publications.—Aeronautical charts, like nautical charts, show latitude and longitude scales, parallels, meridians, and aids to navigation. Unlike their marine counterparts, however, aeronautical charts do not show soundings. Contours and elevations are given more emphasis. Airways (art. 2805), control zones, airports, and radio aids are given considerable prominence.

Except for local, approach, and flight (strip) charts, many aeronautical charts are arranged in coordinated series with no (or uniform) overlapping between charts. In many cases this permits joining of adjacent charts to form a single large one (which

(THIS CHART SHOULD NOT BE USED FOR NAVIGATIONAL PURPOSES.)

ELEVATIONS IN FE

FIGURE 2802.—Part of a typical aeronautical chart.

may be wall mounted), or a strip chart for an individual flight. Because of the wider use of radio aids and great-circle "sailing" in air navigation, the Mercator projection is less commonly used in the air than aboard ship. Many aeronautical charts are on the Lambert conformal projection (art. 314). The Mercator projection may be used near the equator. Several projections are used in polar regions (arts. 321, 2508). Because of the greater speed of aircraft, smaller scales are used for en route navigation. For high-speed, high-altitude aircraft, charts are of even smaller scale, and show less detail. Part of a typical aeronautical chart is shown in figure 2802.

In the United States, aeronautical charts are published chiefly by the U.S. Air Force Aeronautical Chart and Information Center, St. Louis, Mo.; U.S. Coast and Geodetic Survey, Department of Commerce, Washington, D.C., and the U.S. Navy Hydrographic Office, Washington, D.C. Each of these three agencies publishes a catalog of its products. The Federal Aviation Agency, Washington, D.C., publishes regulatory material and other information.

Various publications are of assistance to the air navigator. Among these are the following:

The *Airman's Information Manual* (AIM), published by the FAA, provides information necessary for the planning and conduct of civil flights in the National Airspace System. The manual is divided into six sections each composed of a specific category of information consistent with the operational needs of aviation.

The *Alaska Airman's Guide and Chart Supplement* and the *Pacific Airman's Guide and Chart Supplement* provide civilian pilots with data required to supplement the navigational information on aeronautical charts in the Alaska and Pacific Areas.

The *International Flight Information Manual*, published by the FAA, is designed as a preflight and planning guide for use by U.S. non-scheduled operators, business, and private aviators contemplating flights outside of the United States.

Flight Information Publications (FLIP), published by the Department of Defense, contain textual and graphical information for military pilots. The series consists of publications for (1) flight planning, (2) enroute operations, and (3) terminal operations. Each publication may contain charts, tables, and text material.

Notice to Aviators, published every two weeks by the U. S. Navy Hydrographic Office, is the aviator's counterpart of *Notice to Mariners* (art. 425).

Notice to Airmen (NOTAM) contains urgent information requiring immediate dissemination. These notices are sent by teletype to airports throughout the United States.

Federal Aviation Regulations (FAR), published by the FAA.

A comprehensive book giving complete text and reference material on the principles and practices of air navigation is published by the U.S. Navy Hydrographic Office under the title *Air Navigation* (H.O. Pub. No. 216). A book, in three volumes, giving somewhat similar information on air navigation as practiced in the United States Air Force is published by the USAF under the title *Air Navigation* (Air Force Manual 51–40).

2803. Dead reckoning in the air, as aboard ship, comprises the elements of direction and distance. Several terms related to direction are used:

Heading, the horizontal direction in which an aircraft is pointed. This may be a momentary direction, an average, or the intended direction.

Heading line, a line extending in the direction of a heading.

Course, the intended horizontal direction of travel.

Course line, a line extending in the direction of a course.

Course made good, the direction from one established position to a later one.

Track, the horizontal component of the path followed or intended to be followed, and sometimes the direction of this path.

Drift angle, the angle between the heading line and the track, labeled "right" or "left" depending upon the direction of drift.

Drift correction angle, the angle between the heading line and the course line, or the anticipated drift angle.

As in marine navigation, the various directions can be stated relative to any of several reference directions, true, magnetic, compass, and grid being the usual ones. True directions are usually used for plotting, but magnetic directions are more widely used than in marine navigation because some form of magnetic compass is commonly used for measuring direction. With the development of better directional gyro compasses, grid directions are coming into wider use.

The effect of wind on aircraft is similar to that of current on ships. There is nearly always *some* wind, which varies from place to place and from time to time. The air navigator is alert to indications of changes, and has frequent occasion to solve the **wind triangle,** solutions similar to those for current (art. 807). The usual solution determines the heading to fly to make good the selected course. Because of the frequent, and often urgent, need for solution of the wind triangle, aviators customarily use some form of mechanical **computer.** If direction and speed of the wind are known, both heading (or track) and ground speed can be determined. If only drift angle is known, a quantity which usually can be measured in flight, the approximate heading (or track) can be determined without plot, but not the ground speed. With observed drift on two or more headings of considerable difference in direction, one can solve for wind speed and direction. Such observations might be made before and after a turn.

An **air plot** of heading and **air speed** (rate of motion relative to the air) provides a series of **no-wind positions,** sometimes called **air positions.** These are the successive positions an aircraft would occupy if there were no wind. A **dead reckoning plot** of course and **ground speed** (rate of motion relative to the surface of the earth) provides a series of dead reckoning positions.

Most aircraft compasses are magnetic, but those more commonly used are *remote indicating.* The active element is placed at a location relatively free from magnetic disturbances from the aircraft, such as in a wing or the tail, and provided with indicators at various locations, as needed. Because of the large errors introduced when a magnetic compass tilts, the better aircraft compasses are gyro stabilized. The most widely used aircraft compass is known as the **Gyro Flux Gate compass.** In general, aircraft magnetic compasses are compensated (adjusted) by means of flexible cams mounted within the case and controlled by a screw driver. No adjustment is made for vertical soft iron, for quadrantal deviation, or for heeling. Swinging for residual deviation may be done on the ground, by means of a hand-held compass or a compass rose located on the hard surface of an aerodrome; or in the air by means of celestial bodies or straight roads, power lines, etc. The **compass correction card** (deviation table) is usually made up on the basis of the compass direction to steer for a desired magnetic heading, the value of deviation not being given.

The north-seeking gyro compass commonly used aboard ship has not been practical in the air because of its weight and the fact that it would not work satisfactorily at modern aircraft speeds, which are comparable to or greater than the rotational speed of the earth. However, efforts have been made to overcome these obstacles, and it is possible that a suitable north-seeking gyro compass will be developed for use in aircraft. The **directional gyro** compass is used widely. Such an instrument is essentially a gyroscope pointed in a desired direction which it maintains over a period of several minutes. This instrument was devised primarily to provide directional guidance

during a turn of the aircraft, when the older magnetic compasses are erratic. More recent directional gyros require less frequent resetting, provide greater accuracy, and compensate for rotation of the earth (the gyroscope tends to maintain the same direction *in space*), and they may be monitored by a remote-indicating magnetic compass. With the best modern directional gyros an aircraft is able to follow a great circle with about the same accuracy that it can follow a rhumb line (using a magnetic compass). A directional gyro is checked from time to time by means of a magnetic compass or an astro compass (art. 2515).

Air speed is usually determined by measurement of the difference between static air pressure and the pressure exerted by the apparent wind, which, in the air, is always from dead ahead and equal to the speed of the aircraft through the air. This pressure difference is measured by a device called a "Pitot tube," and transmitted by tubes to the air speed indicator. Corrections are applied for nonstandard air temperature at the pressure altitude, compressibility, and heating effect. Higher speeds are sometimes stated in terms of a percentage of the speed of sound at the aircraft. On this basis the speed is called the *Mach* (mŏk) *number*. A Mach number of one is the speed of sound, which varies with the density of the air; Mach number 0.9 is 90 percent of the speed of sound, etc. A **Mach meter** is an instrument which measures Mach number directly.

Height is usually measured by means of a **barometric altimeter,** which is essentially an aneroid barometer graduated in feet above sea level. If the atmospheric pressure is not standard, the altimeter will not read the correct value at sea level unless adjusted to the existing pressure. A knob is provided for this purpose. If the decrease of pressure with height is not standard, additional error is introduced. Altitude separation of aircraft along airways is based upon indications of an accurate barometric altimeter set to *standard* conditions, so that all instruments at the same height should have the same reading. For landing and take-off the instrument is usually adjusted so that it will read the correct altitude when the aircraft is on the surface. For landings, the necessary information is supplied by radio from the control tower. An instrument which measures height above the surface (absolute altitude) is called an **absolute altimeter.** The usual absolute altimeter is a form of radar beamed vertically downward. It measures height in a manner similar to the measurement of water depth by an echo sounder (art. 619).

As in marine and land navigation, dead reckoning is the basis of navigation in the air, all other forms serving to correct positions so determined. However, because of the nature of air navigation and the aids available, dead reckoning in the air, particularly along airways, is often a mental process, or one in which the dead reckoning for the entire flight is plotted in advance, with DR position at frequent intervals, as every ten minutes, being marked on the plot. The problem is then one of maintaining the schedule or keeping a record of deviation from it.

Various automatic dead reckoning systems show promise of providing accurate means for determining position over long stretches of water or over terrain lacking in distinctive features as aids to navigation. Such systems are based upon accurate means of measuring direction and distance. These, in turn, require accurate directional and horizontal references. Examples of such systems are those based upon measurement of accelerations (**inertial systems**) and those based upon measurement of the Doppler shift (change of frequency) of echoes from radio or radar beams transmitted obliquely from the aircraft to the ground (**Doppler systems**). Additional information on this subject is given in article 809. Systems under development combine one or both of these principles with some other principle, such as automatic celestial navigation.

2804. Piloting, often called **pilotage** in air navigation, is similar in principle to that performed aboard ship. In practice it more nearly resembles land navigation. Lines of position from observed bearings or distances are rarely plotted by air navigators.

The more common practice is to compare observed features with the chart, keeping a record of one's progress as he proceeds. If this is not a *continuous* process, combined with mental or plotted dead reckoning, one can soon become lost, particularly in an area where many features are similar in appearance. One can learn to watch for distinctive features. Two towns may look very much alike, but the pattern of roads, railroads, and streams in the vicinity may be quite different. A race track, mine, or other distinctive feature may help one distinguish between otherwise similar areas. However, it is essential that the air navigator not be hasty in identification, for mistakes can easily be made. A position established by identifying a feature directly below the aircraft is called a **pinpoint.**

Over well-traveled areas, extensive use is made of various radio aids to navigation. These are discussed in article 2805. So complete is coverage across the United States that an experienced aviator with suitable publications can travel from coast to coast without an aeronautical chart, whether or not the surface is visible. Over such areas, navigational duties are customarily performed by the pilot and copilot, a separate navigator being carried only on flights requiring his services, as on long over-water flights or in polar regions.

2805. Electronic navigation is more widely used in the air than on land or sea, for several reasons. Because of the greater height of aircraft, there is less obstruction of radio signals, and higher frequency "line of sight" systems are available over greater ranges. Over land, aids can be placed at suitable intervals to provide essentially continuous, short-range guidance over long distances. The difficulty of observing bearings, celestial bodies, etc., from aircraft renders electronic methods more attractive. Decreased accuracy of other methods when used in the air enhance the value of electronics. The greater speed and adaptability of electronic methods are of higher value aboard a fast-moving aircraft. The electronic navigational equipment carried in aircraft is compact and especially adapted to use in the air. Airborne computers are being developed for use with advanced navigation systems.

The **automatic radio direction finder** commonly used in the air provides a continuous indication of direction toward the transmitter by means of a needle pivoted at the center of a compass rose. The navigator has only to tune to the correct frequency and watch the needle. Its steadiness is some indication of the reliability of the reading.
